Each term of this equation has the dimension of a force; they are, respectively, the inertia force, damping force, spring force, and exciting force, and are usually measured in pounds. The amplitude x is usually measured in inches here, and in centimeters on the European Continent. This, however, is inconvenient and impractical in more than one respect. The essence of dimensional analysis consists of measuring the various units *not* in inches, pounds, or other standardized units, but rather in units which are of particular use for the problem in hand. For instance, in this case it is better to measure the deflection or amplitude x in terms of the static deflection P/k of the spring under the load P. The quantity $x_{st} = P/k$ is a length intimately tied up with our problem. Then, instead of calculating with x in inches, we calculate with $y = x/x_{st}$, that is, with x expressed in the new unit. It is clear that y is a dimensionless quantity, a pure number.

The damping coefficient c is a force divided by a velocity, and can be expressed in terms of lb/in./sec. But it is more convenient to express it in terms of the "critical" damping coefficient c_c, which is of the same dimension. The critical damping is that damping which is just sufficient to prevent the "free" system from oscillating, but makes it return deadbeat to its equilibrium position from any initial displacement. Therefore, instead of c,

$$\frac{c}{c_c} = \frac{c}{2m\omega_n} = \frac{c}{2\sqrt{mk}}$$

will be used.

The time t is measured in seconds. But there is a time unit inherent in the phenomenon, namely, the duration of a "free period," $T = 2\pi/\omega_n$ or $T/2\pi = 1/\omega_n$. Expressing the time t in the unit $T/2\pi$ instead of in seconds has many advantages, so that the new variable:

$$\tau = \frac{t}{T/2\pi} = \omega_n t$$

may be introduced.

With these preliminaries, Equation [1] can be attacked. In order to make all terms dimensionless, divide it by P:

$$\frac{m}{P}\frac{d^2x}{dt^2} + \frac{c}{P}\frac{dx}{dt} + \frac{k}{P}x = \sin \omega t$$

or

$$\frac{m}{k}\frac{d^2\left(\frac{x}{P/k}\right)}{dt^2} + 2\frac{c}{2\sqrt{mk}}\sqrt{\frac{m}{k}}\frac{d\left(\frac{x}{P/k}\right)}{dt} + \frac{x}{P/k} = \sin \omega t$$

or

$$\frac{1}{\omega_n^2}\frac{d^2y}{dt^2} + 2\frac{c}{c_c}\frac{1}{\omega_n}\frac{dy}{dt} + y = \sin\frac{\omega}{\omega_n}\omega_n t$$

The last equation is dimensionless except for the time t. Replacing t by its equivalent, τ/ω_n, the equation becomes:

$$\frac{d^2y}{d\tau^2} + 2\frac{c}{c_c}\frac{dy}{d\tau} + y = \sin\frac{\omega}{\omega_n}\tau \ldots\ldots\ldots\ldots [2]$$

In this form it is seen that the dimensionless amplitude y can be considered as a function of the dimensionless time τ, while there are two dimensionless parameters: c/c_c and ω/ω_n.

All the characteristics of the system can be studied from the behavior of a model in which only the damping c/c_c and the forced frequency ω/ω_n can be varied. Giving the model a mass of, say, 1 lb and a spring constant of 20 lb per inch of deflection and determining $x = f(t)$ for a number of values of c/c_c and ω/ω_n experimentally, enables us to predict the motions of any other model of different mass and spring constant.

This solution gives the transient as well as the steady state. If only the steady state is wanted, the dependence on the time

r is immaterial and there exists only the relation between y, c/c_c, and ω/ω_n. It is customary to consider y as a function of ω/ω_n and plot the curves for various values of c/c_c, which is the usual family of "resonance curves."

The particular example of a classically damped single-degree-of-freedom system has been tested on models many times. However, it is also amenable to a simple exact calculation, and that fact takes away most of the importance of the model test. In cases where only an approximate solution or no solution at all can be found, a model has to be resorted to. In the following, a number of practical cases which have been solved by this method will be discussed.

LANCHESTER TORSIONAL-VIBRATION DAMPER FOR DIESEL ENGINES

In certain Diesel- or gas-engine installations which are called upon to operate over a wide speed range, it is often advisable to use a vibration damper, for instance, of the Lanchester type.[2]

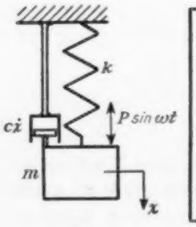

FIG. 1

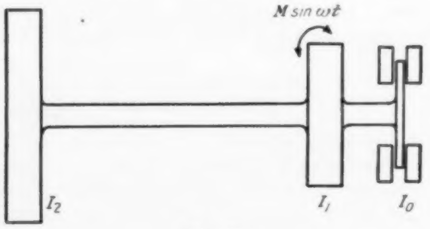

FIG. 2

The calculation of the amplitudes of vibration of such a system is possible only in an approximate manner, so that a model test is useful. Let the simplified system be represented by Fig. 2. A disk of moment of inertia I_2 represents the flywheel or electric generator driven by the engine, and a disk I_1 represents the combined inertia of all cranks, pistons, etc., of the engine. The damper flywheel I_0 can turn freely on the shaft and is restricted from doing so only by the constant friction torque T, which can be given various values by changing the set in the springs provided for that purpose. Let the torque inequalities of the engine be represented by a torque $M \sin \omega t$ acting on I_1. By gradually increasing the frequency ω of this disturbing torque, the angular oscillations α of I_1 will grow larger, until at a certain $\omega_{cr.}$, the "critical speed," the angle α is a maximum. For greater speeds α will decrease again. The maximum of α at the critical speed is naturally of interest, and it is useful to know how this maximum $\alpha_{max.}$ can be affected by changing the damper friction torque T or the damper inertia I_0. In usual constructions I_2 is very large—so large that it can be considered to be "infinitely" large, i.e., I_2 is of no importance for the problem. Then we can write:

$$\alpha_{max.} = f(I_0, I_1, T, M, \omega_{cr.})$$

No other quantities can conceivably affect α. Apply to this equation the usual procedure of dimensional analysis:[3]

$$\alpha_{max.} = I_0^x, I_1^y, T^z, M^u, \omega_{cr.}^v$$

and since $[I_0] = [I_1] = [ml^2]$; $[T] = [M] = [ml^2t^{-2}]$; $[\omega_{cr.}] = [t^{-1}]$ and α is dimensionless, we write:

$$[\alpha_{max.}] = m^{x+y+z+u}\, l^{2x+2y+2z+2u}\, t^{-2z-2u-v}$$

or

$$x + y + z + u = 0$$
$$2z + 2u + v = 0$$

From these equations we solve y and z in terms of the other variables and substitute:

$$\alpha_{max.} = \left(\frac{I_0}{I_1}\right)^x \left(\frac{M}{T}\right)^u \left(\frac{I_1\omega^2_{cr.}}{T}\right)^{\frac{v}{2}} = \left(\frac{I_0}{I_1}\right)^x \left(\frac{T}{M}\right)^{-\frac{v}{2}-u} \left(\frac{M}{I_1\omega_{cr.}^2}\right)^{-\frac{v}{2}}$$

so that the result becomes

$$\alpha_{max.} = f\left(\frac{I_0}{I_1}, \frac{T}{M}, \frac{M}{I_1\omega_{cr.}^2}\right) \qquad [3]$$

More than this the dimensional analysis is not able to predict. Another consideration, however, will lead to the additional fact that $\alpha_{max.}$ is directly proportional to $M/I\omega_{cr.}^2$. This can be seen as follows: If all forces acting on the disk I_1 increase in the same ratio, the motion of I_1 will remain similar to itself. There are four forces (moments) acting, namely: the disturbing moment M, the damper moment T, the spring restoring moment of the shaft, and the inertia moment of the disk. The two latter moments are directly proportional to the angle $\alpha_{max.}$, provided that $\omega_{cr.}$ remains the same. Now assume M and also T to be twice as large as before. In order to get similar motion, it is only necessary to make $\alpha_{max.}$ twice as large so that all four forces increase in the same ratio. In Equation [3] the ratios T/M and I_0/I_1 remain unchanged; $M/I\omega^2_{cr.}$ becomes twice as great and $\alpha_{max.}$ is twice as great. Clearly on account of this, result [3] can be simplified to:

$$\frac{I_1\omega_{cr.}^2\alpha_{max.}}{M} = f\left(\frac{T}{M}, \frac{I_0}{I}\right) \qquad [4]$$

In other words, in a model of the set-up of Fig. 2, we have to measure the various critical $\alpha_{max.}$-values for various values of T and I_0. Then all these results have to be plotted in a diagram with $I_1\,\omega^2_{cr.}\alpha_{max.}/M$ as ordinate and T/M as abscissa. There will be a number of curves, each belonging to a definite value of I_0/I_1.

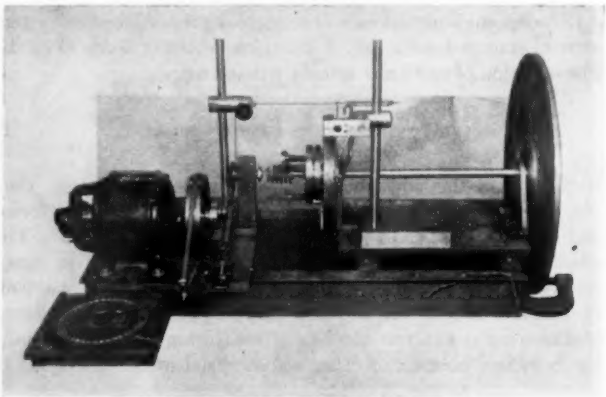

FIG. 3 LANCHESTER DAMPER MODEL

A photograph of the model on which the experiments were actually carried out is shown in Fig. 3, so that it may be said that the problem has been completely solved.[2]

In this example the model analogy has been obtained in the usual manner, without referring to the differential equation as was done with the classical single-degree-of-freedom problem. In the following example, the latter method will again be applied.

Running Through a Critical Speed

It is sometimes practically impossible to construct a gas engine that will be free from torsional critical speeds in the entire range from standstill up to the running speed. Many engines of this kind have one or more critical speeds under the running speed. These are not considered dangerous since it is reasoned that the engine only runs through them during starting, and that so quickly that the vibrations have no time to build up. This qualitative statement leads to the problem of investigating the amplitudes of a one-degree system running through its critical speed at a definite constant rate of acceleration. In order to express the problem in mathematical language Equation [1] has to be modified only in its last term, in which the frequency ω is now proportional to the time t, so that:

$$m\ddot{x} + c\dot{x} + kx = P \sin \alpha t^2 \ldots\ldots\ldots\ldots [5]$$

With these changes, the differential Equation [7] becomes

$$N^2 \frac{d^2y}{d\tau_1^2} + 2N \frac{c}{c_c}\frac{dy}{d\tau_1} + y = \sin \frac{1}{\pi N^3} \cdot \tau_1^2 \ldots\ldots \quad [8]$$

from which it is seen that the amplitude y is a function of τ_1, of N, and of c/c_c. We are interested in knowing the maximum amplitude $y_{\text{max.}}$ and not so much the time at which this occurs. Therefore

$$y_{\text{max.}} = f\left(N, \frac{c}{c_c}\right)$$

A model has been built by Mr. J. G. Baker in which the quantity N can be varied by means of a special drive, consisting of a d-c motor with a flywheel and a constant-current regulator. This gives a constant acceleration, the rate of which can be varied from experiment to experiment by a change in the current-regulator circuit. The damping is by means of a d-c magnet, in which the current can be adjusted over a wide range of values.

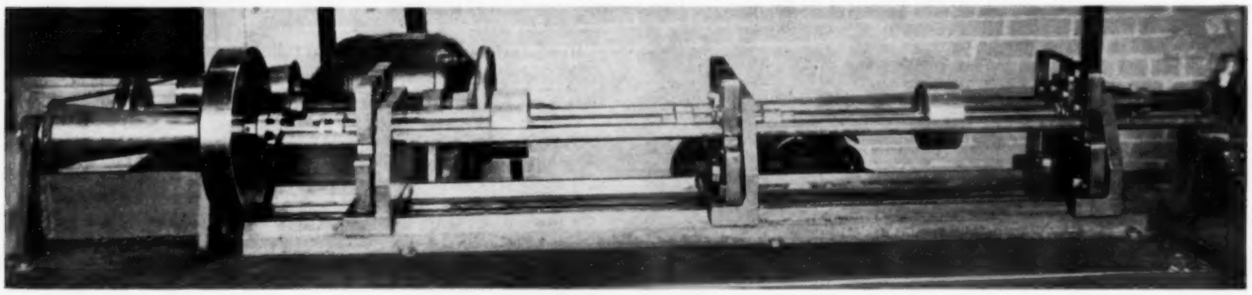

Fig. 4 Model for Testing Critical Speeds

However, to say that αt is the frequency is incorrect. This can be understood from what follows. A cycle of the force occurs when αt^2 increases by 2π. The time T during which this takes place is found from $\alpha(t + T)^2 - \alpha t^2 = 2\pi$, or $2\alpha Tt = 2\pi$, so that $T = \pi/\alpha t$. The frequency thus is:

$$\omega = \frac{2\pi}{T} = 2\alpha t \ldots\ldots\ldots\ldots\ldots\ldots [6]$$

Transform [5] in the same manner that [1] was transformed into [2]:

$$\frac{d^2y}{d\tau^2} + 2\frac{c}{c_c}\frac{dy}{d\tau} + y = \sin\left(\frac{\alpha}{\omega_n^2}\right)\tau^2 \ldots\ldots\ldots [7]$$

The new dimensionless group α/ω_n^2 appears, which is a measure for the rate of acceleration. A more easily imaginable quantity, which is inversely proportional to the acceleration, is the number of "free" cycles N to reach resonance. Since $\omega = 2\alpha t$, in general $\omega_n = 2\alpha t_{\text{res.}}$, where $t_{\text{res.}}$ is the time in which resonance is reached. Since τ is a free period,

$$N = t_{\text{res.}}/\tau = \frac{\omega_n}{2\alpha} \bigg/ \frac{1}{2\pi\omega_n} = \pi\frac{\omega_n^2}{\alpha}$$

Instead of α/ω_n^2, therefore, we write $1/\pi N$.

The various curves reach resonance after N free cycles, that is, at the time $N\tau$. In this manner each rate of acceleration $1/N$ will give a curve with a different resonance point. It is more convenient in this case to have all curves plotted on the same resonance point, which can be done by introducing the new unit of time τ_1:

$$\tau_1 = N\tau$$

The test results are conveniently plotted with y as ordinate against $1/N$ as abscissa, and with c/c_c as the parameter for the various curves.

An analytical solution of this problem has recently been obtained by Lewis.[4]

Models for Lateral-Vibration Phenomena

It may have been noticed that both practical examples discussed thus far deal with the amplitudes of *torsional* vibration. There is a definite reason for this. A torsional model can be built so that all inertia effects are localized in the shaft, flywheels, etc., and that no inertia reaction is transmitted to the bearings. Therefore, in torsional vibrations of this type, flexibility in the bearings does not affect the location of the critical speeds, nor can there be any energy dissipation through the bearings to the foundation.

With lateral vibrations this is not the case, and the loss of energy in the foundation is so difficult to prevent or to predict that no worth-while quantitative model determinations of the amplitude of lateral vibrations have ever been carried out.

The manner in which the critical speeds are affected by gyroscopic action, non-symmetrical shaft sections, bearing flexibilities, etc., can be studied quantitatively. A model for this purpose is shown in Fig. 4, but so far the amplitude determinations made have been only of a qualitative nature.

Lateral vibrations, for instance in whirling shafts, are either due to unbalance and other "forced" effects, or to "self-induction." The phenomena of the latter class are especially interesting, and have become of practical importance in the last few

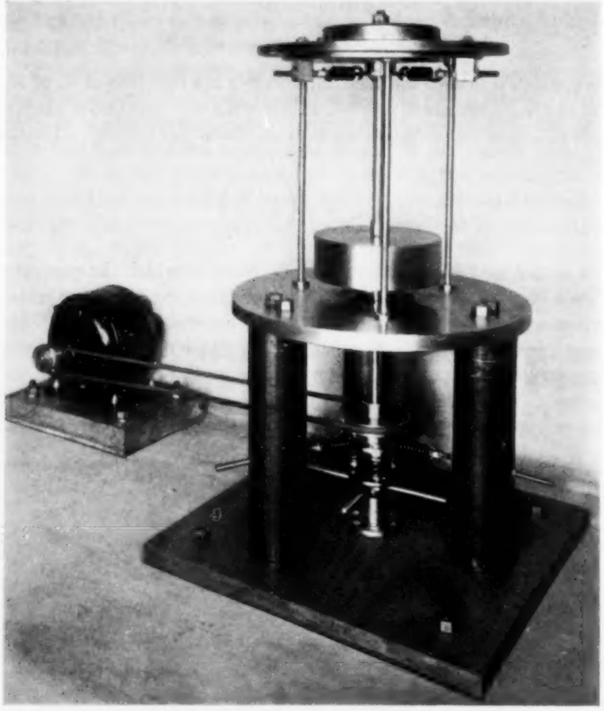

FIG. 5 SELF-INDUCED VIBRATION CAUSED BY THRUST-BEARING FRICTION

years. The first real troubles on machines due to this effect were found in 1924 by Kimball[5] and Newkirk.[6] They explained that the whirling was caused by internal friction in the shaft or by certain lubrication conditions in the bearings, and tested their theories qualitatively on models. Their work has not received the attention it deserves, however; for instance, in Stodola's classical treatise on steam turbines, a phenomenon is described and declared to be inexplicable which is clearly due to internal shaft friction, in the manner that Kimball has explained it.[7]

A different case of self-induced vibration was observed on a vertical-hydraulic-turbine installation, in which the amplitudes grew worse with increasing load on the thrust bearing. A quantitative theory was devised and a model (Fig. 5) built which could be set in violent vibration by the friction on the thrust bearing.[8]

Recently electric transmission lines of which the cables had assumed non-symmetrical sections on account of ice or sleet were found vibrating violently in a transverse wind. The phenomenon was explained as a case of aerodynamic self-induction, and a toy described by Lanchester in 1907 was found to be a model whereby the stability of various ice-coated cable cross-sections could be judged.[9]

In all these cases, however, no reliable amplitude measurements could be made because of the uncertainty of the energy dissipation in the foundation.

Forced Vibrations With Non-Linear Spring Constants

By J. P. Den Hartog[1] and Stanley J. Mikina,[2] East Pittsburgh, PA.

J. P. Den Hartog

In many technical applications, couplings are used which have springs in them with an initial set. In this paper an exact theory of the forced vibrations of a system with such a coupling is given. Conclusions concerning the shift in critical speed with the amount of initial set are made. The solution obtained is compared with the existing approximate solution. The more general case of a coupling with stops is solved in an appendix.

S. J. Mikina

In the classical theory of vibrations it is assumed that the springs figuring in the system have a linear characteristic, i.e., the spring forces are proportional to the displacements. In many applications, however, the dictates of practical design require the use of spring members whose restoring force cannot be formulated analytically as a simple function of the displacement over the entire range of possible displacements, usually because of discontinuities introduced by clearances, initial spring set, "stops," etc. Three cases of non-linear springs which are encountered quite often in practice are represented schematically in Fig. 1.

In the first there are clearances between the mass and the spring, thus allowing the former to move freely a certain distance before striking the spring. The second case differs from the first in that the springs are built into the apparatus with an initial set, while the mass rests free (but without clearance) between the members that maintain the initial set. Under these conditions, the mass cannot move until a force is applied to it which is at least equal to the force in the springs due to the set.[3] Constructions of this type are frequently used for flexible torsional couplings, such, for instance, as those on the engines of the airship "Graf Zeppelin" before the accident of May, 1929.[4] The third sketch (*c*) shown in Fig. 1 represents a system with elastic "stops." Here the mass is free to execute simple harmonic vibrations until its amplitude of motion reaches a certain limit, at which additional springs or "stops" are struck.

The "natural frequency" of *free* vibrations of systems equipped with springs of any of the three types discussed depends on the amplitude of motion. Methods of determining the relation between amplitude and corresponding natural frequency are known and have been discussed at length in the literature.[5] However, the *forced* vibrations which the systems of Fig. 1 execute under the influence of a harmonic force on the mass have found to date only an approximate solution.[6] The approximation involved consists of assuming sinusoidal motion of the mass and gives crude results, especially for the smaller or slower motions. It is fundamentally possible, however, to obtain an exact solution of this problem by fitting together the linear solutions which hold for different portions of the cycle of motion, as applied before to the problem of vibrations with Coulomb damping.[7] In

the present paper, case b of Fig. 1 has been worked out completely. The known approximate solution is discussed and compared with the exact results. Cases a and c are more complicated. The general solution for case c (which includes a and b as special cases) has been worked out, however, and is given in Appendix No. 1. Quantitative results for this case may be obtained only by performing numerical calculations similar to those which have been made for the case treated below.

Exact Solution for Springs With Initial Set

The spring force as a function of the displacement as represented in Fig. 1(b) can be written as $-kx \pm F$; where k is the spring constant, x the displacement, and F the force due to set, the + sign holding for $x < 0$ and the — sign for $x > 0$. The differential equation of the motion for $x > 0$ then is:

$$m\ddot{x} + kx + F = P \sin (\omega t + \varphi) \qquad \text{[1]}$$

where φ is a parameter used for the sake of convenience. The following abbreviations may now be introduced:

$$\frac{k}{m} = \omega_n^2 \qquad \frac{F}{k} = x_f \qquad \frac{P}{k} = a \qquad \text{[2]}$$

but it is to be distinctly understood that ω_n is *not* the "natural frequency of free vibration," but is rather some characteristic frequency which is only used for simplifying the notation.

Substituting the expressions [2] into Equation [1],

$$\ddot{x} + \omega_n^2(x + x_f) = a\omega_n^2 \sin (\omega t + \varphi) \qquad \text{[3]}$$

the general solution of which is:

$$x = A \sin \omega_n t + B \cos \omega_n t + aV \sin (\omega t + \varphi) - x_f \qquad \text{[4]}$$

where

$$\beta = \frac{\omega_n}{\omega} \text{ and } V = \frac{\beta^2}{\beta^2 - 1} = \frac{\omega_n^2}{\omega_n^2 - \omega^2}, \text{ the "resonance function"} \qquad \text{[5]}$$

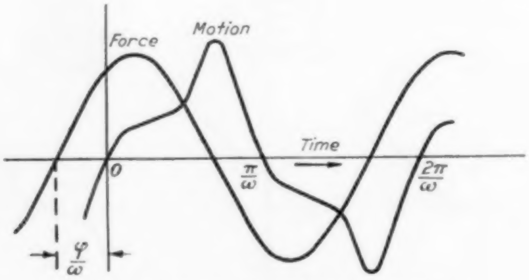

Fig. 2 Force and Motion Curves

Since we desire only the solution representing the steady state of motion and are not interested in transients, the conditions prevailing for forced vibrations are given in Fig. 2. The solution [4] being true for $x > 0$, holds for $0 \leq t \leq \pi/\omega$. Evidently the three boundary conditions which must be satisfied are:

$$\left.\begin{array}{ll} t = 0 & x = 0 \\ t = \dfrac{\pi}{\omega} & x = 0 \\ (\dot{x})_{t=0} = -(\dot{x})_{t=\frac{\pi}{\omega}} & \end{array}\right\} \qquad \text{[6]}$$

or calculated with the aid of [4],

$$\left.\begin{array}{l} B + aV \sin \varphi - x_f = 0 \\ A \sin \beta\pi + B \cos \beta\pi - aV \sin \varphi - x_f = 0 \\ A(1 + \cos \beta\pi) - B \sin \beta\pi = 0 \end{array}\right\} \qquad \text{[7}a, b, c\text{]}$$

These three equations suffice to determine A, B, and the parameter or "phase angle" φ. From [7c],

$$A = B \frac{\sin \beta\pi}{1 + \cos \beta\pi}$$

which, when substituted in [7a, b], gives

$$B + aV \sin \varphi - x_f = 0$$

$$B - aV \sin \varphi - x_f = 0$$

from which

$$A = x_f \frac{\sin \beta\pi}{1 + \cos \beta\pi}; \quad B = x_f; \quad \sin \varphi = 0 \qquad \text{[8]}$$

Substituting these values in [4] gives the solution for the motion:

$$\frac{x}{a} = \frac{x_f}{a}\left(\frac{U}{\beta} \sin \omega_n t + \cos \omega_n t - 1\right) \pm V \sin \omega t \qquad \text{[9]}$$

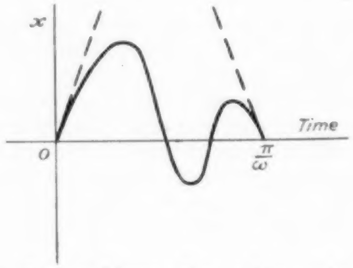

Fig. 3 Type of Motion Ruled Out by Analysis

where

$$U = \frac{\beta \sin \beta\pi}{1 + \cos \beta\pi}$$

the "Coulomb damping function." The $\pm$ sign in [9] follows from the fact that $\sin \varphi$ being zero, φ may be either 0 or 180 deg.

The solution represented by Equation [9] gives only the shape of the motion curve and not its maximum amplitude. The calculation of the latter, however, cannot be effected by the usual analytical methods since these lead to a transcendental in t owing to the simultaneous occurrence of $\sin \omega t$ and $\sin \omega_n t$ which, generally, cannot be expressed in terms of each other. It is therefore necessary to resort in each case to numerical calculation to obtain the maximum amplitude of forced vibrations for a given system. In this connection, it must be remembered that the solution obtained is valid only under the assumptions imposed in Fig. 2: in particular, the motion is not allowed to pass under the zero line in the interval under consideration. In certain cases (for slow forces or large β and small values of P/F), Equation [9] will lead to a motion like that of Fig. 3, which fits all the conditions [6] but passes into the domain of the other differential equation before $t = \pi/\omega$. Such solutions naturally have to be discarded.

Fig. 4 shows a number of calculated motion curves for $\beta = \omega_n/\omega = 1.75$ for various values of $P/F = a/x_f$.[6] It is seen that the curves deviate more and more from a pure sinusoid the smaller P/F becomes. The lowest curve in the figure touches the horizontal axis. Diagrams like that of Fig. 4 have been calculated for a number of values of β. The maximum amplitudes of all the curves in these various diagrams are plotted together in Fig. 5, where the solution appears as a family of curves, each curve giving the amplitude x/a as a function of the frequency for a definite value of P/F. For $P/F = \infty$ the classical resonance curve results, and for smaller values of P/F curves displaced, therefrom. Bearing in mind that the solution is restricted only to values of $x > 0$, an inspection of Equation [9] shows that in the range of $0 < \omega/\omega_n < 1$ these curves must all lie below the classical curve, while in the region above resonance, amplitudes both above and below those corresponding to the classical curve are possible. This is due to the fact that for values of $\beta < 1$, a positive solution may be obtained for φ equal to either 0 or π: $\varphi = \pi$ gives solutions all lying above the classical curve, while $\varphi = 0$ gives solutions lying both above and below it. The solid-line curves in the region where $\omega/\omega_n > 1$ refer to the case in which the phase of the disturbing force is opposite to that of the motion as in the classical curve, while the broken-line curves represent cases where the force and motion are in phase.

---

[6] These curves are symmetrical about $\omega t = \pi/2$, as can be shown by substituting $\pi - \omega t$ for ωt in [9]. That this is the case becomes more evident when the solution is obtained in the form of an infinite

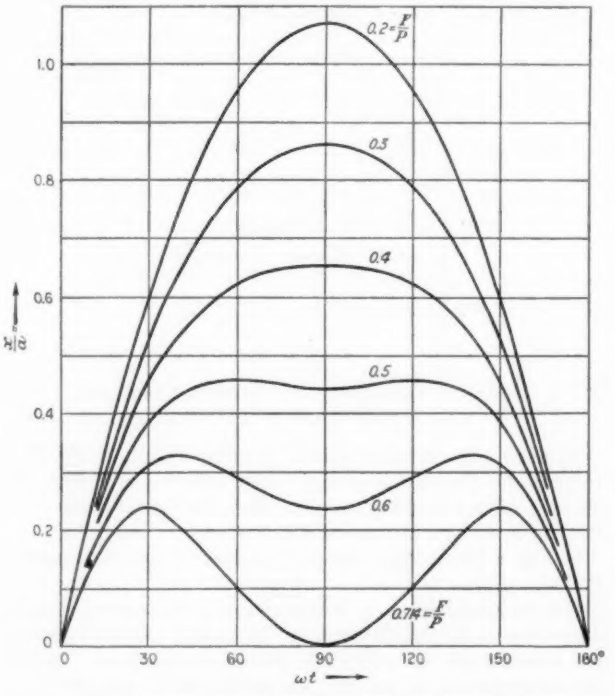

FIG. 4 MOTION CURVES FOR VARIOUS IMPRESSED FORCES

The single solution found below resonance is valid only in a restricted range, the boundary of which is indicated by the thin broken line. Below and to the left of this line no solution of the type of Fig. 2 can exist. It is of interest to know for what values of P/F we obtain no, one, or two solutions. This is shown in Fig. 6 where P/F is plotted against ω/ω_n. Again in the shaded area the analysis does not lead to a result. Outside this area, however, the field is divided into two main regions. Besides the two solutions with real amplitude obviously there must be a trivial solution with zero amplitude for values of P/F less than unity. This is true even in the shaded region where the analytical process breaks down.

The existence of solutions other than $x = 0$ for fractional values of P/F, as indicated in Figs. 5 and 6, seems rather paradoxical at first thought: the impressed force being numerically less than the initial set-up in the springs, we should expect the system to remain quiescent at the origin. It must be remembered, however, that we are dealing here with "forced" vibration, that is to say, with motions which can be maintained by a harmonic force once they have been started, without considering the manner in which the steady state is attained. If, then, we imagine for a moment the existence of an agency here which will displace the system from its position of equilibrium at the origin (as might well be the case in an actual construction as a result of some initial shock or jar due to impact), the resulting motion can be maintained by the existing harmonic force and a solution of the type calculated be realized.

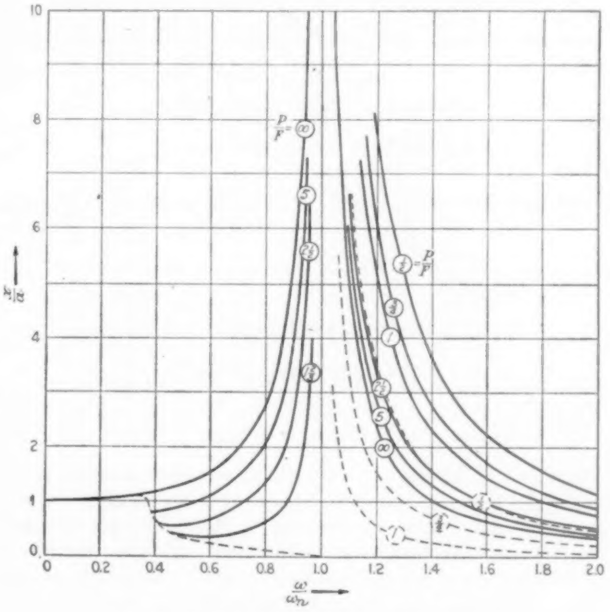

FIG. 5 AMPLITUDE-FREQUENCY DIAGRAM

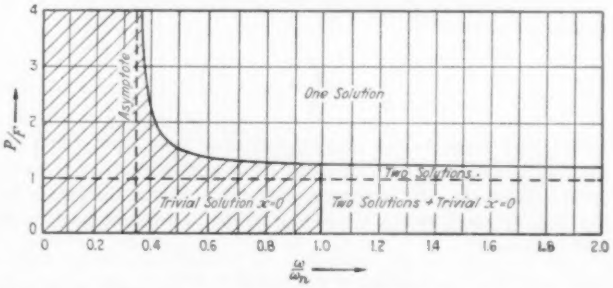

FIG. 6 SHOWING REGIONS OF ONE OR MORE THAN ONE SOLUTION

EXISTING APPROXIMATE SOLUTION[9]

The differential Equation [1] can be written as $m\ddot{x} + f(x) =$

---

series by representing the set-up force in the springs by its Fourier development. The motion is then given by

$$\frac{x}{a} = \frac{x_f}{a}\frac{4\beta^2}{\pi}\sum_{n=1,3,5,\ldots}^{\infty}\frac{\sin n\omega t}{n(n^2-\beta^2)} \pm V\sin\omega t$$

The analysis involved in this method of solution is analogous to that used in the problem of forced vibrations with Coulomb damping, loc. cit., footnote 7.

[9] Rüdenberg, loc. cit., footnote 6.

$P \sin \omega t$, where $f(x)$ stands for the entire diagram of Fig. 1(*b*). The motion, which in reality is not sinusoidal, is now assumed to have the following property of a sinusoid, namely, that at the point of maximum amplitude, $\ddot{x} = -\omega^2 x$. Further, it is assumed that this maximum coincides with an extreme value of the force. The equilibrium of all forces at the maximum amplitude is then expressed by:

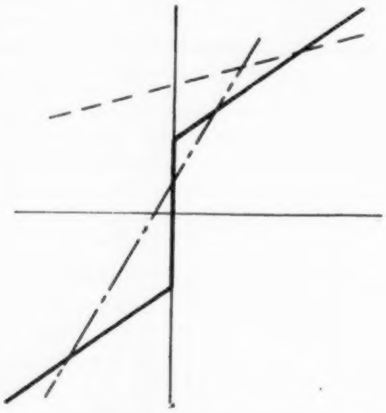

Fig. 7 Illustrating the Approximate Solution

$$-m\omega^2 x + f(x) = \pm P$$

or

$$f(x) = \pm P + m\omega^2 x \quad \text{[11]}$$

This equation admits of a very simple graphical solution, shown in Fig. 7. The right-hand member of [11] is a straight line with slope $m\omega^2$ and ordinate intersection P. Where this line intersects the $f(x)$ curve, a solution for x is obtained. It is seen that besides an intersection at $x = 0$, there may be either one or two intersections, depending on whether P/F is greater or less than unity (whereas the exact solution gives $4/\pi$).

For purposes of calculation, the analytical expression for the points of intersection is:

$$\frac{x}{a} = V\left(\pm 1 - \frac{F}{P}\right) \quad \text{[12]}$$

For very large values of x/a, i.e., near resonance, when the motion is practically a sinusoid, this approximation is fairly good. However, the accompanying table shows that even for motions as great as $2^1/_2$ times statical the error can be as large as 75 per cent.

Values of x/a for $\beta = 1.05$

P/F	Exact solution	Existing approximate solution
1.67	2.46	4.28
2.50	5.21	6.43
5.00	8.96	8.57

This is not very surprising since for small values of the amplitude the motion deviates considerably from a sinusoid, as can be seen, for instance, in Fig. 4. The approximate solution really expresses only a certain relation between the maximum curvature and amplitude of the actual motion curve and the sinusoid replacing it, and does not enter into the wave shape. Therefore rather large errors are to be expected.

Shift of Resonant Speed Due to the Set in Springs

Fig. 5 shows that the resonance curves for all values of P/F go to infinity at $\omega = \sqrt{k/m}$, that is, at the "natural frequency" of the system without set-up in the springs. This at first thought would indicate that the "critical speed" of the system is not affected by a set in the springs, which, however, is contrary to experimental evidence. As mentioned earlier, the failure of the crankshafts of the "Graf Zeppelin" was due to the fact that before the fatal trip a change was made in the set-up of the couplings with a consequent shift in the critical speed.

The results of Fig. 5 are academic in that no damping has been considered. Infinite amplitudes are, after all, unreal quantities. For practical purposes it is better to consider at which frequency the amplitudes become, say, four times the statical. Examining Fig. 5, it is seen very clearly, for instance, in the curve $P/F = 2^1/_2$, that both branches of the (undamped) resonant curve have been shifted to the right.

The influence of damping on the classical case is known to have the effect of rounding the top of the two branches, extending to infinity; the maximum of this top lying approximately midway between the two undamped branches.

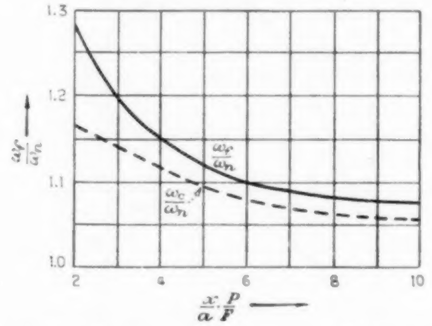

Fig. 8 Resonant Frequency and Natural Frequency Versus Amplitude of Vibration

To draw a practical conclusion from the results of Fig. 5 we define as the "critical frequency" ω_c of a certain P/F curve the frequency lying midway between the two intersections of the P/F curve with the horizontal $x/a = 4$.

In Fig. 8 this critical speed ω_c/ω_n has been plotted against P/F as a broken line.

The "natural frequency of free vibration" is another quantity depending on the amplitude or on P/F, which does not necessarily coincide with our arbitrarily defined critical speed. The free natural frequency ω_f can be easily calculated by computing the time necessary to move one-quarter cycle from the middle position to one extremity. The result of such a calculation is

$$\frac{\omega_f}{\omega_n} = \frac{\pi}{2 \operatorname{arc\,cos}\left(\dfrac{1}{1 + \dfrac{x}{a}\dfrac{P}{F}}\right)} \quad \text{[13]}$$

and is shown graphically as the full line of Fig. 8. It is seen that the natural free frequency and the arbitrary critical frequency do not coincide but follow the same tendency.

An exact solution for the case with viscous damping may be obtained either in a manner similar to that used above for the undamped motion or in terms of a Fourier series, but involves very considerable numerical calculations.

Conclusions

An exact solution for the forced vibrations without damping under a harmonic force of the system of Fig. 1(*b*) has been given, the main results of which appear in Fig. 5.

The existing approximate solution has been discussed and is shown to lead to considerable errors.

The shift in the critical speed, due to the set in the springs, has been discussed in an approximate manner.

In Appendix No. 1 a complete theory of the general case shown in Fig. 1(*c*) is worked out.

Appendix No. 1

SOLUTION OF THE GENERAL CASE

Consider the general case of Fig. 1(*c*), where two different linear flexibilities are involved. The spring force [Fig. 9(*a*)] can be expressed as $-k_1x$ until it reaches the value F; above that, it becomes $-\left\{F + k_2\left(x - \frac{F}{k_1}\right)\right\}$ or using the abbreviation $x_f = F/k_1$ it can be written:

$$-k_2x - (k_1 - k_2)x_f$$

Take as the origin of time the instant when the mass just strikes the stop in its upward motion in Fig. 1(*c*) and call t_1 the (unknown) time at which the mass just leaves the stop in its downward motion [Fig. 9(*b*)]. The differential equations then become:

$$m\ddot{x} + k_2x + (k_1 - k_2)x_f = P \sin(\omega t + \varphi) \ldots\ldots [14]$$

between $0 < t < t_1$ and

$$m\ddot{x} + k_1x = P \sin(\omega t + \varphi) \ldots\ldots\ldots\ldots [15]$$

between $t_1 < t < \pi/\omega$. The general solution of [14] is:

$$x_a = A \sin \omega_2 t + B \cos \omega_2 t + a_2V_2 \sin(\omega t + \varphi) + \left(1 - \frac{k_1}{k_2}\right)x_f \ldots\ldots [16]$$

and of [15] is:

$$x_b = C \sin \omega_1 t + D \cos \omega_1 t + a_1V_1 \sin(\omega t + \varphi) \ldots [17]$$

For the determination of the six unknown A, B, C, D, φ, and t_1, we have the six boundary conditions:

$$\left.\begin{array}{lll} t = 0 & x_a = x_f \ldots\ldots\ldots\ldots & (a) \\ t = t_1 & x_a = x_b = x_f \ldots\ldots & (b, c) \\ t = \pi/\omega & x_b = -x_f \ldots\ldots\ldots & [d] \\ t = t_1 & x_a = x_b \ldots\ldots\ldots\ldots & [e] \\ (\dot{x}_a)_{t=0} & = -(\dot{x}_b)_{t=\pi/\omega} \ldots\ldots & [f] \end{array}\right\} \ldots\ldots\ldots [18]$$

From [18, *a*, *b*, *c*, *d*] we can express the four integration constants in terms of t_1 and φ with the following results:

$$\left.\begin{array}{l} A = \left(\frac{k_1}{k_2}x_f\frac{1 - \cos \omega_2 t_1}{\sin \omega_2 t_1}\right) + \sin \varphi\left(\frac{a_2V_2}{\tan \omega_2 t_1} - \frac{a_2V_2 \cos \omega t_1}{\sin \omega_2 t_1}\right) - \cos \varphi\left(a_2V_2\frac{\sin \omega t_1}{\sin \omega_2 t_1}\right) \\ B = \frac{k_1}{k_2}x_f - \sin \varphi(a_2V_2) \\ C = x_f\frac{\cos \beta_1\pi + \cos \omega_1 t_1}{\sin(\omega_1 t_1 - \beta_1\pi)} + \sin \varphi \cdot a_1V_1 \cdot \left(\frac{\cos \omega t_1 \cos \beta_1\pi + \cos \omega_1 t_1}{\sin(\beta_1\pi - \omega_1 t_1)}\right) + \cos \varphi\left(a_1V_1\frac{\sin \omega t_1 \cos \beta_1\pi}{\sin(\beta_1\pi - \omega_1 t_1)}\right) \\ D = x_f\frac{\sin \beta_1\pi + \sin \omega_1 t_1}{\sin(\beta_1\pi - \omega_1 t_1)} + \sin \varphi \cdot a_1V_1 \cdot \left(\frac{\cos \omega t_1 \sin \beta_1\pi + \sin \omega_1 t_1}{\sin(\omega_1 t_1 - \beta_1\pi)}\right) + \cos \varphi\left(a_1V_1\frac{\sin \omega t_1 \sin \beta_1\pi}{\sin(\omega_1 t_1 - \beta_1\pi)}\right) \end{array}\right\} .[19]$$

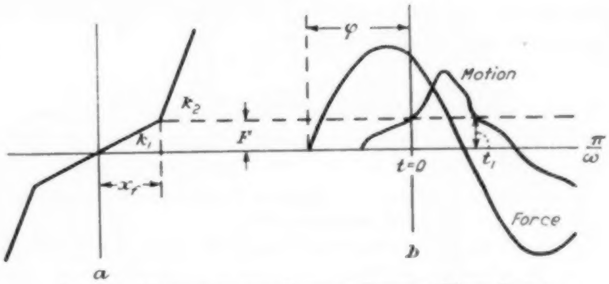

FIG. 9 MOTION IN THE CASE OF SPRINGS WITH STOPS

Substituting these values in [18(*e*)] and [18(*f*)] leads to two equations which can be written in the form:

$$\left.\begin{array}{l} P_1 \cos \varphi + Q_1 \sin \varphi + R_1x_f = 0 \\ P_2 \cos \varphi + Q_2 \sin \varphi + R_2x_f = 0 \end{array}\right\} \ldots\ldots\ldots [20]$$

where P, Q, and R are functions of t_1 and the various frequencies only, but do not contain either φ or x_f, as follows:

$$\left.\begin{array}{l} P_1 = \omega \cos \omega t_1(a_2V_2 - a_1V_1) + a_1\omega_1V_1 \sin \omega t_1 \times \cot(\omega_1 t_1 - \beta_1\pi) - a_2\omega_2V_2 \sin \omega t_1 \cot \omega_2 t_1 \\ Q_1 = \omega \sin \omega t_1(a_1V_1 - a_2V_2) + a_1\omega_1V_1 \cdot \frac{1 + \cos \omega t_1 \cos(\omega_1 t_1 - \beta_1\pi)}{\sin(\omega_1 t_1 - \beta_1\pi)} + a_2\omega_2V_2 \cot \omega_2 t_1 \cdot \frac{\cos \omega_2 t_1 - \cos \omega t_1}{\sin \omega_2 t_1} \\ R_1 = R_2 = \frac{k_1}{k_2}\omega_2\frac{\cos \omega_2 t_1 - 1}{\sin \omega_2 t_1} - \omega_1\frac{1 + \cos(\omega_1 t_1 - \beta_1\pi)}{\sin(\omega_1 t_1 - \beta_1\pi)} \\ P_2 = \omega_1(a_2V_2 - a_1V_1) + a_1\omega_1V_1\frac{\sin \omega t_1}{\sin(\omega_1 t_1 - \beta_1\pi)} + a_2\omega_2V_2\frac{\sin \omega t_1}{\sin \omega_2 t_1} \\ Q_2 = a_1\omega_1V_1\frac{\cos \omega t_1 + \cos(\omega_1 t_1 - \beta_1\pi)}{\sin(\omega_1 t_1 - \beta_1\pi)} + a_2\omega_2V_2\frac{\cos \omega t_1 - \cos \omega_2 t_1}{\sin \omega_2 t_1} \end{array}\right\} .[21]$$

From [20] we can solve for $\sin \varphi$ and $\cos \varphi$ in terms of x_f. Noting that $R_1 = R_2$,

$$\cos \varphi = \frac{R_1(Q_1 - Q_2)x_f}{P_1Q_2 - P_2Q_1}; \quad \sin \varphi = \frac{R_1(P_2 - P_1)}{P_1Q_2 - P_2Q_1}x_f \ldots [22]$$

and since $\sin^2 \varphi + \cos^2 \varphi = 1$, the following condition for x_f is obtained:

$$x_f^2 = \frac{(P_1Q_2 - P_2Q_1)^2}{R_1^2[(P_1 - P_2)^2 + (Q_1 - Q_2)^2]} \ldots\ldots\ldots [23]$$

With these results, the problem is reduced to numerical calculation. At each value of β_1, for a number of values of t_1 (ranging between zero and π/ω), P, Q, R, φ and x_f can be calculated by means of [21], [22], and [23]. With these values substituted in [19] and [16] the shape of the motion of the part between $t = 0$ and $t = t_1$ in Fig. 9(*b*) can be calculated and the maximum amplitude can be found. The results can be plotted as in Fig. 5, one such diagram for each value of the ratio k_1/k_2. The diagram given in Fig. 5 is the one for $k_1/k_2 = \infty$, while the condition of Fig. 1(*a*) is represented by $k_1/k_2 = 0$.

Appendix No. 2

LIST OF NOTATIONS

$a_1 = \frac{P}{k_1}; a_2 = \frac{P}{k_2}$ = static deflection of spring under maximum of impressed force

A, B, C, D = integration constants given by Equation [19]

F = spring force at which stop is hit [Fig. 9]

k_1, k_2 = spring constants in pounds per inch of deflection

P = maximum of impressed force $P \sin \omega t$

$P_{1,2}, Q_{1,2}, R_{1,2}$ = functions given by Equations [21]

t = time

t_1 = time of motion with the stiff springs [Fig. 9]

$U = \frac{\beta \sin \beta\pi}{1 + \cos \beta\pi}$ "Coulomb damping function"

$V_1 = \frac{\beta_1^2}{\beta_1^2 - 1}; \quad V_2 = \frac{\beta_2^2}{\beta_2^2 - 1}$, = "resonance function"

x = displacement

$x_f = F/k_1$ = displacement at which stiff spring is hit

x_a = displacement smaller than x_f, Equation [16]

x_b = displacement larger than x_f, Equation [17]

$\beta_1 = \frac{\omega_1}{\omega}; \quad \beta_2 = \frac{\omega_2}{\omega}$ = frequency ratios

φ = phase angle, Equation [1]

ω = frequency of impressed force: $P \sin \omega t$

$\omega_1^2 = \frac{k_1}{m}; \; \omega_2^2 = \frac{k_2}{m}; \; \omega_n^2 = \frac{k}{m}$ = characteristic frequencies

ω_f = natural frequency of free vibration

ω_c = "critical frequency" as defined in text.

Discussion

J. G. **Baker.**[10] The authors have found periodic motions of the mass of a non-linear single-degree system with which there is equilibrium between the inertia, the restoring force, and the disturbing force of the system. In their analysis they have considered only the possibility that the disturbing-force frequency (the disturbing force was considered simple harmonic) coincides with the fundamental frequency of the motion. It seems equally likely that a forced vibration could exist if the disturbing-force frequency coincided with a higher frequency component of the motion than the fundamental.

It is difficult to speak thus superficially of this possibility in systems with no damping, such as the authors treat, since steady vibrations may be either free or forced. For this reason let us discuss a similar system with a slight amount of linear damping so that any steady vibration must be forced. Suppose this non-linear system is vibrating freely and that there is a large second harmonic in its motion. If we apply a small simple harmonic force at the frequency of and in proper phase relation with this harmonic of the motion, there will be work done by this force on the motion. The energy lost in damping can thus be supplied, and it looks as if the motion could be maintained in this way practically unaltered.

In a linear system, a force at one frequency cannot furnish the energy dissipated by a force at another frequency. If this were true for the non-linear case in question, the energy dissipated by the damping at the fundamental frequency of the motion could not be supplied by the disturbing force we consider, and our proposed condition would be impossible. This objection can be quickly removed, however, by studying for a moment the cases similar to those solved by the authors. The motions are obviously never simple harmonic, so that with damping there will be energy dissipated at other frequencies than that of the disturbing force; yet this energy must come from the disturbing force. It is clear, then, that the theorem mentioned about the impossibility of exchange of energy in linear systems does not apply to non-linear systems.

A series of cases of forced vibrations of non-linear systems with damping can be exactly solved in a very simple manner. These are the cases in which the disturbing force is always equal and opposite to the damping force. If this is the condition, of course the problem may be looked upon as simply the academic case of a free non-linear undamped vibration. The latter case is always solvable. The disturbing force for the foregoing condition would not be simple harmonic, but it would be not far from it, since the motions are usually not far from sinusoidal. In a real case the disturbing force is not often simple harmonic anyway, so that there is no more reason why we should discuss a simple harmonic force than any other arbitrary periodic force. (There is clearly a reason for discussing simple harmonic forces for linear systems since the superposition of solutions is allowable, but this obviously is not the case for non-linear systems.) Further, if only an approximation is desired, it appears that the force could be considered as simple harmonic and of a magnitude large enough to supply all of the energy required by the damping. This would not satisfy the equilibrium requirement, but it would doubtless come very close to it.

To all these remarks and to the paper also can be put the following question: Even if a motion satisfies the equilibrium condition, how do you know that it is stable? Perhaps an infinitesimal change will bring about an entirely different motion. For some cases this question on inspection does not offer difficulty, while for others it appears that there is considerable study required to answer it.

M. **Stone.**[11] The work that the authors have carried out in this paper is a happy continuation of the type of analysis that one of the authors has sponsored in earlier work—i.e., the seeking of complete solutions over restricted ranges of validity and fitting the solutions together at the discontinuities. This type of solution provides the only real basis for adopting any approximate solution that may be analytically simpler.

Under this general subject head, this discusser some time ago had the task of properly designing a spring gear of variable flexibility characteristic with set-up forces that was used for locomotive transmission purposes. The scheme is shown diagrammatically in Fig. 10, together with its flexibility characteristic in Fig. 11. The purpose of such a characteristic is to introduce flexibility variable with displacement, so that no single critical frequency will exist—it will depend on the amplitude of oscillation. The curvature also supplies an automatic stop to the motion; i.e., the force approaches infinity, with little deflection—which is also desirable.

[10] Mechanics Division, Westinghouse Research Laboratories, East Pittsburgh, Pa.

[11] Development Section Engineer, Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

The differential equation of free oscillatory motion is:

$$m\frac{d^2y}{dt^2} + f(y) = 0 \qquad [24]$$

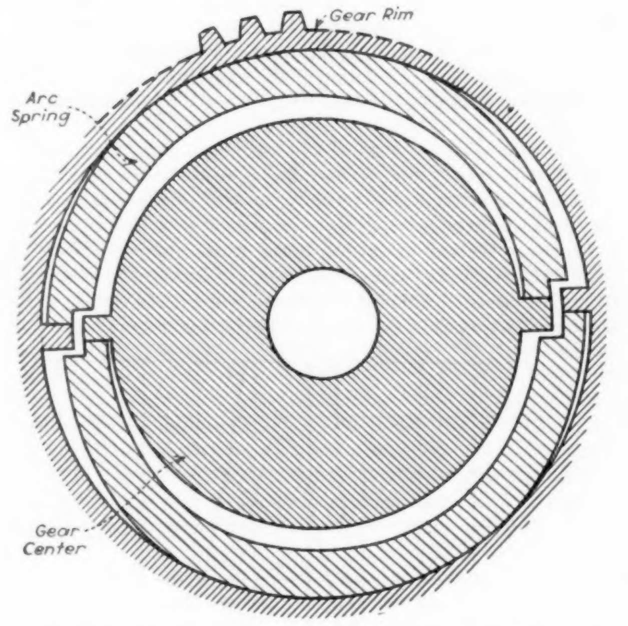

FIG. 10 SPRING GEAR OF VARIABLE FLEXIBILITY CHARACTERISTICS

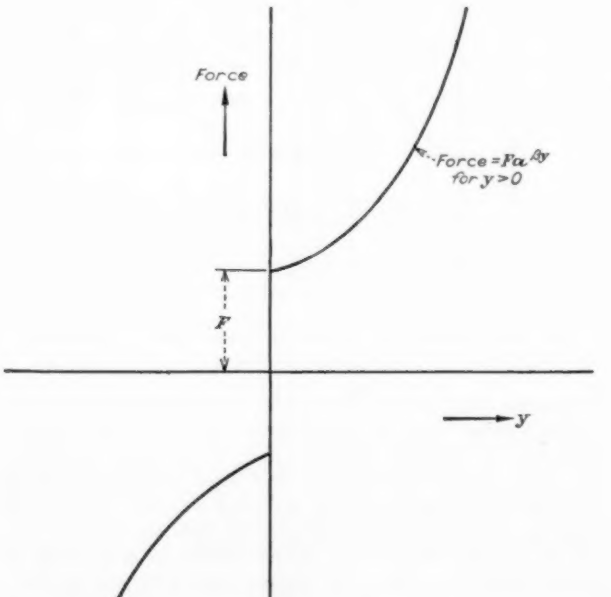

FIG. 11 SPRING GEAR ELASTIC CHARACTERISTICS

By confining attention to the range where $y > 0$, and knowing that the motion is mirrored for $y < 0$, it was found possible to satisfactorily solve this rather difficult case by substituting for $f(y)$:

$$f(y) = Fa^{\beta y} \qquad [25]$$

so that our motion equation becomes

$$m\frac{d^2y}{dt^2} + Fa^{\beta y} = 0 \qquad [26]$$

Here F is the set-up force. It is important to note that if F were zero, the use of this type of function would not be permitted. Continuing the solution:

$$m\left(\frac{dy}{dt}\right)d\left(\frac{dy}{dt}\right) = -Fa^{\beta y}dy$$

or

$$\frac{dy}{dt} = \sqrt{\left[\frac{2F}{m\beta\log_e a}\left(a^{\beta y_0} - a^{\beta y}\right)\right]} \qquad [27]$$

which integrates again into

$$\int_0^t dt = t = \int_{y_0}^0 \frac{dy}{\sqrt{\left[\frac{2F}{m\beta\log_e a}\left(a^{\beta y_0} - a^{\beta y}\right)\right]}}$$

or

$$t = \sqrt{\frac{m}{2F\beta\log_e a}}\left[-\frac{2}{\sqrt{(a^{\beta y_0})}}\tanh^{-1}\sqrt{\frac{a^{\beta y_0} - 1}{a^{\beta y_0}}}\right]. \qquad [28]$$

Now the period of oscillation, for a given amplitude y_0, is 4 × t, as given in [28], and the corresponding natural frequency is defined as

$$w_{cr} = \frac{\pi\sqrt{\frac{F\beta\log_e a\cdot a^{\beta y_0}}{8m}}}{\tanh^{-1}\sqrt{\left(\frac{a^{\beta y_0} - 1}{a^{\beta y_0}}\right)}} \qquad [29]$$

from which it is directly seen that w_{cr} is a function of the amplitude of oscillation y_0, and of the set-up force F as well. This relation is interesting and worth retaining as to its significance. This relation [29] is shown qualitatively in the curve, Fig. 12, and shows a high natural frequency for small amplitudes, a fast-decreasing natural frequency, and then increasing again with large amplitudes.

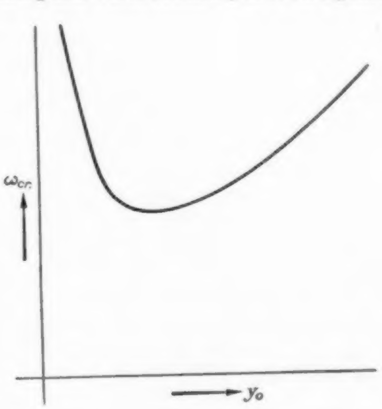

FIG. 12 RELATION SHOWN QUALITATIVELY

The equation of the forced vibration of such a system, or even the free vibration about a steadily deflected position (from 0), does not permit of a complete analytical solution, however. To this end, Rüdenberg's approximate method mentioned in the author's paper gives satisfactory practical results. Where

$$m\frac{d^2y}{dt^2} + Fa^{\beta y} = P\sin wt \qquad [30]$$

it is assumed that at $y = y_{\max}$, $y''_{\max} = -w^2 y_{\max}$, and that $y_{\max}$ occurs where the impressed force is also a maximum. Then

$$m \left. \frac{d^2y}{dt^2} \right|_{\max} + Fa^{\beta y \max} = P \ldots\ldots\ldots\ldots [31]$$

means

$$-mw^2 y_{\max} + Fa^{\beta y \max} = P \ldots\ldots\ldots\ldots [32]$$

from which $y_{\max}$ is obtained graphically.

E. O. WATERS.[12] The authors are dealing with an equation of motion which can be solved easily enough, but which is very clumsy for practical use on account of the ambiguity in the sign of the spring force. However, by an ingenious choice of initial conditions, they have very nearly sidestepped this difficulty, and have been able to present results which give the velocity and displacement of the vibrating body in a form which is no more complicated than that which is encountered in the classical case. But it is only fair to point out that their solution is a very special one; from the standpoint of the pure mathematician, there is not one chance in a million that a mass vibrating between elastic stops, as in Fig. 1(*b*), will behave *precisely* as predicted by their equations. The authors' formulas might be said to give a standard or type form of motion, just as $x/a = V \sin \omega t$ might be considered a standard solution for the classical case.

Actually, the motion of a vibrating body is a composite of that due to the spring force, which gives it one periodicity, and that due to the impressed force, which in general gives it a different periodicity. The result is a vibration with beats. For the classical case, with spring force proportional to displacement from the mean position, this gives an amplitude at the middle of each beat which is far greater than that indicated by the "standard" solution. For example, if $\beta = 1.25$, the "standard" amplitude is 2.778, whereas the actual amplitude at the middle of a beat (assuming initial displacement and velocity of zero, and a phase angle of 90 deg.) is twice this, or 5.555. The same thing occurs with the set-spring case; the "standard" amplitude, for $F = 0.4\ P$, is about 1.33 (see Fig. 5), whereas the maximum amplitude at the middle of a beat, as computed by a step-by-step solution of Equation [4], evaluating the constants and changing the sign of x_f each time that $x = 0$, is about 2.8. It is interesting to note that, for the classical case, the period of the vibrations within any given beat is constant, while with a set spring it increases with the amplitude, so that at the middle of a beat the vibrations take more time than they do at either end.

The exact solution of any problem of this type, with any given initial conditions, is of course possible, but extremely laborious. The authors are to be commended for their analysis of a particular case which is comparatively simple, and which gives an approximate indication of the motion that will generally occur with this kind of spring mounting.

AUTHORS' CLOSURE

Mr. Baker's discussion is a very valuable contribution to the subject, and calls attention to a condition the authors had overlooked. His remarks naturally can be also directly applied to a Coulomb-damped linear vibrating system of which the analysis is very similar. In other words, harmonic forces having frequencies 3, 5, 7...... times higher than the natural frequency of the undamped system are capable of setting up considerable vibrations at the natural frequency due to the presence of Coulomb damping.

Mr. Stone discusses the free vibrations of a spring somewhat different from ours. Comparing his Fig. 11 with our Fig. 1(*b*), it is evident that for small oscillations the same expression for the natural frequency as a function of the amplitude must be found. Indeed, our formula [13] and Mr. Stone's [29] both reduce to

$$\frac{\omega_f}{\omega_n} = \pi \sqrt{\frac{F}{8ky_0}}$$

for small values of y_0.

Professor Waters' discussion bears on the difference between transient and steady-state vibrations. Naturally, any analysis where no viscous friction is considered will lead to results where the transients stay in the system forever, but nevertheless such an analysis is capable of disclosing interesting and useful relations.

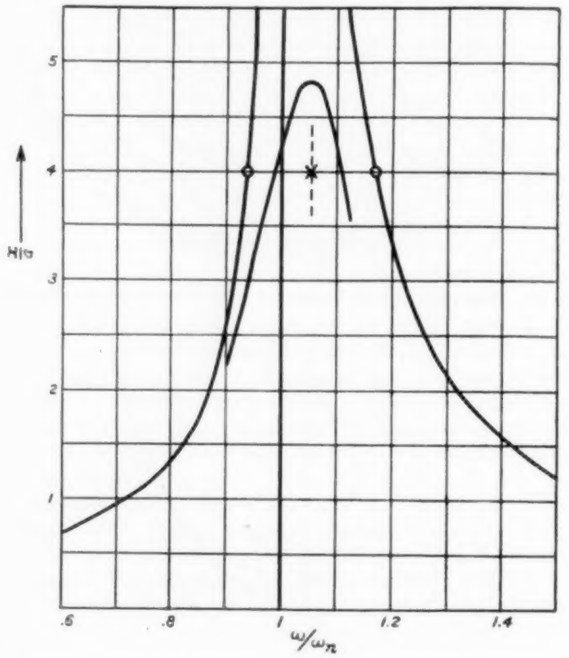

FIG. 13 EXACT CALCULATION INCLUDING VISCOUS DAMPING ($c/c_c = 0.1$; $P/F = 2.5$.)

The authors have not been satisfied with the rather arbitrary definition of "critical speed" on page 4. In order to judge its accuracy they have performed the detail calculations for one case with the exact solution including viscous friction. The analysis follows the lines indicated in footnote 8 and is very involved. The result for a viscous friction of $c/c_{cr} = 0.1$ are shown in Fig. 13. The curve without viscous friction for $P/F = 2.5$ is drawn in also, and the middle between the two intersections with $x/a = 4$ is indicated by a cross. It is seen that the maximum amplitude of the damped curve occurs just above the cross, showing that the arbitrary definition of "critical speed" is justified.

Design of Columns of Varying Cross-Section[1]

By DR. A. DINNIK,[2] DNIEPROPETROVSK, U.S.S.R.

Translated by M. Maletz,[3] Chicago, Ill.

In this paper the author develops formulas for special cases of columns of varying cross-section. The uses of these formulas are illustrated by many problems from practice, and tables of constants for every special case facilitate the application of the theory without going into the solution of differential equations.

COMPRESSION members are often given varying cross-sections, the section being increased where an increase in the bending moment is expected; i.e., making the member approximately uniform in strength. So far very little has been done in the development of formulas for the design of such members. In the present paper the author deals with compression members the middle portions of which are of uniform cross-section, and the end portions are tapered according to definite mathematical laws. Such members are quite frequently met in engineering structures, and those with hinged and with free ends will both be considered.

Members With Free Ends

Let us consider a compression member the middle portion of which is of uniform prismatic cross-section, and which has both of its ends tapered as shown in Fig. 1. Let l denote the total length of the member, λ the length of its middle portion, I the constant moment of inertia of the middle part, and i the moment of inertia of the extreme end sections (smallest). Let the moment of inertia of both tapered portions AB and CD vary according to the law:

$$I_x = I\left(\frac{x}{b}\right)^m \qquad [1]$$

where b denotes the distance between section CC and the point of intersection O of the lines CD and C_1D_1. This point O will be taken as the origin of coordinates (not shown in the figure). The solution of the differential equation of the elastic curve for both the mid-portion and the ends shows that the critical load may be expressed in the simple form:[4]

$$P_K = \frac{KEI}{l^2} \qquad [2]$$

which is similar to Euler's well-known formula. Here P_K denotes the critical load, E Young's modulus of elasticity, I the moment of inertia of the middle portion of the strut, l the total length of the member, and K the coefficient of stability, its magnitude being a function of the geometrical form and the method of fastening the strut. Values of this "coefficient of stability" K for various values of i/I and λ/l for the case of a strut with free ends are given in Table 1. The use of this table is illustrated in the following problems.

TABLE 1 VALUES OF THE COEFFICIENT OF STABILITY K FOR STRUTS WITH FREE ENDS

	Values of λ/l					
Values of i/I	0	0.2	0.4	0.6	0.8	m
0.0	5.78	7.04	8.35	9.36	9.80	1
0.0	1.00	1.56	2.78	6.25	9.57	2
0.0	0.0	0.0	0.0	0.0	0.0	3

Problem 1. An airplane pine strut, the total length of which is $l = 100$ in., has its middle portion 60 in. long and of constant rectangular cross-section (4 in. × 1 in.). The width of both end portions is tapered according to a straight-line law and is 2.4 in. at the end. The modulus of elasticity is to be taken as $E = 1{,}500{,}000$. It is required to figure this strut for buckling.

Solution. Here is a case where the rigidity EI of the end portions varies according to a straight-line law; i.e., $m = 1$; further, $i/I = 0.6$, and also $\lambda/l = 0.6$. From Table 1 it is accordingly found that $K = 9.76$, and from Equation [2] the critical load is 488 lb. The maximum compressive stress is about 196 lb per sq in., which is considerably less than that allowable.

Problem 2. Same strut as in Problem 1, but with the thickness of the end portions varying according to a straight-line law from 1 in. to 0.59 in., the width being constant (4 in.).

Solution. In this case the moment of inertia varies according to the law of cubes; i.e., $m = 3$; $i/I = 0.2$, and $\lambda/l = 0.6$. From Table 1 it is found that $K = 9.39$, and from [2] the critical load is 470 lb.

Problem 3. The connecting rod of a steam engine is 210 in. long; its middle portion, of a cylindrical cross-section, is 42 in. long. Both ends are conical. The largest diameter of the connecting rod is 8 in., the smallest, 6.36 in. Find the critical load. (These dimensions were taken from a mine hoist in the Don Basin. The influence of the head of the connecting rod is so small that it may be neglected. The diameter of the cylinder is 42 in. and the steam pressure 110 lb; the load on the rod is to be taken as 150,000 lb, i.e., with a factor of safety of 7.)

Solution. Here $\lambda/l = 0.2$, $i = 80.3$ in.^{4}, $I = 201$ in.^{4}, $i/I = 0.4$, and $m = 4$ (the moment of inertia of a cone varying as the law of the fourth power). From Table 1, $K = 8.33$, and from

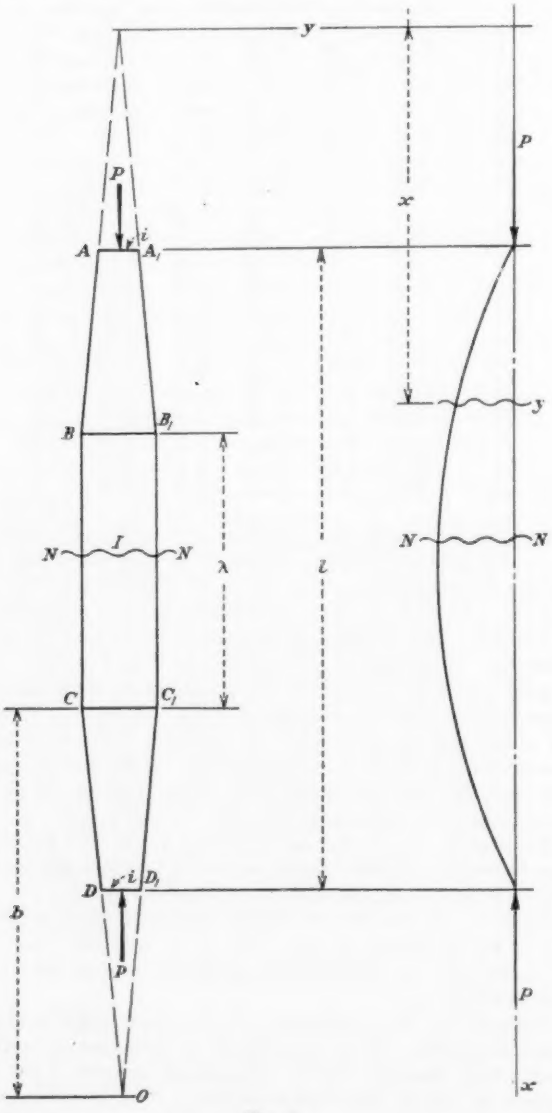

FIG. 1

Equation [2] $P = 1{,}140{,}000$ lb, assuming $E = 30{,}000{,}000$. The critical stress in the smallest section is 36,500 lb per sq in., which does not exceed the elastic limit for steel.

MEMBERS WITH FIXED ENDS

In this case the critical load may be also determined by using Equation [2]. The coefficients of stability are given in Table

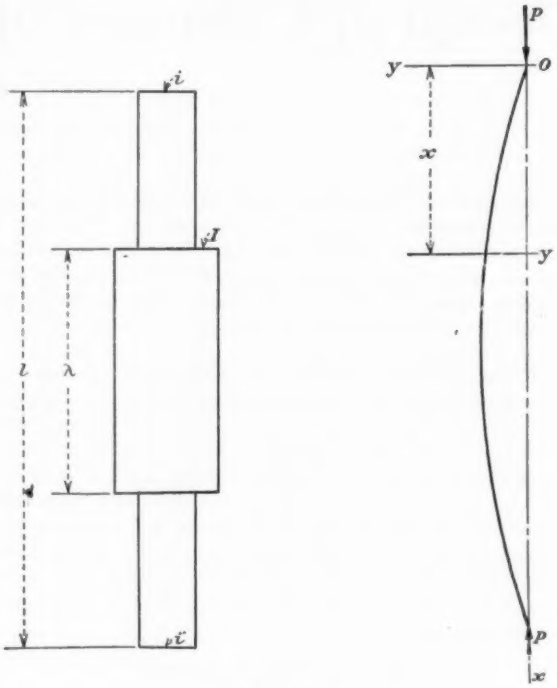

FIG. 2

2, which was computed exactly in the same manner as was Table 1. It is well to bear in mind that for a column of rectangular cross-section with both ends fixed the coefficient of stability is $K = 4\pi^2 = 39.48$.

VARIATION OF RIGIDITY OF COLUMN ACCORDING TO AN EXPONENTIAL LAW

If the moment of inertia varies along the length of the column according to an exponential law such that

$$I_x = Ie^{-\frac{mx}{l}} \qquad [3]$$

then the equation is also integrated in Bessel's functions. The general formula for the critical load is same as Equation [2]. The coefficients of stability for the case of a strut hinged at both ends are given in Table 3.

TABLE 3 VALUES OF THE COEFFICIENT OF STABILITY K FOR STRUTS HINGED AT BOTH ENDS

	Values of λ/l				
Values of i/I	0	0.2	0.4	0.6	0.8
0.01	1.27	1.91	3.14	5.77	9.24

1.0	9.87	....	....	....	....

PROBLEM. An airplane pine strut is 6 ft 8 in. long, its middle portion is 16 in. long, and its cross-section is elliptical. The axes of the (constant) cross-section of the middle portion are $2a = 4$ in. and $2b = 2$ in. The strut is tapered toward both ends according to an exponential law, the axes of the ellipses at the ends being $2a_1 = 3.2$ in. and $2b_1 = 1.6$ in. Assuming an allowable compressive stress of 900 lb per sq in. and taking $E = 1{,}500{,}000$, examine this strut for buckling.

Solution. First compute the moment of inertia of the middle cross-section about its axis of minimum rigidity; i.e. where the danger of buckling is the greatest.

$$I = \frac{\pi ab^3}{4} = \frac{\pi}{2}$$

and for the end sections the moment of inertia is $i = 0.205\pi$; therefore $i/I = 0.4$, and $\lambda/l = 0.2$. From Table 3, $K = 8.23$, whence $P = 3040$ lb. The compressive stress will be only 480 lb per sq in., which is below the assumed allowable stress of 900 lb. Taking a factor of safety of 6, the allowable load on the strut will be a little above 500 lb.

The Stepped Strut

Such a strut consists of parts of different cross-sections as shown in Fig. 2. Let i and I denote the moments of inertia of the end portions and middle portion, respectively, l the total length, and λ the length of the middle portion. The critical load for such a strut is also given by Equation [2]. The coefficients of stability for the case where both ends are hinged are given in Table 4, and where both ends are fixed, in Table 5.

Problem. A column is built up of two 6-in. 8.2-lb channels 20 ft 10 in. long, riveted web to web as shown in Fig. 3. The critical load according to Euler's formula is

$$P_e = \frac{30 \times 10^6 \times 2 \times 1.34}{62{,}500} = 12{,}700 \text{ lb}$$

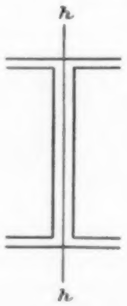

Fig. 3

where 1.34 is the moment of inertia of each channel about the axis *hh*. Assume that it is required to strengthen the mid-portion by riveting on two 4-in. × $^3/_8$ in. cover plates so that the critical load may be increased to 27,300 lb. What should be the length of the stiffened portion?

Solution. The moment of inertia of the two additional plates about *hh* (Fig. 3) is $2 \times 3 \times 64/8 = 4$ in.^{4}. Thus, the moment of inertia of the stiffened portion is $I = 6.68$, the moment of inertia of the end portion, $i = 2.68$, and the ratio $i/I = 0.4$. From [2] the coefficient K is determined as

$$K = \frac{Pl^2}{EI} = \frac{27{,}300 \times 62{,}500}{30 \times 10^6 \times 6.68} = 8.51$$

In Table 4 it is seen that for $K = 8.51$, $i/I = 0.6$, and $\lambda/l = 0.6$; i.e., it is sufficient to strengthen the column along a length $\lambda = 0.6l = 12$ ft 6 in.

Built-Up Columns Stiffened by Lattice Bars

Consider a column built up of four angles and consisting of three parts: the middle part, of constant cross-section, and two end parts of varying cross-section in which the edges follow a curved path (Fig. 4). Let I denote the moment of inertia of the center portion of constant cross-section, and i the moment of inertia of the end section of each of the end portions.

The moment of inertia of any section distant x from the point of intersection of the curved paths is

$$I_x = 4I_c + 4S\eta^2 \ldots\ldots\ldots\ldots\ldots\ldots [4]$$

where I_c denotes the moment of inertia of each angle about its center of gravity, S the sectional area of each angle, and η the distance of the center of gravity of each angle from the neutral plane of the column in bending. Often the first quantity in the second member of Equation [4] may be neglected as being very small in comparison with $4S\eta^2$, and we may put

$$I_x = 4S\eta^2 \ldots\ldots\ldots\ldots\ldots\ldots\ldots [5]$$

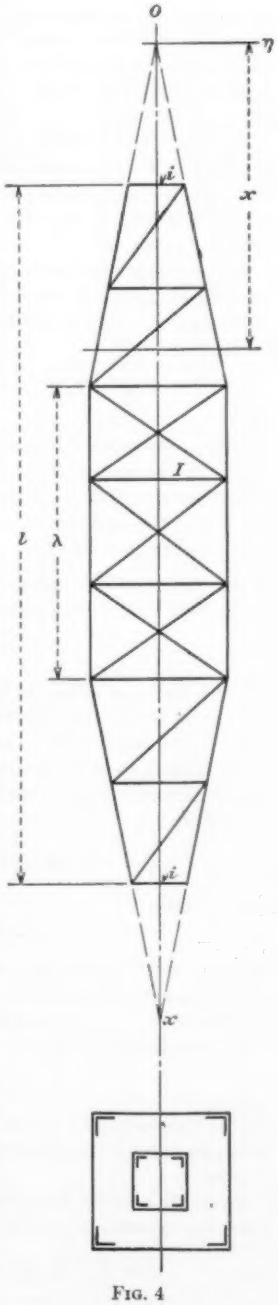

Fig. 4

Let us now consider a special case, when the edge of the column follows a curved path the equation of which is

$$\eta = Ax^n \ldots\ldots\ldots [6]$$

A and n being constants. The moment of inertia will then be

$$I_x = 4SA^2x^{2n} \ldots\ldots [7]$$

i.e., will vary according to an exponential law.

We may now investigate a few special cases. When $n = 0$, the moment of inertia is constant along the whole length of the column—Euler's case.

When $n = {}^1/_2$, then the equation of the edge is

$$\eta^2 = A^2x$$

and the moment of inertia,

$$I_x = 4SA^2x \ldots\ldots [8]$$

i.e., the edge of the column is a parabola, the axis of which coincides with the vertical center line of the column (Fig. 4). The moment of inertia of the end portions varies according to a straight-line law; the coefficients of stability may be found in Tables 1 and 2, for $m = 1$. When $n = 1$, the column is of a pyramidal shape, its moment of inertia varies as the law of squares, and the coefficients of stability are also found in Tables 1 and 2, but for $m = 2$. When $n = 3/2$, the edge of the column is a semi-cubic parabola, the axis of which coincides with the center line of the column. The moment of inertia varies as the law of cubes, and the coefficients of stability are found in Tables 1 and 2 for $m = 3$.

When $n = 2$, the edge of the column is a parabola, the axis of which is perpendicular to the center line of the column and coincides with the ordinate $O\eta$.

$$\eta = Ax^2;\ I_x = 4SA^2x^4 \ldots\ldots\ldots\ldots\ [9]$$

The moment of inertia varies as the law of the fourth power; the coefficients of stability are taken from Tables 1 and 2 for $m = 4$.

If in general the edges follow a curve the equation of which is

$$\eta = Ae^{-\frac{nx}{l}} \ldots\ldots\ldots\ldots\ [10]$$

the moment of inertia varies according to an exponential law, and the coefficients of stability are given in Tables 4 and 5.

The foregoing reasoning is true not only for columns when the edges are curved, but also when they are polygonal, provided the vertices of the polygons lie in the paths of the curves [6] or [10].

Problem. A supporting column in a mine structure 66 ft 8 in. high carries a compressive load of 70,000 lb. The cross-section is conical and the column is built up of four equal-leg angles connected with lattice bars. Select the size of the angles and the distances between them, assuming an allowable compressive stress of 7000 lb per sq in. and a factor of safety of 4.

Solution. Considering the column under simple compression, it is found that the sectional area of each angle must be 2.5 sq in. This corresponds to a $2^3/_4 \times 2^3/_4 \times {}^1/_2$-in. angle,[5] the area of which is 2.53 sq in., and the compressive stress will then be 6900 lb per sq in.

Let us now select the distance between the back of the angles so that the column will not buckle. If the width of the column is taken as 12 in., then the moment of inertia of the section will be—see Equation [4]:

$$I = 4\,(1.62 + 2.53 \times 5.15^2) = 273 \text{ in.}^4$$

where

1.62 = moment of inertia of each angle about the axis through its center of gravity

5.15 = 6 — 0.85, where 0.85 is the distance from the back of the angle to its center of gravity. (All figures taken from a standard steel handbook.)

If the section of the column is uniform along the whole length, the critical load in accordance with Euler's theory will be

$$P = 126{,}000 \text{ lb}$$

i.e., the factor of safety is less than 2.

In order to increase the stability of the column let us make it wider in the middle only. Let us space the angles in the middle of the column 18 in. back to back. The moment of inertia of the new section consisting of the same angles but 18 in. center to center will be

$$I = 4\,(1.62 + 2.53 \times 8.15^2) = 680 \text{ in.}^4$$

and the ratio

$$i/I = 0.4$$

As the moment of inertia varies in this case very closely as the law of squares, the coefficient of stability may be taken from Table 1. For $m = 2$, $\lambda = 0$ and $i/I = 0.4$, $K = 7.61$, and the critical load according to [2] is

$$P_K = 242{,}000 \text{ lb}$$

i.e., by increasing the width of the column in its middle part we have increased its stability nearly twice with a factor of safety of over 3.

Let us try making the width 20 in. at the middle of the column. Then the moment of inertia

$$I = 4\,(1.62 + 2.53 \times 9.15^2) = 855 \text{ in.}^4$$

and $i/I = 0.32$ or about 0.3. The corresponding coefficient of stability from Table 1 is $K = 7.05$, and the critical load

$$P_K = 280{,}000 \text{ lb}$$

i.e., the factor of safety is exactly 4.

But instead of increasing the width from 18 in. to 20 in., we can keep it at 18 in. and make the mid-portion of constant cross-section (prismatic) as shown in Fig. 4. As before let us make the width at the ends 12 in. with a moment of inertia $i = 273$ in.^{4}, and at the middle 18 in. with a moment of inertia $I = 680$ in.^{4}, and let us also make the prismatic mid-portion 13 ft 4 in. long.

Then $l = 800$ in., $\lambda = 160$ in., and from Table 1 for $i/I = 0.4$ and $\lambda/l = 0.2$, $K = 8.42$, and from [2] the critical load

$$P_K = 268{,}000 \text{ lb}$$

i.e., again too low a factory of safety.

Trying another ratio $\lambda/l = 0.4$; i.e., $\lambda = 320$ in. (26 ft 8 in.) and the coefficient of stability $K = 9.15$,

$$P_K = 292{,}000 \text{ lb}$$

This value is again too high. By making $\lambda/l = 0.3$ we find $K = 8.78$ and $P = 280{,}000$ lb, giving exactly the required factor of safety. It is evident that by widening the column in the middle along a certain distance we can increase the stability of the column without increasing the sectional area of the angles, provided that the connections employed are rigid enough to prevent any relative displacement of the angles and the column will act as a whole.

If the angles were bent and given the shape of a parabola with its axis vertical, with the ratios $\lambda/l = 0.3$ and $i/I = 0.4$, the critical load would be 283,000 lb. If the angles were bent and given the shape of a parabola with its axis horizontal, the critical load would be 278,000 lb, or but slightly less.

Remarks

Tables 1, 4, and 5 give coefficients of stability for the case of a column with hinged ends, and of the type shown in Fig. 1. Considering the upper part of the column only, we arrive at the solution of the problem where the lower end is fixed, the upper end free, the lower part is of constant cross-section and the upper part of varying cross-section, varying according to [1] or [3]. The critical load for this case can also be obtained from [2], but the coefficients of stability given in Tables 1 and 3 should be divided by 4. This remark holds good for the coefficients of Table 4 and the cases to which these coefficients are applied.

Conclusion

The author has given formulas for designing columns, the mid-portions of which are of constant cross-section and the ends are of varying cross-section, their moments of inertia varying as the law of exponents or the law of powers. The formula for the critical load in all cases is

$$P_K = K\,\frac{EI}{l^2}$$

The coefficient K is a function of the shape of the column and conditions at the ends. Tables 1–5 give these coefficients for a great variety of cases. Special tables are given for the case where the width of the column varies according to a straight-line law, the thickness however remaining the same; for the case of a column with edges bent to the form of a parabola, the width being kept constant and the thickness varying according to a straight-line law; and further for the cases of a conical column, a built-up column, etc. Finally the case of a stepped column is considered and tables for a column consisting of three parts of different but constant moments of inertia are computed.

---

[5] British standard—Translator.

Appendix

Let us consider a column consisting of three parts (Fig. 1), the middle part BC of prismatic and constant cross-section, and two end parts of varying cross-section, tapering toward the ends. Let l denote the total length of the column, λ the length of the middle part, I the constant moment of inertia of the middle part, and i the moment of inertia of the end section. Let the moment of inertia of the end parts AB and CD vary as the exponential law

$$I_x = I\left(\frac{x}{b}\right)^m \ldots\ldots\ldots\ldots\ldots\ldots [11]$$

where m is a positive whole or fractional integer, b is the distance from the section CC to the apex O where the moment of inertia I_x becomes zero. This point is taken as the origin of the coordinates and is not shown in the figure. In view of the symmetry of the column it is sufficient to analyze its upper half only.

The differential equation for flexure for the middle portion of the column is

$$EIy'' + Py = 0 \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

and for the upper portion AB,

$$EI\left(\frac{x}{b}\right)^m y'' + Py = 0 \ldots\ldots\ldots\ldots\ldots [13]$$

Both equations are of the second order, and there are four constants of integration which will have to be determined from the following conditions at the ends:

(1) At the middle of the column in section NN,

$$y' = 0$$

(2), (3) At the section BB, the deflection y and the slope of the deflection curve y' can be found by solving Equation [12] or [13].

(4) At the end AA of the column, $y = 0$.

Remarks. Equation [13] and condition (4) are for the case of hinged ends. In case of fixed ends, we shall have in Equation [13] the reactive moment m at the end section AA, and to condition (4) another condition will be added: namely, at the end of the column $y = 0$ and $y' = 0$.

Equation [13] is generally solved by means of Bessel's functions for any value of m except for $m = 2$. For $m = 2$, however, the integral of [13], as shown in the following paragraphs, can be obtained very simply. This exceptional case is of the greatest practical importance.

CASE WHEN $m = 2$

Equation [13] for this case is

$$EI\left(\frac{x}{b}\right)^2 y'' + Py = 0 \ldots\ldots\ldots\ldots\ldots [14]$$

and its integral

$$y = \sqrt{x}\left\{C\cos(\mu\log_e x) + D\sin(\mu\log_e x)\right\} \ldots\ldots [15]$$

where

$$\mu^2 = \frac{Pb^2}{EI} - \frac{1}{4} \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

The integral of [12] for the middle portion of the column is

$$y = A\cos nx + B\sin nx \ldots\ldots\ldots\ldots [17]$$

where

$$n^2 = \frac{P}{EI}$$

For the case of hinged ends the conditions (1)–(4) at the ends give us the following equation for the determination of the magnitude of 2μ:

$$\sqrt{1+4\mu^2}\tan\left[\sqrt{1+4\mu^2}\,\frac{(1-k^2)\lambda}{2(l-\lambda)}\right] = 1 + 2\mu\cot\left[2\mu\log_e k\right] \ldots\ldots\ldots [18]$$

Substituting the value of 2μ thus found from [18] in [16], the critical load is found to be

$$P = \frac{(1+4\mu^2)\,(1-k^2)^2}{4\left(1-\dfrac{\lambda}{l}\right)^2}\,\frac{EI}{l^2} = K\frac{EI}{l^2} \ldots\ldots\ldots [19]$$

where $k^4 = i/I$.

To find the coefficients of stability K for different ratios i/I and λ/l we first assume in [18] that $i/I = 0, 0.1, 0.2\ldots$ and $\lambda/l = 0, 0.1, 0.2\ldots$ and determine the first root (2μ) of this equation and then substitute the value of 2μ in [19]. The values of the roots of [18], 2μ, are given in Table 6 for various values of i/I and λ/l.

0.8	28.78	23.33	17.67	11.83	5.87

In the case of a column with fixed ends, Equations [12], [13], and [14] will have an additional constant M_0 (reactive moment), and Equations [15] and [17] will have a constant M_0/P.

From the conditions at the ends the following equation is found for the determination of the magnitude 2μ:

$$\sqrt{1+4\mu^2}\cot\left[\sqrt{1+4\mu^2}\,\frac{(1-k^2)\lambda}{2\,(l-\lambda)}\right] = 1 + 2\mu\cot(2\mu\log_e k) \ldots\ldots\ldots [20]$$

The roots of this equation are given in Table 7, and the coefficients of stability K are given in Table 2 for $m = 2$.

TABLE 7

	Values of λ/l				
Values of i/I	0	0.2	0.4	0.6	0.8
0.2	7.81	6.60	5.10	3.42	1.62
0.4	13.71	11.34	8.66	5.85	2.94
0.6	24.60	20.06	15.21	10.24	5.20
0.8	56.32	45.44	34.25	22.96	11.61

CASE WHEN $m = 4$

In this case the solution is in elementary functions. The differential Equation [13] is now

$$EI\left(\frac{x}{b}\right)^4 y'' + Py = 0 \ldots\ldots\ldots\ldots\ldots [21]$$

or more simply,

$$x^4y'' + U^2y = 0 \ldots\ldots\ldots\ldots\ldots\ldots [22]$$

where

$$U^2 = \frac{Pb^4}{EI} \ldots\ldots\ldots\ldots\ldots\ldots [23]$$

Its integral is

$$y = x\left\{A\cos\frac{U}{x} + B\sin\frac{U}{x}\right\} \ldots\ldots\ldots\ldots [24]$$

From the conditions at the ends in the case of hinged ends, we arrive at the following equation for determining U:

$$\tan\frac{(1-k^2)\,U\lambda}{l-\lambda}+\cot\frac{(1-k^2)\,U}{k^2}=\frac{1}{U}\ldots\ldots\;[25]$$

where

$$k^8=\frac{i}{I}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\;[26]$$

Substituting the roots of the [25] in [23] we find the critical load

$$P=\left\{\frac{(1-k^2)\,U}{1-\dfrac{\lambda}{l}}\right\}^2\frac{EI}{l^2}=K\,\frac{EI}{l^2}\ldots\ldots\ldots\;[27]$$

The roots U of Equation [25] are given in Table 8 for various values of i/I and λ/l, and the coefficients of stability K are given in Table 1 at $m = 4$.

TABLE 8

Values of i/I	Values of λ/l					
	0	0.1	0.2	0.4	0.6	0.8
0.1	..	3.39	2.26	1.90	1.38	0.71
0.2	3.70	3.49	3.24	2.63	1.85	0.95
0.4	6.68	6.18	5.64	4.42	3.03	1.53
0.6	12.14	11.10	10.01	7.69	5.21	2.62
0.8	28.00	25.39	22.71	17.21	11.52	5.79

In the case of fixed ends the conditions at the ends give the following equation for determining U:

$$U\tan\frac{(1-k^2)\,\lambda U}{l-\lambda}=1+\frac{k^2+U\tan\dfrac{1-k^2}{k^2}\,U}{k^2\tan\dfrac{1-k^2}{k^2}\,U-U}\,U\ldots\;[28]$$

The roots of [28] are given in Table 9, and the coefficients of stability K in Table 2 for $m = 4$.

TABLE 9

Values of i/I	Values of λ/l				
	0	0.2	0.4	0.6	0.8
0.2	6.44	5.50	4.30	2.95	1.57
0.4	12.27	10.18	7.80	5.30	2.78
0.6	23.10	21.03	16.61	9.66	4.97
0.8	54.77	44.21	33.32	22.36	11.33

CASE WHEN $m = 1$

In this case Equation [13] is solved by means of Bessel's functions; its integral

$$y=\sqrt{x}\left\{AJ_1\left[\sqrt{\frac{4Pbx}{EI}}\right]+BN_1\left[\sqrt{\frac{4Pbx}{EI}}\right]\right\}\ldots\;[29]$$

where J_1 and N_1 are cylindrical functions.

From the conditions (1)–(4) at the end for columns with hinged ends we arrive at the following equation for determining the auxiliary magnitude U:

$$\tan\frac{(1-k^2)\lambda U}{4\,(l-\lambda)}=\frac{J_1\,(kU)N_0(U)-N_1(kU)J_0(U)}{J_1\,(kU)\,N_1\,(U)-N_1\,(kU)\,J_1(U)}$$

where $k^2 = i/I$ and the coefficient of stability

$$K=\left[\frac{(1-k^2)\,Ul}{l-\lambda}\right]^2\ldots\ldots\ldots\ldots\;[31]$$

U is found from [30], and from [31] and [2] the critical load is determined.

Table 10 contains the roots of Equation [30], and the coefficients of stability are given in Table 1 under $m = 1$.

TABLE 10

Values of i/I	Values of λ/l				
	0	0.2	0.4	0.6	0.8
0	2.41	2.12	1.73	1.22	0.63
0.1	2.83	2.45	1.96	1.37	0.70
0.2	3.31	2.83	2.24	1.56	0.78
0.4	4.68	3.91	3.03	2.08	1.05
0.6	7.33	6.04	4.63	3.12	1.57
0.8	15.22	12.35	9.33	6.27	3.14

For columns with fixed end, instead of Equation [30] we have

$$\tan\frac{(1-k^2)\lambda U}{2\,(l-\lambda)}=\frac{J_0\,(U)\,N_0\,(kU)-N_0\,(U)\,J_0\,(kU)}{J_1\,(U)\,N_0\,(kU)-N_0\,(U)\,J_1\,(kU)}\cdot[32]$$

The roots of this equation are given in Table 11, and the coefficients of stability for this case are found in Table 2 under $m = 1$.

TABLE 11

Values of i/I	Values of λ/l				
	0	0.2	0.4	0.6	0.8
0	2.40	2.12	1.73	1.22	0.63
0.2	5.64	4.73	3.67	2.52	1.35
0.4	8.53	7.03	5.38	3.66	1.92
0.6	13.93	11.35	8.61	5.81	2.99
0.8	29.80	24.0	18.10	12.14	6.15

CASE WHEN $m = 3$

The differential equation for flexure is

$$EI\left(\frac{x}{b}\right)^3y''+Py=0$$

and its integral is

$$y=\sqrt{x}\left\{AJ_1\left[\sqrt{\frac{4\pi b^3}{EIx}}\right]+BN_1\left[\sqrt{\frac{4\pi b^3}{EIx}}\right]\right\}\ldots\;[33]$$

From the conditions at the ends for columns with hinged ends we arrive at the following equation:

$$\tan\frac{(1-k^2)\lambda U}{2\,(l-\lambda)}=\frac{J_1\left(\dfrac{U}{k}\right)N_2\,(U)-N_1\left(\dfrac{U}{k}\right)J_2\,(U)}{J_1\left(\dfrac{U}{k}\right)N_1\,(U)-N_1\left(\dfrac{U}{k}\right)J_1\,(U)}\ldots\;[34]$$

where $k^8 = i/I$

Computing the roots U of Equation [34] for various values of i/I and λ/l and substituting them in [31], we find the coefficients of stability given in Table 1 under $m = 3$. The roots of [34] are given in Table 12.

TABLE 12

Values of i/I	Values of λ/l				
	0	0.2	0.4	0.6	0.8
0.2	5.97	5.21	4.21	2.95	....
0.4	10.42	8.80	6.87	4.70	....
0.6	18.61	....	....	....	....
0.8	42.39	....	....	....	....

For columns with both ends fixed, U is determined from the following equation:

$$\tan\frac{(1-k^2)\lambda U}{2\,(l-\lambda)}=\frac{J_2\,(U)\,N_2\left(\dfrac{U}{k}\right)-N_2\,(U)\,J_2\left(\dfrac{U}{k}\right)}{J_1\,(U)\,N_2\left(\dfrac{U}{k}\right)-N_1\,(U)\,J_2\left(\dfrac{U}{k}\right)}\ldots\;[35]$$

The roots of this equation are given in Table 13 and the coefficients of stability in Table 2 under $m = 3$.

TABLE 13

Values of i/I	Values of λ/l				
	0	0.2	0.4	0.6	0.8
0.2	10.35	8.81	6.87	4.72	2.51
0.4	19.13	15.85	12.15	8.26	4.33
0.6	35.40	28.90	21.9	14.80	7.62
0.8	32.90	66.90	50.5	33.8	17.15

NOTE. Table 12 is not complete because the coefficients of stability K in Table 2 can be figured with sufficient accuracy from comparison of the values under $m = 2$ and $m = 4$ in Table 1.

EXPONENTIAL LAW OF VARIATION OF MOMENT OF INERTIA

Referring to Fig. 1, let the moment of inertia of both end portions CD and AB of the column vary along their lengths according to the following exponential law:

$$I_x = I e^{-\frac{m(b-x)}{b}} \qquad [36]$$

where I is the largest moment of inertia of the portion of varying cross-section and at the same time the moment of inertia of the middle portion, and b is the length of the end portion.

The length of the column is l as before, and λ denotes the length of the middle portion. Let the origin of coordinates be at the center of section AA, and let us denote the smallest moment of inertia, at $x = 0$, by i. From [36]

$$i = Ie^{-m} = k^2 I$$

where

$$k^2 = \frac{i}{I} = e^{-m} \qquad [37]$$

The differential equation for flexure for the middle portion remains as given by Equation [12], and for the upper portion

$$EIe^{-\frac{m(b-x)}{b}} y'' + Py = 0 \qquad [38]$$

This equation is integrated by means of Bessel's function of zero order:

$$y = A\,J_0(u) + B_0\,N(u) \qquad [39]$$

where

$$u = \frac{2}{m}\sqrt{\frac{Pb^2}{EI}}\,e^{-\frac{m(b-x)}{b}} \qquad [40]$$

From the conditions at the ends of a hinged-ended column we arrive at the following equations for determining the critical load:

$$\tan\frac{m\lambda U}{2(l-\lambda)} = \frac{J_0\left(\frac{U}{k}\right)N_1(U) - N_0\left(\frac{U}{k}\right)J_1(U)}{J_0\left(\frac{U}{k}\right)N_0(U) - N_0\left(\frac{U}{k}\right)J_0(U)} \qquad [41]$$

where

$$U = \frac{2}{m}\sqrt{\frac{Pb^2}{EI}}; \qquad k^2 = \frac{i}{I} = e^{-m} \qquad [42]$$

Substituting 0.1, 0.2, etc., for i/I and λ/l in [41], we determine for each value the first root U of [41], and from [42] we then determine the critical load

$$P_{cr} = \left[\frac{mU\lambda}{2(l-\lambda)}\right]^2 \frac{EI}{l^2} = K\frac{EI}{l^2} \qquad [43]$$

Table 14 gives the roots of [41], and the coefficients of stability are to be found in Table 3.

STEPPED COLUMNS

The column consists of three parts of two different cross-sections (Fig. 2). Let i and I denote the moment of inertia of the upper and lower portions and the middle portion, respectively, l the total length of the column, and λ the length of the middle portion.

TABLE 14

	Values of λ/l				
Values of i/I	0	0.2	0.4	0.6	0.8
0.01	0.25	0.24	0.23	0.21	0.13
0.1	0.83	0.82	0.70	0.52	0.27
0.2	3.31	1.31	1.07	0.76	0.39
0.4	4.68	2.51	1.97	1.35	0.68
0.6	7.33	4.69	3.61	2.44	1.23
0.8	15.22	11.04	8.35	5.62	2.82

The differential equations for flexure of the upper or lower and middle portions are:

$$\begin{aligned} E\,i\,y_1'' + P\,y_1 &= 0 \\ E\,I\,y_2'' + P\,y_2 &= 0 \end{aligned} \qquad [44]$$

The conditions at the ends are

$$\begin{aligned} &(1)\quad x = 0 \quad y_1 = 0 \qquad &(3)\quad x = \frac{l-\lambda}{2} \quad y = y_2 \\ &(2)\quad x = \frac{l}{2} \quad y_2' = 0 \qquad &(4)\quad x = \frac{l-\lambda}{2} \quad y_1^1 = y_2^1 \end{aligned} \qquad [45]$$

The integral of [44] is [17]. Taking into account the conditions at the ends when integrating [17] we obtain the following equation for the determination of the critical load:

$$\tan U \tan\frac{k\lambda U}{l-\lambda} = -\frac{1}{k} \qquad [46]$$

$$P_{cr} = \left[\frac{k\lambda U}{l-\lambda}\right]^2 \frac{EI}{l^2} = K\frac{EI}{l^2} \qquad [47]$$

where

$$k^2 = i/I$$

The roots of Equation [46] for various values of i/I and λ/l are given in Table 15, and the coefficients of stability in Table 4.

TABLE 15

	Values of λ/l			
Values of i/I	0.2	0.4	0.6	0.8
0.01	1.50	1.55	1.56	1.57
0.1	0.43	1.34	1.47	1.58
0.2	0.69	1.86	1.38	1.50
0.4	0.49	0.92	1.23	1.43
0.6	0.40	0.79	1.11	1.36
0.8	0.35	0.69	1.02	1.31

For a stepped column with both ends fixed the critical load is found by using Equation [47], but U is found from the following equation:

$$\tan U + k\tan\frac{k\lambda U}{l-\lambda} = 0 \qquad [48]$$

The roots U of this equation for various values of i/I and λ/l are given in Table 16, and the coefficients of stability K in Table 5.

Compression of Rectangular Blocks, and the Bending of Beams by Non-Linear Distributions of Bending Forces[1]

By J. N. Goodier,[2] Toronto, Ont.

An existing method for the approximate analysis of two-dimensional stress distributions is extended in scope and applied to two examples of some practical interest. The first is a rectangular plate or block compressed by forces applied centrally to two opposite sides, as by knife edges. Tensions of considerable magnitude are developed across the middle plane through the knife edges. These tensions are determined, and illustration given of their dependence on the extent of spreading of the load over the bearing area.

The second is intended as quantitative example of Saint-Venant's principle in the bending of beams. The stresses due to a non-linear distribution of bending forces on the ends are investigated in order to estimate how far from the end one must go to find the linear distribution assumed in the elementary theory of flexure. Conclusions are given in the paper proper and the mathematical analyses from which they are drawn are given in appendices.

Compression of Rectangular Blocks

The thickness (perpendicular to the rectangular section) is either very great (plane strain) or very small (plane stress). Referring to Fig. 1, the forces are confined to small middle portions ab, cd, of opposite edges, and this concentration results in the development of considerable *tensile* stresses across the section $EFGH$, a matter of importance for materials weak in tension, as cast iron and concrete are.

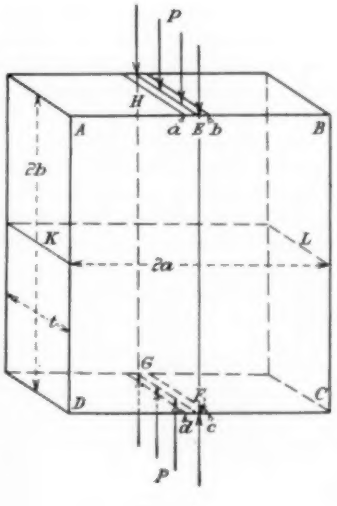

Fig 1

Forces Ideally Concentrated. The tensions are greatest when the forces are ideally concentrated, that is, confined to the lines EH and FG. Numerical results have been worked out for three rectangles, $b/a = 2$, the square $b/a = 1$, and $b/a = {}^1/_2$ (Fig. 2), and are shown in Fig. 3 as curves drawn on ordinates from EF. The greatest tension in each case is given in Table 1, in terms of $P/\pi bt$ (P being the total force), which is the average tension whatever the proportions of the rectangle—and indeed whether the section is rectangular or not (Ap-

[1] Including portions of a dissertation prepared under the direction of Dr. S. Timoshenko for presentation to the faculty of the University of Michigan in partial fulfilment of the requirements for the degree of Doctor of Science.

[2] Ontario Research Foundation. Mr. Goodier was educated in England at Downing College, Cambridge University, where he studied mathematics and mechanical sciences. He took the degree of B.A. through the Mechanical Sciences Tripos, with the Rex Moir Prize for general distinction and the Ricardo Prize for thermodynamics. For two years he worked as a research student under Prof. C. E. Inglis, F.R.S., on problems of elasticity and applied mechanics, stress distributions, bridge vibrations, and the phenomenon of rail corrugation, and, together with H. S. Sayles, B.A., was awarded the John Steddy Winbolt Prize of Cambridge University for a dissertation on "Some Problems of Plane Stress." He was elected a Commonwealth Fellow in 1929. He then went to Ann Arbor to continue work under the supervision of Professor Timoshenko at the University of Michigan, remaining there until August, 1931, when he assumed his present duties.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

pendix No. 2). If the section is circular, for instance, the tensions are constant across the diameter joining the forces and so equal to the average value $P/\pi bt$.

TABLE 1

b/a	2	1	$^1/_2$
Greatest tension	$1.82\ \frac{P}{\pi bt}$	$1.33\ \frac{P}{\pi bt}$	$1.50\ \frac{P}{\pi bt}$

The excessive labor involved in the calculations has limited the number of rectangles investigated to the three already mentioned, but it is possible that rectangles of other proportions $b/a > 2$ might have tensions still higher than that of 1.82 $P/\pi bt$ for $b/a = 2$.

Forces Not Ideally Concentrated. Ideally concentrated forces were considered first for mathematical convenience. They set an upper limit to the tensions, and we have now to show how these tensions are modified when the load is spread over short elements ab and cd, Fig. 1. The correction consists of compressive stresses, intense near the load, and falling off very rapidly as we move away from E or F. But as they begin by being at least as great as the mean applied pressure, they may, even at some distance from E or F, be still great enough to be comparable with $P/\pi bt$. It is shown elsewhere[3] that if we assume the loads uniformly distributed on ab, cd (of length 2α), the local compressive stress, to be superposed on the tensions of Fig. 3, can be found from

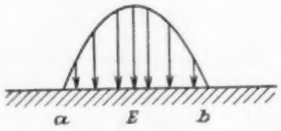

FIG. 4

$$-\frac{P}{\pi\alpha t}\left[\tan^{-1}\frac{\alpha}{y}-\frac{\alpha/y}{1+\alpha^2/y^2}\right]\quad\ldots\ldots\ldots[1]$$

where, confining attention to the end E, y is the distance from E along EF. If the distribution is taken as parabolic (Fig. 4) instead of uniform, the corresponding expression is

$$-\frac{3}{2}\frac{P}{\pi\alpha t}\left[\left(1+3\frac{y^2}{\alpha^2}\right)\tan^{-1}\frac{\alpha}{y}-3\frac{y}{\alpha}\right]\ldots\ldots\ldots[2]$$

This is probably the more practical case.

TABLE 2 LOCAL COMPRESSIVE STRESSES

		y/α							
		0	1	2	4	6	8	10	Factor
Compressive stress	Uniform distribution of load	$\pi/2$	0.2854	0.0636	0.00969	0.00299	0.00128	0.00066	$\frac{P}{\pi bt}\cdot\frac{b}{a}\cdot\frac{a}{\alpha}$
	Parabolic distribution of load	$3/2.\pi/2$	0.2124	0.0412	0.00594	0.00182	0.00077	0.00040	

In order to superpose these compressive stresses on the tension curve from Fig. 3 we choose b/a, and the degree of spreading of the load α/a. Then α/b is fixed, and since the vertical EF in Fig. 3 is equal to $2b$, the distances α, 2α, etc. can be set off along it. For these points we find the compressive stress from Table 2 as a numerical coefficient multiplying $\frac{b}{a}\cdot\frac{a}{\alpha}\cdot\frac{P}{\pi bt}$; b/a, a/α are chosen, and $P/\pi bt$ is the mean ordinate (perpendicular to EF) of the curve of tensions. The ordinate representing the compressive stress can then be drawn on the diagram, and the final curve of stress across EF constructed. The mean of course will no longer be $P/\pi bt$, and the stress close to the loads will be compressive, elsewhere tensile.

The two full curves in each of Figs. 5 and 6 show the effects of distributing each force uniformly and parabolically on $^1/_{10}$th and $^1/_5$th of the loaded sides of the rectangle $b/a = 2$. The broken-line curves, Figs. 5 to 10, are for the concentrated forces. The reduction of maximum tension is much less marked for the parabolic distribution than for the uniform distribution.

Figs. 7 and 9 are for comparison with curve II of Fig. 5. If we imagine the three rectangles to have the same height, as in Fig. 2, and the loads spread uniformly over the same length ab in each case, ab being $^1/_{10}$th of the height $2b$, then curve II in Fig. 5 gives the tensions for the rectangle $b/a = 2$ (that is, the width half the height), Fig. 7 gives the tensions for $b/a = 1$ (a square of the same height), and Fig. 9 the tensions when the width is twice the height ($b/a = {}^1/_2$). These curves show, in short, the effects of adding to the width of the rectangle. It is unlikely, by Saint-Venant's principle, that further addition beyond $b/a = {}^1/_2$ would make much difference.[4]

Figs. 6, 8, and 10 represent the same thing when the loads are distributed parabolically. It appears that, except in the square, both the mode and the extent of distribution of the forces may have an appreciable effect on the maximum tensions.

The distribution of pressure on the middle horizontal section KL (Fig. 1) is drawn for $b/a = 1$ and $b/a = {}^1/_2$ (Fig. 11). It is of course unaffected by the spreading of the load. For $b/a = 2$, the distribution should be uniform.[5] Actually in this solution it departs from the mean value by 5 per cent. This would be accounted for by errors of the same order in the approximate parts of the calculations. The approximations contribute much more to these pressure distributions than to the tension distributions with which we have been concerned, and an error of the same order could only affect the tensions by about 2 per cent.

BENDING OF BEAMS BY NON-LINEAR DISTRIBUTIONS OF BENDING FORCES

According to Saint-Venant's principle, distributions of forces on the ends of a beam which are statically equivalent will produce the same distribution of stress at some distance from the end. The distribution of bending stress to be expected in the interior is of course the familiar linear distribution of the elementary theory. That this distribution may be transmitted throughout the length of the beam without change is shown by the exact stress-function ϕ = constant xy^3, so that if the distribution were linear at the ends it would be the same on all cross-sections.

We consider a non-linear distribution of bending forces on the ends, of intensity proportional to the cube of the distance from the neutral axis (Fig. 12).

If the beam is so short that its span is equal to its depth, the distribution of bending stress is given approximately by Equation [3].

$$\eta^3-2(1-\xi^2)^2\left\{0.08392(5\eta^3-3\eta)+0.004108(21\eta^5-20\eta^3+3\eta)\right\}$$
$$-2\xi^2(1-\xi^2)^2\left\{0.07308(5\eta^3-3\eta)+0.04179(21\eta^5-20\eta^3+3\eta)\right\}$$

where $\xi = x/a$, $\eta = y/b$, as in Fig. 13. At the middle cross-section, $x = 0$, the distribution is not far from linear. It is drawn in Fig. 14. If the span of the beam is twice its depth, i.e., $b/a = {}^1/_2$ the distribution is given approximately by Eq. [4]:

$$\eta^3-2(1-\xi^2)^2\left\{0.09434(5\eta^3-3\eta)-0.001674(21\eta^5-20\eta^3+3\eta)\right\}$$
$$-2\xi^2(1-\xi^2)^2\left\{0.3110(5\eta^3-3\eta)+0.03940(21\eta^5-20\eta^3+3\eta)\right\}$$

---

[3] J. N. Goodier and H. S. Sayles in Winbolt Prize Essay, University of Cambridge, 1929.

[4] Comparison of the curve, from Fig. 3, for $b/a = {}^1/_2$, with the corresponding curve for infinite width given by F. Seewald, "Abhandlungen aus dem Aerodyn. Inst. an der Tech. Hochschule Aachen," 1927, shows no agreement, but it may be observed that the mean ordinate of Seewald's curve is not $P/\pi bt$, as it should be according to Appendix No. 2 of this paper.

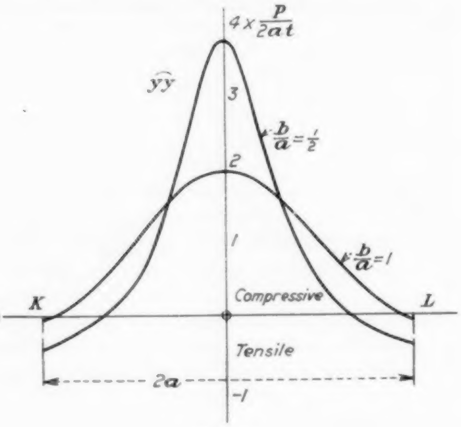

FIG. 11

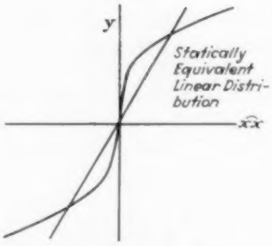

FIG. 12 SQUARE AND RECTANGLE. APPLIED CUBIC DISTRIBUTION ON ENDS

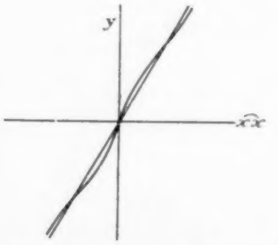

FIG. 14 SQUARE. DISTRIBUTION AT MIDDLE SECTION *AB*, FIG. 13

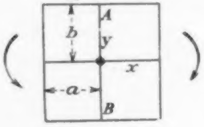

FIG. 13

The distributions over various cross-sections are drawn in Fig. 15. At a distance from the end equal to three-eighths of the depth, linearity is not yet attained. At a distance from the end equal to half the depth, the curve bends slightly the other way, indicating a slightly excessive correction to the cubic distribution represented by the term η^3. At three-fourths of the depth, away from the end, the curve is practically linear, but in the middle of the beam there is again a slight curvature, this time in the same sense as that of the end curve. It appears that the approximate solution does not give an asymptotic approach to the linear distribution, as a true solution would, but, having once attained it, overshoots the mark, then recovers a little too much, and so oscillates slightly about the desired result. This is a defect in the method, arising from the necessity of composing the correction to the end distribution from two curves of the types

$$5\eta^3 - 3\eta \text{ and } 21\eta^5 - 20\eta^3 + 3\eta$$

affected at any cross-section ξ by factors $(1-\xi^2)^2$ and $\xi^2(1-\xi^2)^2$.

We conclude that the linear distribution is probably attained at a distance from the end equal to half the depth. If this is true for the beam of span twice the depth, it will of course hold for longer beams.

Appendix No. 1

THE DETERMINATION OF TWO-DIMENSIONAL STRESS DISTRIBUTIONS IN THE RECTANGLE

1 The solution of two-dimensional problems in elasticity by means of the Airy stress function ϕ, satisfying the biharmonic equation $\Delta^4\phi = 0$ and the prescribed boundary conditions, is equivalent to the determination of the form of ϕ which makes the strain-energy integral—

$$V = \frac{1}{2E}\int\int[\phi_{xx}^2 + \phi_{yy}^2 - 2\sigma\phi_{xx}\phi_{yy} + 2(1+\sigma)\phi_{xy}^2]dxdy \quad [5]$$

taken over the volume of the plate or prism, a minimum. The approximate method applied in this paper consists in assuming a form for ϕ which satisfies the boundary conditions and contains a number of adjustable parameters. These parameters are found from the minimum condition of the integral V.

Such a form may be represented as

$$\phi = \phi_0 + \alpha_1\phi_1 + \alpha_2\phi_2 + \alpha_3\phi_3 + \ldots [6]$$

in which ϕ_0 satisfies the boundary conditions for ϕ, and ϕ_1, ϕ_2, etc. give no contributions to the normal and shear stresses at the boundaries. The adjustable parameters are α_1, α_2, etc. Stresses derived from this function will satisfy the conditions of equilibrium and the boundary conditions, but in general they will only fulfil the compatibility condition for the special values of an infinite number of the parameters α_1, α_2, etc. which make [5] a minimum. The approximation consists in discarding all but the first few terms of [6] and making [5] a minimum with the few remaining parameters α_1, α_2, etc.

If we substitute [6] in [5] we obtain the integrand as a quadratic function of the parameters α. The conditions that V

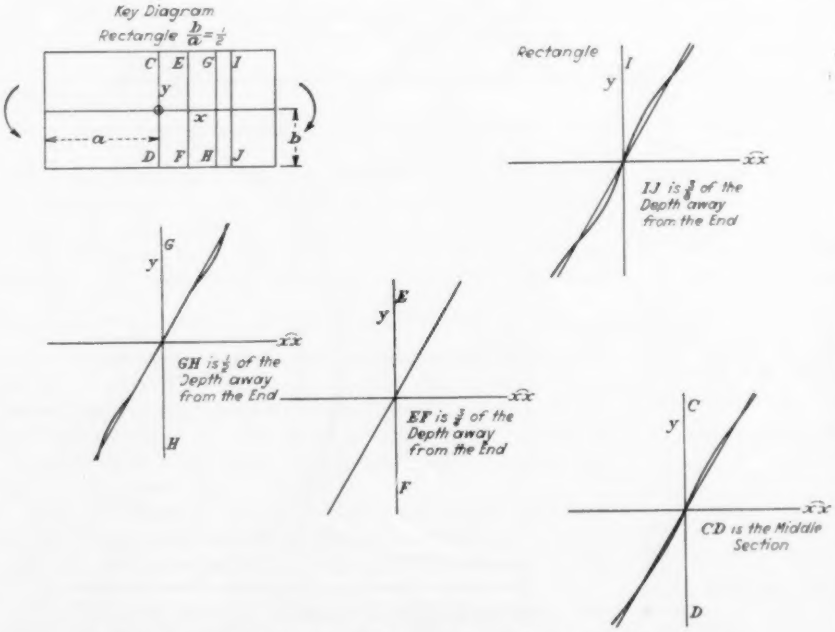

FIG. 15 DISTRIBUTIONS OVER VARIOUS CROSS-SECTIONS OF RECTANGLE

should be a minimum with respect to variations of these parameters, viz.,

$$\frac{\partial V}{\partial \alpha_1} = 0 \qquad \frac{\partial V}{\partial \alpha_2} = 0, \text{ etc.} \ldots\ldots\ldots\ldots\ldots [7]$$

are a set of linear equations for the α's. Writing the stresses derived from [6] as

$$\widehat{xx} = \frac{\partial^2 \phi}{\partial y^2} = \phi_{yy} = \phi_{0yy} + \Sigma \alpha_n \phi_{nyy}$$

$$\widehat{yy} = \frac{\partial^2 \phi}{\partial x^2} = \phi_{xx} = \phi_{0xx} + \Sigma \alpha_n \phi_{nxx}$$

$$\widehat{xy} = -\frac{\partial^2 \phi}{\partial x \partial y} = -\phi_{xy} = -\phi_{0xy} - \Sigma \alpha_n \phi_{nxy}$$

the linear equations for the α's take the typical form

$$\iint \left\{ (\phi_{0xx} + \Sigma \alpha_m \phi_{mxx})\phi_{nxx} + (\phi_{0yy} + \Sigma \alpha_m \phi_{myy})\phi_{nyy} - \sigma(\phi_{0xx} + \Sigma \alpha_m \phi_{mxx})\phi_{nyy} - \sigma(\phi_{0yy} + \Sigma \alpha_m \phi_{myy})\phi_{nxx} + 2(1+\sigma)(\phi_{0xy} + \Sigma \alpha_m \phi_{mxy})\phi_{nxy} \right\} dxdy = 0 \ldots\ldots [8]$$

The first equation is obtained by taking $n = 1$, the second by taking $n = 2$, and so on, the summations in each case comprising all the terms $\alpha_m \phi_m$ from $\alpha_1 \phi_1$ to the end of the series.

When the boundary conditions are prescribed loads and not prescribed displacements, the stress distribution is independent of the elastic constants. We may then take $\sigma = 0$ without affecting the results, and, putting all terms in ϕ_0 on the right, rewrite [8] as

$$\iint \left[\sum_m \alpha_m \phi_{mxx}\phi_{nxx} + \sum_m \alpha_m \phi_{myy}\phi_{nyy} + 2\sum_m \alpha_m \phi_{mxy}\phi_{nxy} \right] dxdy = -\iint \left[\phi_{0xx}\phi_{nxx} + \phi_{0yy}\phi_{nyy} + 2\phi_{0xy}\phi_{nxy} \right] dxdy \ldots [9]$$

For the rectangle bounded by $x = \pm a$, $y = \pm b$, we may conveniently take

$$\phi = \phi_0 + (x^2 - a^2)^2(y^2 - b^2)^2[\alpha_1 + \alpha_2 x^2 + \alpha_3 y^2 + \alpha_4 x^2 y^2 + \ldots \ldots\ldots\ldots [10]$$

provided that the stresses are to be symmetrical with respect to both axes. Retaining only the four parameters written down, [9] gives four equations in which the coefficients of the α's on the left are integrals in terms of the polynomials on the right of [10], and can be integrated at once. The four equations[6] become, putting $b^2/a^2 = k$,

$$\left[\frac{64}{7} + \frac{256}{49}k + \frac{64}{7}k^2\right]\alpha_1 + \left[\frac{64}{77} + \frac{64}{49}k^2\right]\alpha_2 a^2 + \left[\frac{64}{49} + \frac{64}{77}k^2\right]\alpha_3 b^2 + \left[\frac{64}{539} + \frac{64}{539}k^2\right]\alpha_4 a^2 b^2$$
$$= -\frac{9.5.5}{128a^9b^5}\int_0^a\int_0^b \left[\phi_{0xx}\phi_{1xx} + \phi_{0yy}\phi_{1yy} + 2\phi_{0xy}\phi_{1xy}\right] dxdy$$

$$\left[\frac{64}{11} + \frac{64}{7}k^2\right]\alpha_1 + \left[\frac{192}{143} + \frac{256}{77}k + \frac{192}{7}k^2\right]\alpha_2 a^2 + \left[\frac{64}{77} + \frac{64}{77}k^2\right]\alpha_3 b^2 + \left[\frac{192}{1001} + \frac{192}{77}k^2\right]\alpha_4 a^2 b^2$$
$$= -\frac{9.7.5.5}{128a^{11}b^5}\int_0^a\int_0^b \left[\phi_{0xx}\phi_{2xx} + \phi_{0yy}\phi_{2yy} + 2\phi_{0xy}\phi_{2xy}\right] dxdy$$

$$\left[\frac{64}{7} + \frac{64}{11}k^2\right]\alpha_1 + \left[\frac{64}{77} + \frac{64}{77}k^2\right]\alpha_2 a^2 + \left[\frac{192}{7} + \frac{256}{77}k + \frac{192}{143}k^2\right]\alpha_3 b^2 + \left[\frac{192}{77} + \frac{192}{1001}k^2\right]\alpha_4 a^2 b^2$$
$$= -\frac{9.7.5.5}{128a^9b^7}\int_0^a\int_0^b \left[\phi_{0xx}\phi_{3xx} + \phi_{0yy}\phi_{3yy} + 2\phi_{0xy}\phi_{3xy}\right] dxdy$$

$$\left[\frac{64}{11} + \frac{64}{11}k^2\right]\alpha_1 + \left[\frac{192}{143} + \frac{192}{11}k^2\right]\alpha_2 a^2 + \left[\frac{192}{11} + \frac{192}{143}k^2\right]\alpha_3 b^2 + \left[\frac{576}{143} + \frac{256}{121}k + \frac{576}{143}k^2\right]\alpha_4 a^2 b^2$$
$$= -\frac{9.7.7.5.5}{128a^{11}b^7}\int_0^a\int_0^b \left[\phi_{0xx}\phi_{4xx} + \phi_{0yy}\phi_{4yy} + 2\phi_{0xy}\phi_{4xy}\right] dxdy \; [11]$$

2 It remains, before the parameters can be found from these equations, and the function [10] completed, to choose the function ϕ_0 satisfying the symmetrical boundary conditions, and representing the anticipated stress system as closely as possible.

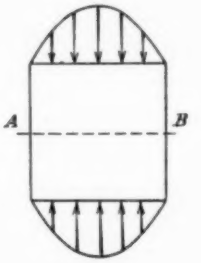

FIG. 16

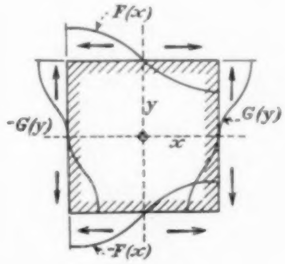

FIG. 17

When two opposite sides of the rectangle are loaded with normal pressures distributed in the same manner (e.g., Fig. 16), say $\widehat{yy} = p(x)$ on the two sides $y = \pm b$, we have to determine ϕ_0 so that

$$\begin{array}{lll} \phi_{0xx} = p(x) & \text{at} & y = \pm b \\ \phi_{0yy} = 0 & \text{at} & x = \pm a \\ \phi_{0xy} = 0 & \text{at} & x = \pm a \text{ and } y = \pm b \end{array}$$

In all the cases occurring subsequently we take simply

$$\phi_0 = \iint p(x)dxdx \ldots\ldots\ldots\ldots\ldots\ldots [12]$$

so that

$$\phi_{0xx} = p(x), \phi_{0yy} = 0, \phi_{0xy} = 0$$

everywhere.

When the applied loads are shearing forces the function ϕ_0 is not so simple. For a stress system symmetrical about both axes, the intensity of the shearing forces on the boundary $y = b$ will be an odd function of x say, $F(x)$, and on $y = -b$ it will be $-F(x)$ (Fig. 17). Similarly we may have a distribution $G(y)$

---

[6] The method of the preceding section of this Appendix is from a paper by Dr. S. Timoshenko, *Phil. Mag.*, vol. 47, June, 1924, p. 1095. Dr. Timoshenko uses three parameters and gives three such equations, which, inter alia, are applied to determine the stresses in a square plate due to parabolic distributions of pressure on opposite sides (Fig. 16). The introduction of the fourth term in [10], viz., $\alpha_4 x^2 y^2 (x^2 - a^2)^2 (y^2 - b^2)^2$, affects the distribution of the pressures across AB by only 2 per cent at most, chiefly at the ends.

on $x = a$ and $-G(y)$ on $x = -a$. The boundary conditions for ϕ_0 are then

$$-\phi_{0xy} = \left\{\begin{array}{ll} F(x) & \text{at } y = b \\ -F(x) & \text{at } y = -b \\ G(y) & \text{at } x = a \\ -G(y) & \text{at } x = -a \end{array}\right. \qquad \ldots\ldots [13]$$

and $\phi_{0xx} = 0$ at $y = \pm b$, $\phi_{0yy} = 0$ at $x = \pm a$

A suitable form for ϕ_0 is

$$\frac{x^2 - a^2}{2a}\int_b^y\left[-G(y) + \frac{y}{2b}G(b)\right]dy$$
$$+ \frac{y^2 - b^2}{2b}\int_a^x\left[-F(x) + \frac{x}{2a}F(a)\right]dx \ldots\ldots [14]$$

It may be verified directly by differentiation that this function fulfils conditions [13]. Its derivation ab initio is given in the next article.

3 Consider a function

$$\psi = (x^2 - a^2)g(y) + (y^2 - b^2)f(x) \ldots\ldots [15]$$

where $g(y)$ is an even function of y only, and $f(x)$ is an even function of x only. Differentiating,

$$\frac{\partial^2\psi}{\partial x^2} = 2g(y) + (y^2 - b^2)f''(x)$$

At $y = \pm b$ this has the constant value $2g(b)$. Similarly[7]

$$\frac{\partial^2\psi}{\partial y^2} = (x^2 - a^2)g''(y) + 2f(x)$$

has the constant value $2f(a)$ at $x = \pm a$.

These constant boundary values can be eliminated without affecting $\partial^2\psi/\partial x\partial y$ by adding to [15] the terms

$$-x^2g(b) - y^2f(a)$$

Further,

$$-\frac{\partial^2\psi}{\partial x\partial y} = -2xg'(y) - 2yf'(x)$$

a function odd in both x and y. If this is to be $\pm F(x)$ at $y = \pm b$

$$-2xg'(b) - 2bf'(x) = F(x) \ldots\ldots [16]$$

and if it is to be $\pm G(y)$ at $x = \pm a$,

$$-2ag'(y) - 2yf'(a) = G(y) \ldots\ldots [17]$$

Equation [16] is to hold for all values of x between $-a$ and $+a$. In particular it will hold for $x = a$, so that

$$2ag'(b) + 2bf'(a) = -F(a) \ldots\ldots [18]$$

Similarly [17] will hold for $y = b$ and

$$2ag'(b) + 2bf'(a) = -G(b) \ldots\ldots [19]$$

Since the shear stresses $F(x)$, $G(y)$, are complementary at $x = a$, $y = b$, $F(a) = G(b)$ and [18] and [19] become identical. They are fulfilled if

$$2bf'(a) = 2ag'(b) = -\frac{1}{2}F(a) = -\frac{1}{2}G(b) \ldots\ldots [20]$$

Taking therefore

$$2f(a) = -\frac{1}{2b}F(a)$$

[17] gives

$$2ag'(y) = -G(y) + \frac{y}{2b}F(a)$$

so that, from this and [20],

$$g(y) = \frac{1}{2a}\int\left[-G(y) + \frac{y}{2b}G(b)\right]dy \ldots\ldots [21]$$

In the same manner, [16] and [20] give

$$2bf'(x) = -F(x) + \frac{x}{2a}G(b)$$

and

$$f(x) = \frac{1}{2b}\int\left[-F(x) + \frac{x}{2a}F(a)\right]dx \ldots\ldots [22]$$

Substituting these results in [15] and adding the terms $-x^2g(b)$ and $-y^2f(a)$ to eliminate the boundary values of $\frac{\partial^2\psi}{\partial x^2}$ and $\frac{\partial^2\psi}{\partial y}$ on $y = \pm b$ and $x = \pm a$, respectively, we obtain the function

$$\phi_0 = \frac{x^2 - a^2}{2a}\int\left[-G(y) + \frac{y}{2b}G(b)\right]dy$$
$$+ \frac{y^2 - b^2}{2b}\int\left[-F(x) + \frac{x}{2a}F(a)\right]dx - x^2g(b) - y^2f(a) \ldots [23]$$

But from [21] and [22]

$$g(b) = \frac{1}{2a}\left\{\int_{y=b}\left[-G(y) + \frac{y}{2b}G(b)\right]dy\right\},\ f(a)$$
$$= \frac{1}{2b}\left\{\int_{x=a}\left[-F(x) + \frac{x}{2a}F(a)\right]dx\right\}$$

Consequently [23] can be expressed as

$$\phi_0 = \frac{x^2 - a^2}{2a}\int_b^y\left[-G(y) + \frac{y}{2b}G(b)\right]dy$$
$$+ \frac{y^2 - b^2}{2b}\int_a^x\left[-F(x) + \frac{x}{2a}F(a)\right]dx \ldots [14]$$

the constants $b^2f(a)$ and $a^2g(b)$ being included for symmetry.

By means of [12], its analogue in terms of y for pressures on the other pair of opposite edges $x = \pm a$, and [14], we can obtain a composite function ϕ_0, satisfying the boundary conditions for ϕ, for the most general case of continuous symmetrical loading of normal pressures and shearing forces on the four sides of a rectangle. After evaluating the integrals in the right-hand members of the Equations [11], α_1, α_2, α_3, α_4, can be found for any value of the ratio b/a and the approximate stress function [10] is completely determined. The results are usually satisfactory if the sides of the rectangle are not of very different magnitudes.

4 For stresses which will be symmetrical about the y-axis, but anti-symmetrical—i.e., the normal stresses represented by odd functions of y—about the x-axis, as in the bending problem of this paper, we take

$$\phi = \phi_0 + (x^2 - a^2)^2(y^2 - b^2)^2[\alpha_1 y + \alpha_2 x^2 y$$
$$+ \alpha_3 y^3 + \alpha_4 x^2 y^3] \ldots [24]$$

Then the Equations [9] for determining the α's become

---

[7] It is necessary that $f''(x)$ and $g''(y)$ should be finite.

$$\left[\frac{64}{7} + \frac{256}{105}k + \frac{64}{55}k^2\right]\alpha_1 b + \left[\frac{64}{77} + \frac{64}{385}k^2\right]\alpha_2 a^2 b$$
$$+ \left[\frac{64}{21} + \frac{512}{1155}k + \frac{192}{715}k^2\right]\alpha_3 b^3 + \left[\frac{64}{231} + \frac{192}{5005}k^2\right]\alpha_4 a^2 b^3$$
$$= -\frac{9\cdot7\cdot5}{128\,a^9b^6}\int_0^a\int_0^b\left[\phi_{0xx}\phi_{1xx} + \phi_{0yy}\phi_{1yy} + 2\phi_{0xy}\phi_{1xy}\right]dxdy$$

$$\left[\frac{64}{7} + \frac{64}{35}k^2\right]\alpha_1 b + \left[\frac{192}{91} + \frac{256}{105}k + \frac{192}{35}k^2\right]\alpha_2 a^2 b$$
$$+ \left[\frac{64}{21} + \frac{192}{455}k^2\right]\alpha_3 b^3 + \left[\frac{192}{273} + \frac{512}{1155}k + \frac{576}{455}k^2\right]\alpha_4 a^2 b^3$$
$$= -\frac{11\cdot9\cdot7\cdot5}{128a^{11}b^6}\int_0^a\int_0^b\left[\phi_{0xx}\phi_{2xx} + \phi_{0yy}\phi_{2yy} + 2\phi_{0xy}\phi_{2xy}\right]dxdy$$

$$\left[\frac{64}{21} + \frac{512}{1155}k + \frac{192}{715}k^2\right]\alpha_1 b + \left[\frac{64}{231} + \frac{192}{5005}k^2\right]\alpha_2 a^2 b$$
$$+ \left[\frac{832}{231} + \frac{4352}{15015}k + \frac{64}{715}k^2\right]\alpha_3 b^3 + \left[\frac{832}{2541} + \frac{192}{15015}k^2\right]\alpha_4 a^2 b^3$$
$$= -\frac{9\cdot7\cdot5}{128a^9b^8}\int_0^a\int_0^b\left[\phi_{0xx}\phi_{3xx} + \phi_{0yy}\phi_{3yy} + 2\phi_{0xy}\phi_{3xy}\right]dxdy$$

$$\left[\frac{64}{21} + \frac{192}{455}k^2\right]\alpha_1 b + \left[\frac{192}{273} + \frac{512}{1155}k + \frac{576}{455}k^2\right]\alpha_2 a^2 b$$
$$+ \left[\frac{832}{231} + \frac{192}{1365}k^2\right]\alpha_3 b^3 + \left[\frac{64}{77} + \frac{4352}{15015}k + \frac{576}{1365}k^2\right]\alpha_4 a^2 b^3$$
$$= -\frac{11\cdot9\cdot7\cdot5}{128a^{11}b^8}\int_0^a\int_0^b\left[\phi_{0xx}\phi_{4xx} + \phi_{0yy}\phi_{4yy} + 2\phi_{0xy}\phi_{4xy}\right]dxdy \qquad \ldots\ldots\ldots\ldots[25]$$

Appendix No. 2

THE RECTANGULAR PLATE COMPRESSED BY CONCENTRATED FORCES

The existence of the tensions across the plane *EFGH* (Fig. 1) may be demonstrated (following a suggestion of Dr. Timoshenko) with the help of the well-known "radial distribution"—the two-dimensional stress distribution induced in the semi-infinite plane by a single concentrated force normal to the boundary (Fig. 18), and given in polar coordinates, as in the figure, by

$$\overset{\frown}{rr} = \frac{2P}{\pi rt}\sin\varphi, \quad \overset{\frown}{r\varphi} = \overset{\frown}{\varphi\varphi} = 0$$

Considering a small semi-cylindrical surface round the line of application of the force, it can be shown that the horizontal resultant of the stresses on each side of the vertical is P/π. Separating the rectangle from the semi-infinite plane section, we obtain the radial system within it maintained by the concentrated force and a set of boundary tractions. Then we may superpose another such system, this time with the force acting on the lower edge, adding another set of boundary tractions. The horizontal components of the complete boundary tractions on one half of the rectangle are balanced by the two horizontal forces P/π (Fig. 19). These boundary tractions are eliminated by applying an equal and opposite set of tractions. It follows that this equal and opposite set will develop tensions across *EF* of total amount $2P/\pi$. The same is true, of course, of a circular disk compressed by forces at the ends of a diameter. It is clear, in fact, that the argument does not depend on the shape of the section except that, if the elements on which the forces bear are not perpendicular to the direction of the forces, the total tension will be $(2P/\pi)\sin\alpha$, where α is the angle which the force makes with the boundary.

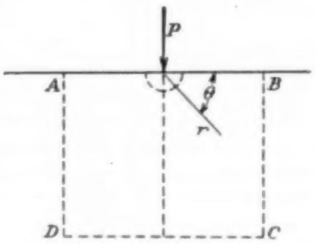

Fig. 18

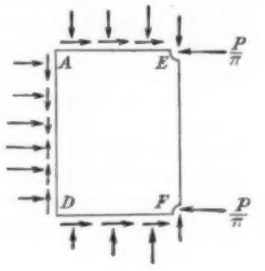

Fig. 19

Taking the origin at the middle of the rectangle, and measuring y upward, the radial distribution due to the upper force P (Fig. 18), in the semi-infinite plane below the horizontal *AB*, is given by

$$\overset{\frown}{xx} = -\frac{2P}{\pi t}\frac{x^2(b-y)}{[x^2+(b-y)^2]^2}, \quad \overset{\frown}{yy} = -\frac{2P}{\pi t}\frac{(b-y)^3}{[x^2+(b-y)^2]^2},$$
$$\overset{\frown}{xy} = \frac{2P}{\pi t}\frac{x(b-y)^2}{[x^2+(b-y)^2]^2}\ldots\ldots\ldots\ldots[26]$$

a positive force P being tensile. This gives tractions on the three sides of the rectangle, *AD*, *DC*, and *CB*. Superposing the radial distribution in the semi-infinite plane above *DC*, due to the lower force P (Fig. 1), i.e.,

$$\overset{\frown}{xx} = -\frac{2P}{\pi t}\frac{x^2(b+y)}{[x^2+(b+y)^2]^2}, \quad \overset{\frown}{yy} = -\frac{2P}{\pi t}\frac{(b+y)^3}{[x^2+(b+y)^2]^2},$$
$$\overset{\frown}{xy} = -\frac{2P}{\pi t}\frac{x(b+y)^2}{[x^2+(b+y)^2]^2}\ldots\ldots\ldots[27]$$

tractions are added on the three sides of the rectangle *DA*, *AB*, and *BC*, so that there are now tractions on all four sides in addition to the required concentrated forces. These boundary tractions are:

(1) A distribution of compressive forces on *AB* of intensity

$$-\frac{P}{\pi bt}\frac{b^4}{a^4}\cdot\frac{16a^4}{(x^2+4b^2)^2}\ldots\ldots\ldots\ldots\ldots\ldots[\text{A}]$$

and the same distribution on the opposite side *DC*.

(2) A distribution of compressive forces on *BC* of intensity

$$-\frac{P}{\pi bt}2\frac{b}{a}a^3\left[\frac{b+y}{[a^2+(b+y)^2]^2} + \frac{b-y}{[a^2+(b-y)^2]^2}\right]\ldots[\text{B}]$$

and the same distribution on the opposite side *AD*.

(3) Shearing forces on all four sides of intensities:

$$\left.\begin{array}{ll}
\text{On } AB(y=b), & -\dfrac{P}{\pi bt}8\dfrac{b^3}{a^3}\dfrac{a^3x}{(x^2+4b^2)^2} = F(x), \text{ say} \\[2ex]
\text{On } DC\ (y=-b), & -F(x) \\[2ex]
\text{On } BC\ (x=a), & \dfrac{P}{\pi bt}2\dfrac{b}{a}a^2\left\{\dfrac{(b-y)^2}{[a^2+(b-y)^2]^2}\right. \\[2ex]
 & \left.\qquad -\dfrac{(b+y)^2}{[a^2+(b+y)^2]^2}\right\} = G(y), \text{ say} \\[2ex]
\text{On } AD\ (x=-a), & -G(y).
\end{array}\right\} \cdot[\text{C}]$$

These three sets of boundary tractions [A], [B], [C], have to be annulled by superposing three stress systems with equal and opposite boundary values. To determine these stress systems we apply the minimum energy method of Appendix No. 1. The first step is to calculate the integrals on the right of Equations [11].

For system [A], we take, in accordance with [12],

$$\phi_{0xx} = \frac{P}{\pi bt}\frac{b^4}{a^4}\frac{16a^4}{(x^2+4b^2)^2}, \quad \phi_{0yy} = \phi_{0xy} = 0$$

The integrations on the right of Equations [11] can now be carried out, and the values of α_1, α_2, α_3, α_4 found for this system. The calculations are too lengthy to record.

In the same manner, system [B] leads to

$$\phi_{0xx} = \phi_{0xy} = 0, \quad \phi_{0yy} = \frac{P}{\pi bt}\,2\,\frac{b}{a}\,a^3\left\{\frac{b+y}{[a^2+(b+y)^2]^2} + \frac{b-y}{[a^2+(b-y)^2]^2}\right\}$$

and the solution for this system can be completed from Equations [11].

System [C] is dealt with by means of the function [14]. The derivatives of the particular form of this function which annuls [C], are

$$\phi_{0xx} = -\frac{P}{\pi bt}\frac{b}{a}\left[\tan^{-1}\frac{2ab}{a^2-b^2+y^2} - \tan^{-1}\frac{2b}{a} - \frac{a(b+y)}{a^2+(b+y)^2} - \frac{a(b-y)}{a^2+(b-y)^2} - 4ab\frac{(3x^2-4b^2)(y^2-b^2)}{(x^2+4b^2)^3} - \frac{4aby^2}{(a^2+4b^2)^2} + \frac{2ab(a^2+6b^2)}{(a^2+4b^2)^2}\right]$$

$$\phi_{0yy} = -\frac{P}{\pi bt}\frac{b}{a}\left[\frac{2a(x^2-a^2)(b+y)[a^2-(b+y)^2]}{[a^2+(b+y)^2]^3} + \frac{2a(x^2-a^2)(b-y)[a^2-(b-y)^2]}{[a^2+(b-y)^2]^3} - \frac{4ab}{x^2+4b^2} - \frac{4abx^2}{(a^2+4b^2)^2} + \frac{8ab(a^2+2b^2)}{(a^2+4b^2)^2}\right]$$

$$-\phi_{0xy} = \frac{P}{\pi bt}\frac{b}{a}\left[\frac{2ax(b+y)^2}{[a^2+(b+y)^2]^2} - \frac{2ax(b-y)^2}{[a^2+(b-y)^2]^2} + \frac{8abxy}{(x^2+4b^2)^2} - \frac{8abxy}{(a^2+4b^2)^2}\right]$$

whence the right sides of Equations [11] can be evaluated, and the approximate stress function for system [C] completed. These somewhat lengthy forms compare unfavorably with the simple expressions we are able to use for the normal boundary tractions. It does not appear, however, that there is any undue complication, if we observe that the expression for $-\phi_{0xy}$, and any "shear stress" derived from [14] gives a linear transition of a value on the boundary to the opposite value at the opposite boundary.

Instead of evaluating α_1, α_2, α_3, and α_4 separately for each of the three systems [A], [B], [C], we may add the right sides of Equations [11] for the three systems and obtain at once the values of the α's corresponding to the complete set of boundary tractions, [A], [B], and [C] together. These total values of the α's are given in Table 3.

The complete stress system for a rectangular block compressed by concentrated forces is now determined as the radial distributions [26] and [27], the contributions from the ϕ_0-functions [A], [B], and [C] and the "correction stresses" derived from

$$(x^2-a^2)^2(y^2-b^2)^2[\alpha_1 + \alpha_2x^2 + \alpha_3y^2 + \alpha_4x^2y^2]$$

as from an ordinary stress function, with the values of α_1, α_2, α_3, and α_4 appropriate to the particular value of b/a in question, as given in Table 3.

If the loads are not ideally concentrated, but distributed on *ab* and *cd*, Fig. 1, the boundary tractions corresponding to [A], [B], and [C] will not be effectively altered if *ab* and *cd* are less than about one-third of the smallest side of the rectangle *ABCD*. The curves of Fig. 3, representing the tensions introduced by superposing equal and opposite boundary tractions, will still be valid, but they must now be combined with the curves of local compressive stresses in the manner already explained in the paper.

Appendix No. 3

BENDING OF BEAMS BY A NON-LINEAR DISTRIBUTION OF BENDING FORCES

The boundary conditions for the cubic distribution are that on the ends $x = \pm a$, $\widehat{xx} = Ay^3$, the boundaries being otherwise free from load. Clearly the stress function must be even-valued in x and odd-valued in y, so that the form [24] of Appendix No. 1 is appropriate. Also we may take $\phi_0 = \int\int Ay^3dydy$ giving $\phi_{0xx} = \phi_{0xy} = 0$, $\phi_{0yy} = Ay^3$. Then the values of the α's in [24] can be found by solving Equations [25], after evaluating the coefficients.

Discussion

Max M. Frocht.[8] The paper is interesting both from the point of view of method and that of results. The formulation of a suitable stress function for the removal of shear stresses from the boundaries of rectangles represents a valuable contribution to

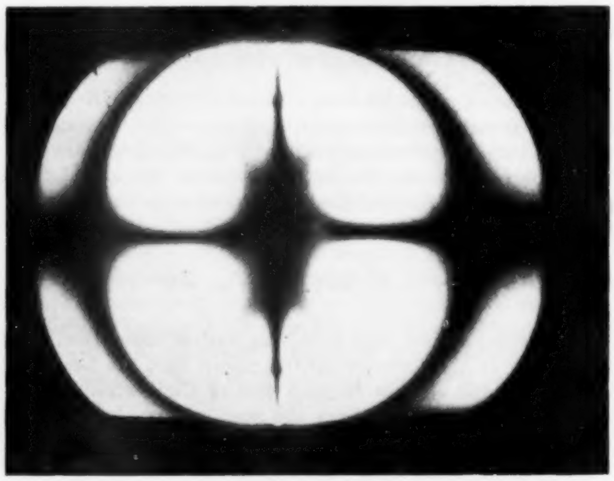

Fig. 20 Glass Model. Cross Represents Zero Isoclinic

the science of stress analysis. Such a function is given by Equation [14], and the shears that are to be removed are shown in Fig. 17.

---

[8] Associate Professor of Mechanics, Carnegie Institute of Technology, Pittsburgh, Pa. Participant Applied Mechanics Division, A.S.M.E.

The results regarding the stress distribution in rectangular blocks under concentrated loads are rather significant. Consider, for example, the curves of Fig. 11. It is seen that the maximum compressive stress is about twice the average stress. In other words, an error of approximately 100 per cent is introduced when the compressive stress is computed by the elementary formula $S = P/A$.

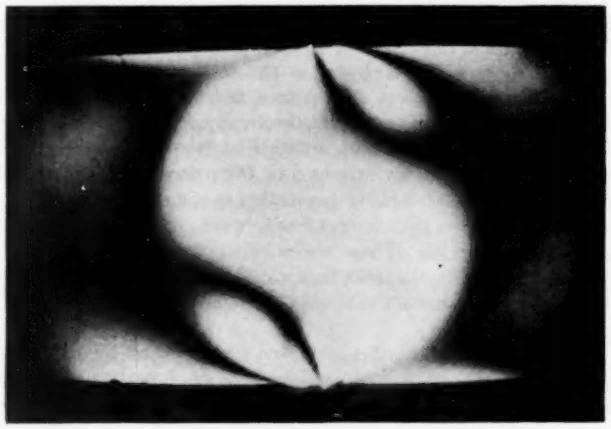

FIG. 21 GLASS MODEL CONTAINING 30-DEG ISOCLINIC
(b/a valve differs from that in Fig. 20.)

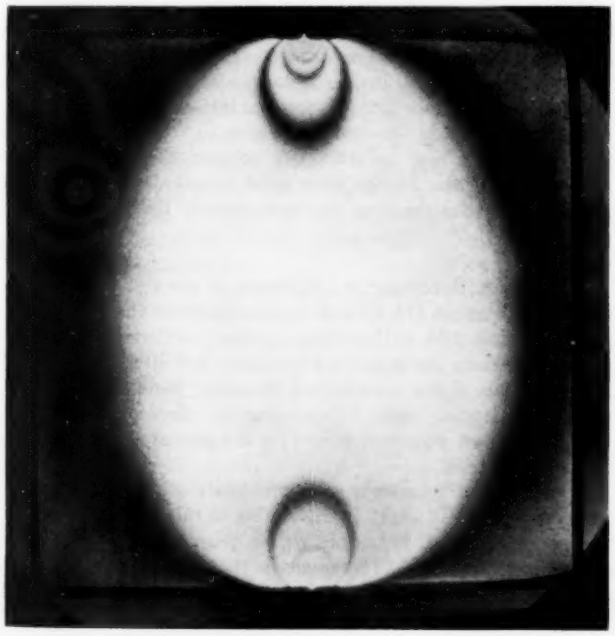

FIG. 22 GLASS MODEL. SQUARE PLATE, ISOCLINICS REMOVED

Average Tensile Stress. The existence of large tensile stresses across the middle plane is no doubt of considerable practical importance, and it is instructive to find that the average stress $P/\pi bt$ is independent of the proportions of the rectangle. It may perhaps be added that the average tension would remain the same as long as the product bt, that is, the cross-sectional area, remains the same, even if b varied. It may further be noted that the total tension is constant for all rectangles and equals $2P/\pi$, regardless of their dimensions.

The generalization, however, that the average tension is always equal to $P/\pi bt$ "whether the section is rectangular or not," is open to question. In Appendix No. 2 the author modifies this statement to take care of concentrated loads inclined to the surfaces upon which they act, and he gives the total tension as $2P \sin \alpha/\pi$, where α is the angle which the force makes with the boundary. The opposing forces may, however, have different inclinations. It would therefore be more correct to state that the total tension is given by (P/π) $(\sin \alpha_1 + \sin \alpha_2)$. But even this correction will not take care of all non-rectangular shapes. Consider, for example, the case of a square block subjected to concentrated diagonal loads. In this the total tension is given by $2P/(\pi + 2)$ and not by the above expression.

Maximum Tension. It is well known that the middle portion of slender bars acted on by axial concentrated loads is subjected to approximately uniformly normal stress and to no lateral stresses. This, together with the previously stated property that the total tension across the central vertical section of a rectangle remains constant, would lead us to believe that the maximum tension increases with the ratio b/a. The results, however, given in Table 1 do not entirely agree with this conclusion. Thus the maximum tension for the square block seems to be less than for the flat block. The discusser is somewhat puzzled by this result.

Need for Further Work. It would be advisable to continue further work on rectangular blocks in order to ascertain that ratio b/a for which the tension becomes a maximum. In view of the laboriousness of the method employed by the author, it would seem more advisable to attack further cases of this problem photoelastically. The shape being rather simple, models could be made of glass and the stress distribution determined with great precision. The discusser has made a start in this direction, and hopes to continue when opportunity permits. Figs. 20, 21, and 22 represent some of the results from this preliminary investigation. These photographs were taken in connection with a study of the isoclinic systems of rectangular blocks. Attention is called to the dark, circle-like curves which persist among all isoclinics and also when the isoclinics are removed, as is the case when a circularly polarized beam of light is used. These curves do not belong to the isoclinics and may thus have one of two meanings: they are either the locus of points of zero stress or of equal principal stresses. Fig. 11 shows two points of zero stress for the square block at approximately the points where the oval cuts the horizontal axis of symmetry. The discusser is wondering whether the author could from his analytical solution throw further light on the meaning of these curves.

C. A. GARABEDIAN.[9] There can be no question that the problems studied by the author are of both theoretical and practical interest. Incidentally, the paper seems to suggest the possibility of further profitable studies in non-linear distributions. And if we may assume that closely similar problems of this sort can be solved by two or more equally ingenious methods applicable to plates and beams, there would still remain the problem of a comparative study to ascertain the relative merits of the methods employed and results obtained. Unfortunately, the value of such a comparative study must be left to conjecture; the individual investigator is sufficiently occupied to solve his special problem by one effective method.

The comment just made is obviously concerned only indirectly with the particular paper under discussion. The author's excellent contribution is but one of many theoretical studies in elasticity which remind us that this field, besides presenting many special problems as yet unsolved, also offers a challenge to those interested in comparison of methods, uniformity of treatment, synthesis of isolated results—in short, in studies which aim at comprehensiveness. So far as the writer is aware, there has been little done in this direction since Saint-Venant.

Theodor von Kármán.[10] The author states that the curve he obtained for the stress distribution in the case of a rectangular block with the ratio 1/2 between the height $2b$ and the width $2a$ shows no agreement with the corresponding curve for infinite width given by F. Seewald in his paper published in the "Abhandlungen des Aerodynamischen Instituts Aachen," 1927. He also points out that the mean ordinate of Seewald's curve is not $P/\pi bt$, as it should be according to Appendix No. 2 of the paper.

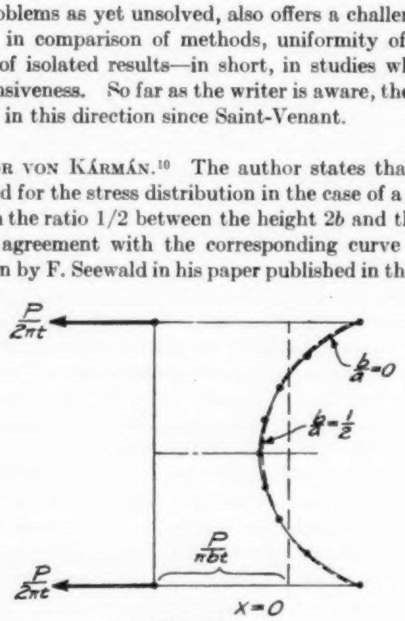

FIG. 23

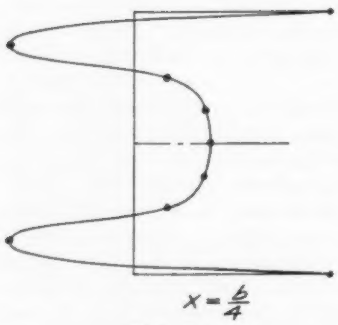

FIG. 24

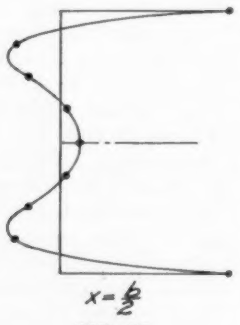

FIG. 25

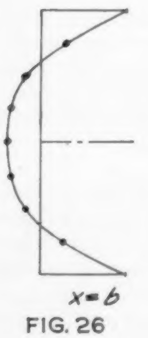

FIG. 26

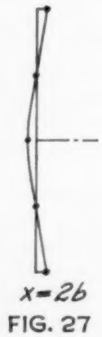

FIG. 27

As Dr. Seewald obtained his *exact* solutions in the case of a block with infinite width, by using a method introduced by the writer in the theory of beams in a previous paper, the latter was interested in this alleged discrepancy and checked the author's and Mr. Seewald's solutions. The result is shown in Fig. 23. Using Seewald's numerical values and diagrams (page 23 of his paper), the writer obtains the solid line, while the author's curve is reproduced by the broken line. The agreement of the two is so close that the author is to be congratulated on the accuracy of the method he used for the approximation.

It seems to the writer that the author's remark is based on the schematic sketch given by Seewald on page 26 of his paper. Unfortunately this figure is somewhat misleading, because it refers to a case wherein the lines of action of the two opposite forces are *nearly* coincident and this does not appear in the drawing; the diagram represents the stress distribution in a section which lies between both forces. For this reason it includes the large compression stresses which appear in the sections near the line of action of the forces, but disappear in the section $x = 0$ in the case of opposite forces acting in the same line, as treated by the author. Therefore the mean ordinate in Seewald's curve should not be $P/\pi bt$ but zero. It seems to the writer that even in the author's case the correct representation of the stress distribution should include the two concentrated forces, as shown in the accompanying Fig. 23. These forces belong to stress distribution; they correspond in the limit to the compression stresses and reduce the mean value of the stress to zero, as it appears in the case of other sections.

L. H. Donnell has kindly calculated for the writer the distribution of the stresses in different sections of a beam of infinite length, the beam being compressed by two opposite forces acting perpendicularly to the length of the beam. Completing Seewald's work, he obtained the curves reproduced in Figs. 24–27. The curves represent the stresses in the sections corresponding to $x = {}^1/_4b$, ${}^1/_2b$, b, and $2b$. It will be noted that the stresses in the section $x = 2b$ are very small; this explains the good agreement between the two curves in Fig. 23. Another interesting point is that the difference between the stresses appearing in the sections $x = 0$ and $x = b$ is nearly constant. The writer recalls that Bleich and the author found a uniform stress distribution across the section $x = 0$ in the case where $a = b$. It is an interesting fact that in this case the difference between the stresses in the two sections of the infinite beam gives apparently a fairly good approximation for the stresses which occur in the block of finite width.

Michael A. Sadowsky.[11] Referring to the test immediately following Equation [6], on page 4, the condition that ϕ_1, ϕ_2, etc. give no contribution to the stresses at the boundaries is true only in the case where the prescribed boundary conditions refer to the stresses. But if these prescribed boundary conditions refer to other magnitudes, such, for instance, as displacements, then ϕ_1, ϕ_2, etc. must give zero values for the prescribed magnitudes at the boundaries.

Appendix No. 2 presents an approximate solution of the proposed problem. It might be interesting to calculate the value of the energy integral, Equation [5], on page 4, for the obtained approximate solution. The reason is that if many approximate solutions of the same problem are found, the values of the energy integral may give a good idea of the achieved degree of approximation.

Author's Closure

Dr. Frocht's remarks on the function [14] raise a question of terminology. This function is not in the strict sense entitled to the description of "stress function." It gives stress formulas which satisfy the boundary conditions [13] and the conditions of equilibrium, but does not in general give compatible strains. It is to correct, as far as possible, this shortcoming that the functions added to ϕ_0 in [10] and [24] are introduced. In the paper I have used the term "approximate stress function" for truncated series, such as [10] and [24], having the form of [6].

[10] Director of the Guggenheim Laboratory for Aeronautics, Pasadena, Calif.

[11] 703 Delaware St., Minneapolis, Minn.

The generalization that the average tensile stress is always equal to $P/\pi bt$, whether the section is rectangular or not, was intended to carry with it all the limitations implied by the argument in Appendix 2 on which it is based. To have enumerated all these and to have considered the analogous cases not included, such as those raised by Dr. Frocht, would have been perhaps to sacrifice conciseness. My own inclination was not to attach very much importance to an estimate of the average tensile stress except as a check on the accuracy of the final results. The maximum tensile stress appears to be the really important quantity.

The considerations brought forward by Dr. Frocht under the heading of *Maximum Tension* imply that as the rectangle is narrowed the tension in the middle portion should steadily decrease until it disappears, the tension near the ends meanwhile increasing so as to preserve the constant mean $P/\pi bt$. This expectation is of course a very plausible one, but nevertheless it is not completely fulfilled by the author's calculations, which indicate that the flat block has a smaller tensile stress in its middle portion than has the narrower square block. I agree with Dr. Frocht that this is a surprising result. It is supported, however, by a consideration of the curves for the infinite strip contributed by Dr. von Kármán. Taking out the middle square from the infinite strip, we should have the boundary tractions of Fig. 26 to annul. It is easily seen that the effect of doing this would almost certainly be to modify the curve in Fig. 23 so as to increase the tension in the middle portion. Certain shears would remain on the edges $x = \pm b$, but there is not much likelihood of their being important.

The question of what shape of rectangle has the greatest tensile stress is one which the author has had in mind throughout the work, although the method of the paper is not sufficiently general to afford a direct answer. The following argument shows that the tension has no upper limit, but may be made to exceed any value by making the rectangle narrow enough. Let us consider in the first place a series of rectangles of given height, but of decreasing widths. When a certain narrowness is attained, the stress distribution in the middle portion will be effectively uniform unidirectional compression. The stress distribution in the upper half of the rectangle is then the same as in the congruent region in the three-boundary problem indicated by Fig. 28—the fourth boundary being at infinity. Any stress formula in this problem must be, for dimensional reasons, of the form

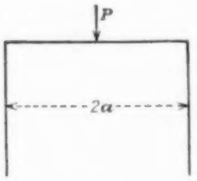

FIG. 28

$$p = \frac{P}{at} f\left(\frac{x}{a}, \frac{y}{a}\right)$$

or, in conformity with the formulas of the paper:

$$p = \frac{P}{\pi bt} \cdot \pi \frac{b}{a} \cdot f\left(\frac{x}{a}, \frac{y}{a}\right)$$

The function $f\left(\frac{x}{a}, \frac{y}{a}\right)$ will have a numerical maximum independent of a. If, therefore, the half-width a is diminished, the maximum tension will increase in the inverse proportion, without limit. In a model the load will be spread on a finite length, and the argument ceases to apply when the width of the rectangle itself becomes comparable with this length. For a given extent of spreading and mode of distribution of the load there *will* be some ratio b/a giving a maximum greatest tensile stress.

There is clearly scope for the photoelastic method in these problems, but optical investigation would bring with it its own peculiar difficulties. The maximum tension is always found close to the applied forces, and it is in such regions that the optical method appears to be least accurate. As the calculations of the paper show, the maximum tension is appreciably affected by both the mode and extent of the distribution of the applied forces, and some degree of spreading of the load is inevitable in a model. These features would detract from the precision of photoelastic results. The theoretical analysis has the advantage of being able to furnish curves, such as those of Fig. 3, setting an upper limit to the tensions. But the full-line curves in Figs. 7 and 9 would appear to be ideal for photoelastic investigation, the uniform distribution having already been realized by Dr. Frocht himself by transmitting the load to a glass model through soft copper.

If the nearly circular curves in the photographs were loci of zero stress, the stress distribution within them would be nearly the same as that in a circular disk. This would be quite at variance with the theoretical results. A simple and ingenious method of discriminating between points of zero stress and points of equal principal stresses is described on page 249 of Coker and Filon's recent "Treatise on Photoelasticity."

Professor von Kármán's remarks, disposing of the apparent discrepancy referred to on page 2, are extremely valuable, and the author is also much indebted to him and to Dr. Donnell for contributing the comparison of the formulas of the paper with certain results of his own exact theory of the infinite strip. He is right in supposing that the author's remark was based on a misconception of Seewald's sketch.

The value of the average *stress*, on a section parallel to the forces, must of course be zero in all cases. In the paper attention was directed to the region where the stress, on $x = 0$, is tensile, and for this reason the terms "tensile stress" or "tension" were used instead of merely "stress." Although the mean *stress* must be zero, the mean *tension*, when the loads are concentrated, must be $P/\pi bt$. The concentrated forces appearing in Dr. von Kármán's Fig. 23 might well have been included in my Fig. 3. (It seems that in Fig. 23 they are given only half the magnitude they should have, if t is the whole thickness.) Their existence, however, is pointed out in Appendix 2.

The first of Dr. Sadowsky's remarks provides a necessary correction to a statement left incomplete through confining attention too closely to the special type of boundary conditions, in terms of stresses, occurring in the paper.

APM-54-18

Thermal Stresses in Spheres and Cylinders Produced by Temperatures Varying With Time

By CLARENCE H. KENT,[1] STATE COLLEGE, PA.

In this paper solutions are given of the problem of stress distribution in spheres and cylinders of elastic material for cases in which the temperature is a function of both the radial coordinate and the time. Two types of temperature variation are included; that due to sudden cooling, as in quenching, and that due to linear surface heating, as in furnace heating. These are applied both to the solid and hollow sphere and cylinder. Examples are included of the temperature and stress distribution in a long solid forging of 30 in. diameter and in a cylindrical drum of 50 in. diameter when each is heated by raising the temperature of its convex surface at a uniform rate.

THE state of stress in spheres and long cylinders due to temperatures which vary with the radial coordinate only is well known. The case of the steady flow of heat in hollow cylinders is covered in several textbooks.[2] When the heat flow is variable instead of steady, the same stress equations may be used provided the temperature is a function of the radius and time only.

Such a temperature distribution occurs in the sudden cooling, as in quenching, of spheres and long cylinders and in the furnace heating of these shapes. Other cases not considered in detail here also produce this type of temperature distribution, as in the radiation of heat to the air from a hot body.

The process of solution is to substitute in the already available stress formulas, expressions for the temperature as a function of radius and time for the given condition of heat flow. For the case of the cooling of a sphere by suddenly changing the temperature of its surface, this expression is a trigonometric series, and for the cylinder a series of Bessel's functions. It is found, however, that these series converge so rapidly that one or two terms prove sufficient for a practical solution. For this reason the labor of substitution in the final result is not great.

Figs. 1 to 8 show the temperature and stress distribution for solid and hollow spheres and cylinders when subjected to sudden cooling and linear heating at assumed rates. Fig. 9 shows the time rate of change of stress on the surface of a solid sphere and long cylinder when the body is cooled by suddenly lowering the surface temperature and thereafter maintaining it constant.

It is noticed that the maximum tensile stresses of both bodies occur at the surface at the beginning of the cooling, and that these values are equal in the two cases and are given by $EaT_1/(1 - \mu)$, where T_1 is the temperature change of the surface, a is the linear coefficient of thermal expansion, and E and μ are the elastic constants. This is seen to be independent of the shape and size of the body and to depend only on the temperature change and the properties of the material. It is equivalent to the stress produced in a thin plate when its temperature is changed T_1 degrees and a change of area is prevented. The very thin layer of the external surface of a body of any shape or size, whose temperature is affected by the sudden change, is prevented from changing its area by the relatively very large mass of the rest of the body. As the time curves show, this stress is only momentary and rapidly drops as the reduction of temperature spreads inward and a contraction of the outside layer is permitted.

If the value of the maximum tension at the surface is sufficient to produce a permanent set in the material, residual stresses will be present when the sphere has cooled. It is obvious that as the result of casting or heat treatment these residual stresses may be very high.

Theoretically, the stress formulas for the cylinder are accurate only when the cylinder considered is of infinite length. They will apply, however, to that portion of a long finite cylinder not near the ends. There is no solution at present which will apply to the end portions. We know that in the case of a thin cylindrical shell with free ends the tangential stress at the ends rises to a maximum some 35 per cent above the value for the rest of the cylinder.[3]

As an example of the formulas developed in this paper, let us take the case of a long cylindrical forging, 30 in. in diameter, such as the rotor of a high-speed alternator. If its operating temperature is 180 F, and if the surface of the rotor is brought up to this value in 30 min from room temperature of 60 F, the average rate of change of surface temperature is 4 deg per min. If we assume this rate of change to be constant, we have the condition which has been termed "linear heating." When this form of heating has continued a sufficient length of time the temperature gradient at any point becomes a constant, that is, all parts of the cylinder are being increased in temperature as the constant time rate of the surface. Stresses in the cylinder have now reached a maximum and continue at this value until the point at which they begin a gradual reduction to zero caused by the leveling off of the temperature curve to a uniform value.

Fig. 6 shows the temperature distribution in the forging 20 min after the heating begins, at which time the steady state

[3] See Trans. A.S.M.E., 1931, paper APM-53-13.

has been reached. The exterior has reached a temperature of 140 deg, and the interior, 70 deg. The temperature curve is a parabola, and retains the same form until the surface temperature reaches its maximum. During this time the stresses remain constant, since thermal stresses depend on the form of the body, its material, and the temperature gradient.

As shown in Fig. 6, the stress curves are also parabolas. On the surface the axial and tangential stresses reach a maximum value in compression of 19,920 lb per sq in. At the center the axial stress reaches the same value in tension, but the tangential stress at the same point attains only one-half this value. The last-named stress is of the most importance, since it will add directly to the stresses produced by rotation.

Fig. 6 represents the stress distribution only for that portion of the cylinder not near the ends. At the ends the axial stress must be zero, and the radial and tangential stresses will be considerably changed by this condition.

Another example is the drum of a steam-turbine rotor. We may take such a drum, with an external diameter of 50 in. and internal of 40 in. Assume the temperature of the convex surface of the drum to be raised from 60 F to 700 F in one hour at a constant time rate. The steady state is quickly reached in the hollow cylinder, and Fig. 8 shows the temperature curve 10 min after the heating begins. The exterior has reached a temperature of 167 F, and the interior, 89 deg. The curve is a parabola to which a logarithmic term has been added.

As in the case of the solid cylinder, the tangential and axial stresses reach a common maximum in compression on the external surface of 14,300 lb per sq in. On the internal surface these stresses reach a value of 8050 lb per sq in. in tension.

It will be noticed that the radial stress does not exceed 600 lb per sq in. at any point. But little error would have been introduced in this problem if it had been treated as a thin cylinder by neglecting the radial stress. In that case both the axial and tangential stresses would have been shifted slightly from the positions of Fig. 8 at all points except on the two surfaces, and would completely coincide with one another. For such a thin cylinder, solutions are available for the end portions.[4]

NOTATION

a = linear coefficient of thermal expansion
A = coefficient of thermal diffusivity = $K/\rho s$
b = internal radius of sphere or cylinder
c = external radius of sphere or cylinder
e_r, e_t, e_z = radial, tangential, and axial unit strains
E = modulus of elasticity
K = coefficient of thermal conductivity
m = constant time rate of change of surface temperature, deg F per sec
ρ = density of material
r = radial coordinate of sphere or cylinder
s = specific heat of material
t = time
T = temperature
u = radial displacement of point in sphere or cylinder
$\sigma_r, \sigma_t, \sigma_z$ = radial, tangential, and axial unit stresses
μ = Poisson's ratio.

SOLID SPHERE

The equations expressing the relation between stresses and a temperature which varies in the radial direction in the solid sphere are:[5]

$$\sigma_r = \frac{2Ea}{1-\mu}\left[\frac{1}{c^3}\int_0^c Tr^2dr - \frac{1}{r^3}\int_0^r Tr^2dr\right] \ldots\ldots [1]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{2}{c^3}\int_0^c Tr^2dr + \frac{1}{r^3}\int_0^r Tr^2dr - T\right] \ldots [2]$$

At the point $r = 0$, these equations become:

$$\sigma_r = \sigma_t = \frac{2Ea}{1-\mu}\left[\frac{1}{c^3}\int_0^c Tr^2dr - \frac{1}{3}T\right] \ldots\ldots [3]$$

These equations are developed on the assumption that the sphere is free from stress when all points are at the temperature zero, but since the state of stress is not affected by a uniform temperature change, the symbol T really represents the difference between the temperature of any point and the original uniform condition. We have now to determine the value of T for the given condition of heating or cooling, and substitute in the equations above to determine the stress distribution.

Sudden Cooling. Assume a solid sphere whose initial temperature is uniform throughout and equal to T_1, and whose surface is then kept at zero. The temperature of any point r distant from the center at any time t after cooling begins, is given by the solution of the equation:[6]

$$\frac{\partial}{\partial t}(Tr) = A\frac{\partial^2}{\partial r^2}(Tr)$$

which is:[7]

$$Tr = \frac{2c}{\pi}T_1\left[e^{-pt}\sin\frac{\pi r}{c} - \frac{1}{2}e^{-4pt}\sin\frac{2\pi r}{c} + \frac{1}{3}e^{-9pt}\sin\frac{3\pi r}{c}\right] \ldots\ldots [4]$$

where $p = A\pi^2/c^2$.

EXAMPLE 1. For low-carbon steel the following constants may be used:

$E = 30 \times 10^6$ lb per sq in.
$a = 6.7 \times 10^{-6}$ in. per in. per deg F
$A = 0.027$ sq in. per sec
$\mu = 0.30$

The coefficient A is chosen high because of the low temperature to be assumed. A, a, and E are actually functions of the temperature, but it is sufficiently accurate for practical purposes to choose average values which hold for the temperature range concerned.

Let us assume a solid sphere of 5 in. radius which is heated throughout to a uniform temperature of 100 F and then, by immersion in a liquid, the surface is maintained at zero. Obviously the stress calculation for any temperature difference of 100 deg will be the same regardless of the value of the initial uniform temperature.

Fig. 1 shows the temperature distribution one minute after the cooling has begun. To obtain the temperature at the center, differentiate Equation [4] and place $r = 0$ in a manner similar to that by which Equation [3] was obtained from [1]. The same result may be obtained from [4] by allowing r to approach zero and remembering that:

$$\lim_{r \doteq 0} \frac{\sin\frac{m\pi r}{c}}{\frac{m\pi r}{c}} = 1$$

---

[4] See Trans. A.S.M.E., 1931, paper APM-53-13.

[5] See Appendix No. 1.

[6] See Appendix No. 3.

[7] Byerly, "Fourier's Series," p. 116.

We have then, for $r = 0$,

$$T = 2T_1[e^{-pt} - e^{-4pt} + e^{-9pt} \dots]$$

In this case, $pt = 0.64$, and $T = 200\ (0.526 - 0.0772 - 0.0031 - \dots) = 90.4$ F, which illustrates the rapid convergence of the series involved. Other points of the temperature curve are obtained by substitution of the values of r in Equation [4] for $t = 60$.

To arrive at the corresponding stresses we need to evaluate the integrals:

$$\int_0^c Tr^2dr = \frac{2c^3}{\pi^2} T_1 \left[e^{-pt} + \frac{1}{4} e^{-4pt} + \frac{1}{9} e^{-9pt} + \dots \right] = 1385$$

$$\int_0^r Tr^2dr = \frac{2c^2}{\pi^2} T_1 \left[e^{-pt} \left(\frac{c}{\pi} \sin \frac{\pi r}{c} - r \cos \frac{\pi r}{c} \right) - \frac{1}{4} e^{-4pt} \left(\frac{c}{2\pi} \sin \frac{2\pi r}{c} - r \cos \frac{2\pi r}{c} \right) + \dots \right]$$

These series, owing to the introduction of the coefficient $1/n^2$ converge even more rapidly than the temperature equation illustrated above. Substitution of the value of these integrals in Equations [1], [2], and [3] enables the stress curves of Fig. 1 to be easily plotted.

We note from Fig. 1 and also from the symmetry of the body that at the center of the sphere, $\sigma_r = \sigma_t$. Since the tangential stress has the same value in all circumferential directions, the material at the center is subjected to an equal compression in all directions—the equivalent of hydrostatic pressure. If we reverse the temperature conditions, as by plunging a cold sphere into a hot medium, we can produce at this point a condition of equal tension in all directions which will be the maximum tension produced in the sphere.

Under the conditions of Fig. 1, the maximum tension occurs at the surface when $t = 0$. If we place $r = c$ and $t = 0$ in Equation [2], we find:

$$\text{max. } \sigma_t = \frac{EaT_1}{1 - \mu} = 28{,}700 \text{ lb per sq in.}$$

where

$$\pi^2/6 = \left(1 + \frac{1}{4} + \frac{1}{9} + \frac{1}{16} + \dots\right)$$

This is, of course, a very localized stress existing only at the surface. Fig. 9 shows how rapidly this stress reduces with time as the cooling spreads inward.

The radial stress in this case is always compression and the maximum occurs at the center. The time at which the maximum is reached is found in the usual way by differentiation of Equation [3] with respect to time and equating the result to zero. We obtain:

$$\sum_1^\infty e^{-n^2pt} \left[1 + (-1)^n \frac{n^2\pi^2}{3} \right] = 0$$

$$e^{-pt} = 0.5674; \text{ and } pt = 0.5667$$

$$\text{max. } \sigma_r = 0.385 \frac{EaT_1}{1 - \mu} = 11{,}050 \text{ lb per sq in. compression}$$

The maximum radial and tangential stresses are seen to be independent of the size of the sphere, and the maximum radial is always 38.5 per cent of the tangential. In this example the time at which the maximum radial stress occurs is 53.2 sec after the cooling begins.

Linear Heating.[3] A second important temperature distribution occurs when the sphere is heated or cooled by changing the surface temperature at a known rate. The temperature of any point is found by a solution of the same partial-differential equation as in the preceding case but adapted to the different boundary conditions. Assume the sphere to be heated by increasing the temperature of the surface at a constant rate, producing "linear heating." If the initial temperature of the sphere is zero, the solution becomes:

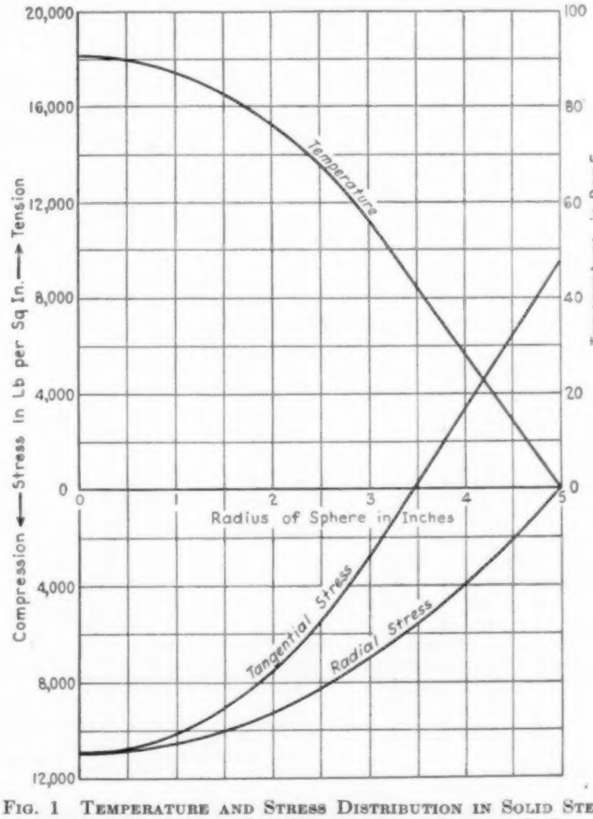

FIG. 1 TEMPERATURE AND STRESS DISTRIBUTION IN SOLID STEEL SPHERE OF 5 IN. RADIUS, ONE MINUTE AFTER SURFACE IS COOLED 100 F BELOW ORIGINAL UNIFORM TEMPERATURE

$$T = mt - \frac{m}{6A}(c^2 - r^2) + \frac{2mc^3}{A\pi^3} \sum_1^\infty \frac{(-1)^{n+1}}{n^3} e^{-n^2pt} \frac{1}{r} \sin \frac{n\pi r}{c} \qquad \dots\dots\dots [5]$$

When this heating has continued long enough to make the product pt, which is $A(\pi^2/c^2)t$, large, the third term of this expression practically vanishes. The temperature gradient has then reached its maximum value and becomes independent of time, as a differentiation of Equation [5] with respect to time will show. In calculating the stresses produced by such heating, we are more interested in the maximum values produced when the steady state has been reached.

They are given by substituting the first two terms of Equation [5] in [1] and [2], from which we obtain:

$$\sigma_r = \frac{Eam}{15A(1 - \mu)}(c^2 - r^2)$$

$$\sigma_t = \frac{Eam}{15A(1 - \mu)}(c^2 - 2r^2)$$

---

[3] See Adams and Williamson, *Physical Review*, vol. 14, pp. 99–114.

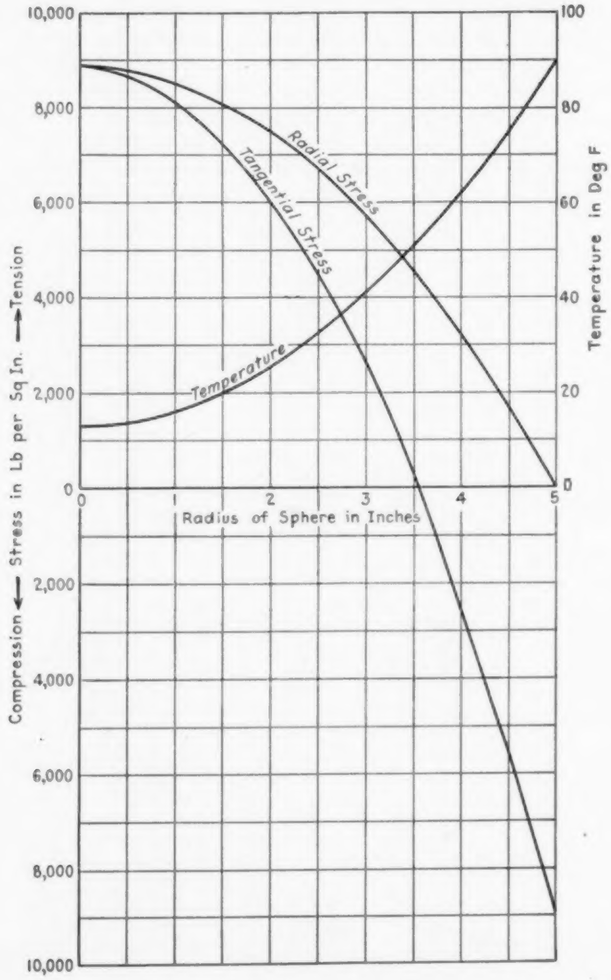

FIG. 2 TEMPERATURE AND STRESS DISTRIBUTION IN SPHERE OF FIG. 1, THREE MINUTES AFTER BEGINNING OF LINEAR SURFACE HEATING AT RATE OF 30 F PER MINUTE

Fig. 2 shows the stresses existing in the sphere of Example 1 after a steady state has been reached, if the temperature of the surface is increased at the rate of 30 deg per min. It is a simple matter, using the equations above, to calculate the rate of heating which will keep the stresses produced below any desired value. The stress distribution is quite similar to that in Fig. 1, except that the curves are parabolic in form. The temperature distribution is shown for a time 3 min after the heating begins at which time the steady state has been reached.

HOLLOW SPHERE

The stress equations for the hollow sphere are:[9]

$$\sigma_r = \frac{2Ea}{1-\mu}\left[\frac{r^3-b^3}{r^3(c^3-b^3)}\int_b^c Tr^2dr - \frac{1}{r^3}\int_b^r Tr^2dr\right]\ldots[6]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{2r^3+b^3}{r^3(c^3-b^3)}\int_b^c Tr^2dr + \frac{1}{r^3}\int_b^r Tr^2dr - T\right]\ldots[7]$$

Sudden Cooling. The problem of the temperature of any point in a hollow sphere when it has been heated throughout to a temperature of T_1 degrees and the external surface is then kept at zero, involves the solution of the same differential equation as for the solid sphere but with different boundary conditions. The result is:[10]

$$Tr = \sum_1^n \beta_n e^{-A\alpha_n^2t}\left[\sin \alpha_n(r-b) + \alpha_n b \cos \alpha_n(r-b)\right]$$

EXAMPLE 2. Assume that the sphere of Example 1 is hollow with an internal radius of 2.5 in. It is originally heated to a uniform temperature of 100 F, and then its external surface is kept at zero. Fig. 3 shows the temperature distribution 20 sec after cooling has begun.

As before, we evaluate the following integrals for use in the calculation of stresses:

$$\int_b^c Tr^2dr = \sum_1^n - e^{-A\alpha_n^2t}\frac{\beta_n c}{\alpha_n}\left[1 + (\alpha_n^2b^2)\cos \alpha_n(c-b)\right] = 1847$$

$$\int_b^r Tr^2dr = \sum_1^n e^{-A\alpha_n^2t}\frac{\beta_n}{\alpha_n^2}\Big[[1+\alpha_n^2b(r-b)]\sin \alpha_n (r-b) + [\alpha_n b - \alpha_n(r-b)]\cos \alpha_n(r-b) - \alpha_n b\Big]$$

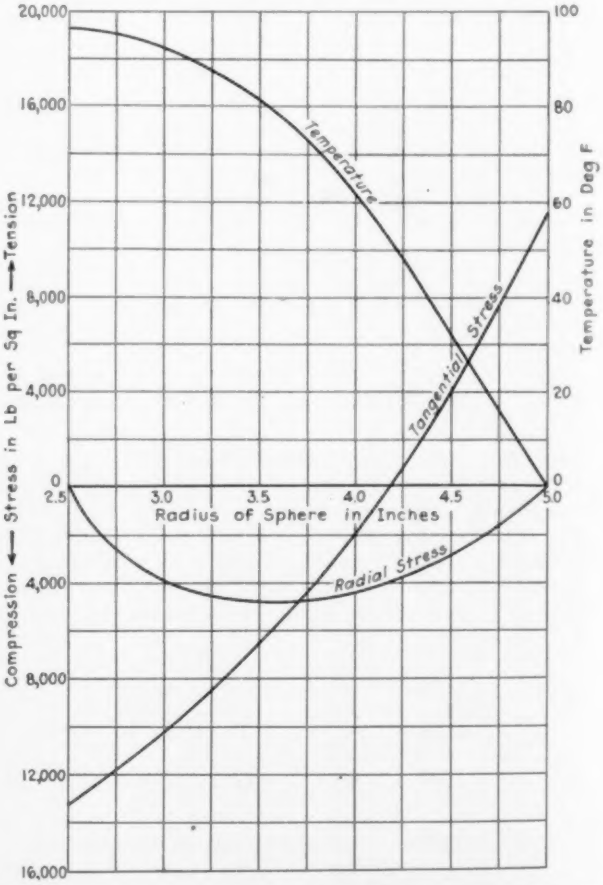

FIG. 3 TEMPERATURE AND STRESS DISTRIBUTION IN HOLLOW STEEL SPHERE OF 5 IN. OUTSIDE AND 2.5 IN. INSIDE RADIUS, 20 SECONDS AFTER EXTERIOR IS COOLED 100 F BELOW ORIGINAL UNIFORM TEMPERATURE

---

[9] See Appendix No. 2.

[10] See Appendix No. 3.

As indicated in Appendix No. 3, the results are sufficiently accurate in this case when three terms of the summation are included and β has been calculated on the basis of $n = 3$. The quick convergence of the series is shown by the numerical value of these integrals when $t = 20$:

$$\int_b^c Tr^2dr = 1833 + 13.95 + 0.0996 = 1847$$

For $r = 3.5$,

$$\int_b^r Tr^2dr = 144 - 5.5 - 0.06 = 138$$

Substitution of the value of these integrals in Equations [6] and [7] makes possible the plotting of the stress curves in Fig. 3.

Linear Heating. If the shell is heated by increasing the temperature of the outer surface at a uniform rate, after heating has continued long enough to reach the steady state, the temperature is:

$$T = mt + \frac{m(r^2 - c^2)}{6A} + \frac{mb}{3Arc}(c - r)$$

Substitution of this expression in Equations [6] and [7] gives:

$$\sigma_r = \frac{Eam}{15A(1-\mu)}\left[-r^2 - 5\frac{b^3}{r} + \phi - \psi\right]$$

$$\sigma_t = \frac{Eam}{15A(1-\mu)}\left[-2r^2 - \frac{5b^3}{2r} + \phi + \frac{\psi}{2}\right]$$

where

$$\phi = \frac{c^5 + 5c^2b^3 - 6b^5}{c^3 - b^3}; \qquad \psi = \frac{c^5b^3 - 6c^3b^5 + 5c^2b^6}{r^3(c^3 - b^3)}$$

Fig. 4 shows the stress distribution in the hollow sphere of Example 2 after a steady state has been reached, when it is heated by increasing the temperature of its external surface at the rate of 30 deg per min.

It is interesting to note that when b is small as compared to c and we let $r = b$, the above equation for tangential stress becomes:

$$\sigma_t = \frac{2Eam}{15A(1-\mu)}c^2$$

This is seen to be twice that produced at the center of a solid sphere by the same heating rate. Thus a small cavity in the center of a sphere will have the effect of doubling the maximum tangential stress under linear heating.

LONG SOLID CYLINDER

The stress equations for the solid cylinder when the temperature varies in any manner with the radial coordinate are:[11]

$$\sigma_r = \frac{Ea}{1-\mu}\left[\frac{1}{c^2}\int_0^c Trdr - \frac{1}{r^2}\int_0^r Trdr\right] \ldots\ldots\ldots [8]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{1}{c^2}\int_0^c Trdr + \frac{1}{r^2}\int_0^r Trdr - T\right] \ldots [9]$$

$$\sigma_z = \frac{Ea}{1-\mu}\left[\frac{2}{c^2}\int^c Trdr - T\right] \ldots\ldots\ldots\ldots\ldots [10]$$

These equations do not apply to those portions of the cylinder near the ends.

Sudden Cooling. When the cylinder is heated to the uniform temperature T_1 and the convex surface is then held at zero, the temperature of any point r distant from the axis at a time t seconds after the cooling begins is given by the solution of the equation:[12]

$$\frac{\partial T}{\partial t} = A\left(\frac{\partial^2 T}{\partial r^2} + \frac{1}{r}\frac{\partial T}{\partial r}\right)$$

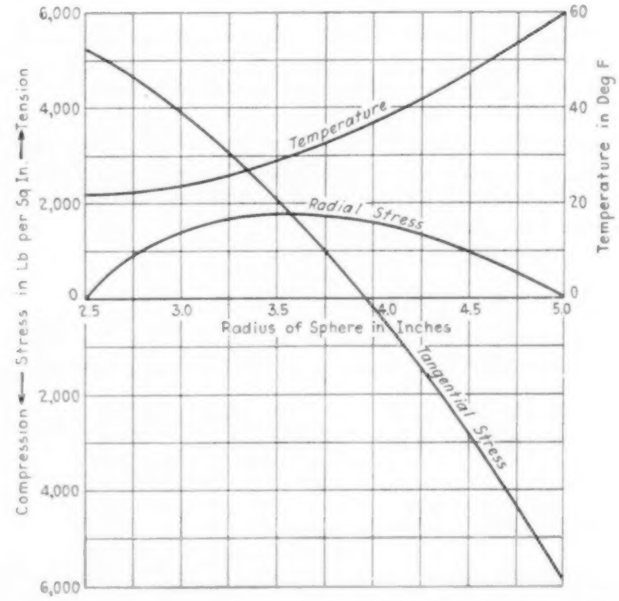

FIG. 4 TEMPERATURE AND STRESS DISTRIBUTION IN HOLLOW SPHERE OF FIG. 3, TWO MINUTES AFTER BEGINNING OF LINEAR SURFACE HEATING AT RATE OF 30 F PER MINUTE

If we let $T = ve^{-A\alpha^2t}$, where v is a function of r only, we have Bessel's equation of order zero:

$$\frac{d^2v}{dr^2} + \frac{1}{r}\frac{dv}{dr} + \alpha^2v = 0$$

For the boundary conditions of this problem the solution is:

$$T = \frac{2}{c^2}\sum_1^\infty e^{-A\alpha_n^2t}\frac{J_0(\alpha_nr)}{[J_0'(\alpha_nc)]^2}\int_0^c T_1rJ_0(\alpha_nr)dr \ldots [11]$$

where $J_0(x)$ is Bessel's function of order zero of the first kind,

$$J_0'(\alpha c) = \left[\frac{d}{dr}J_0(r)\right]_{r = \alpha c}$$

and α is a real and positive root of the equation $J_0(\alpha c) = 0$, of which there are an infinite number.

The value of $J_0(x)$ is given by:

$$1 - \frac{x^2}{2^2} + \frac{x^4}{2^2 \cdot 4^2} - \frac{x^6}{2^2 \cdot 4^2 \cdot 6^2} + \ldots$$

It is a transcendental function which has been found to be a solution of Bessel's equation. It is finite and continuous for all values of x, and it has an infinite number of real roots. Its wave length is approximately 2π, and its amplitude constantly decreases. Tables are available for the determination of its numerical magnitude, and it can be manipulated similarly to other mathematical quantities by the use of known relations. As shown below, the maximum value of $J_0(x)$ occurs where $J_1(x)$ is zero, as is the case with sin x and cos x.

---

[11] See Appendix No. 4.

[12] Carslaw, "Conduction of Heat," p. 115.

By use of the formulas:

$$\int_0^c rJ_0(\alpha_n r)dr = \frac{c}{\alpha_n} J_1(\alpha_n c)$$

and

$$J_0'(\alpha_n c) = -J_1(\alpha_n c)$$

we may write Equation [11]:

$$T = \frac{2T_1}{c}\left[\frac{e^{-A\alpha_1^2 t}}{\alpha_1}\frac{J_0(\alpha_1 r)}{J_1(\alpha_1 c)} + \frac{e^{-A\alpha_2^2 t}}{\alpha_2}\frac{J_0(\alpha_2 r)}{J_1(\alpha_2 c)} + \dots\right]$$

Example 3. Assume a solid cylinder of low-carbon steel 20 in. in diameter and of considerable length. It is initially heated to a uniform temperature of 100 F and the convex surface is then kept at zero.

For this value of c the roots of $J_0(\alpha c) = 0$ are:[13]

$$\alpha_1 = 0.2405; \quad \alpha_2 = 0.5520; \quad \alpha_3 = 0.8654$$

At the center of the cylinder 10 min. after cooling has begun the temperature is:

$$T = \frac{2T_1}{c}\left[\frac{e^{-0.938}}{0.2405}\frac{J_0(0)}{J_1(2.405)} + \frac{e^{-4.96}}{0.5520}\frac{J_0(0)}{J_1(5.520)} + \dots\right] = 61.7 \text{ F}$$

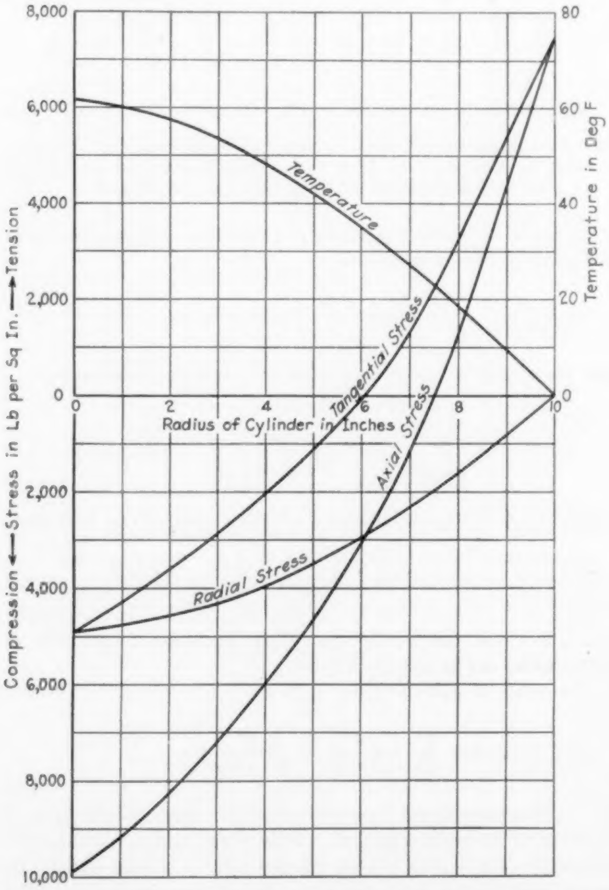

Fig. 5 Temperature and Stress Distribution in Solid Steel Cylinder of 10 In. Radius, 10 Minutes After Surface Is Cooled 100 F Below Original Uniform Temperature

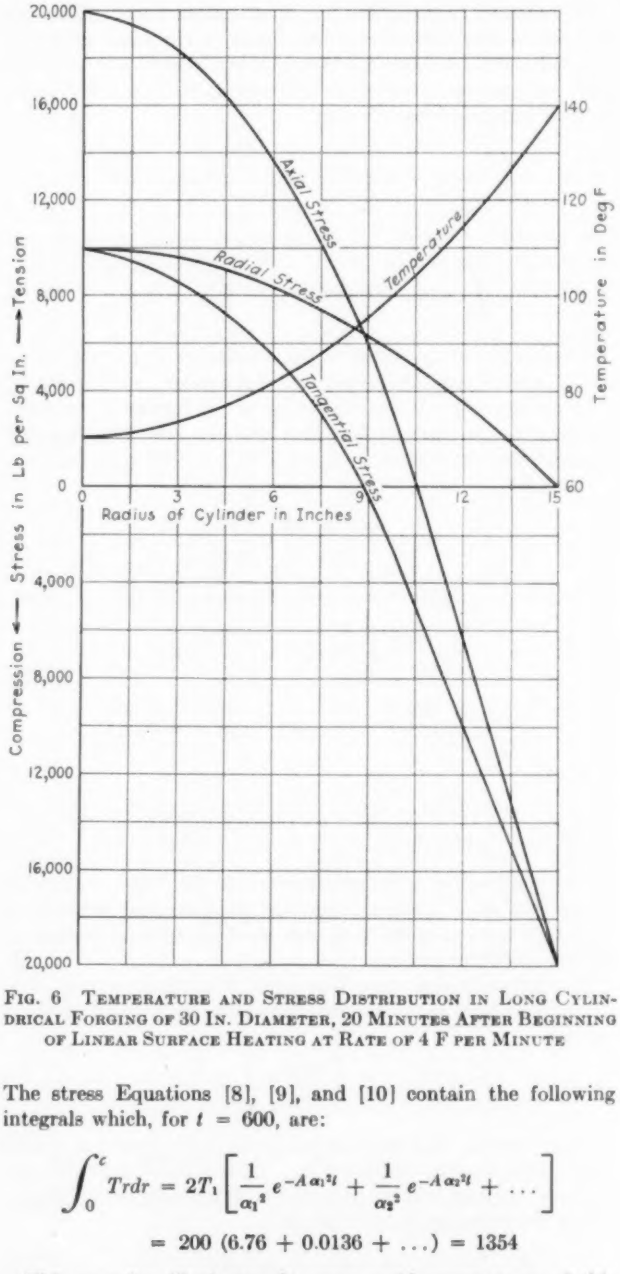

Fig. 6 Temperature and Stress Distribution in Long Cylindrical Forging of 30 In. Diameter, 20 Minutes After Beginning of Linear Surface Heating at Rate of 4 F per Minute

The stress Equations [8], [9], and [10] contain the following integrals which, for $t = 600$, are:

$$\int_0^c Trdr = 2T_1\left[\frac{1}{\alpha_1^2}e^{-A\alpha_1^2 t} + \frac{1}{\alpha_2^2}e^{-A\alpha_2^2 t} + \dots\right]$$

$$= 200\ (6.76 + 0.0136 + \dots) = 1354$$

This equation illustrates the very rapid convergence of this series.

$$\int_0^r Trdr = 2T_1\frac{r}{c}\left[\frac{e^{-A\alpha_1^2 t}}{\alpha_1^2}\frac{J_1(\alpha_1 r)}{J_1(\alpha_1 c)} + \frac{e^{-A\alpha_2^2 t}}{\alpha_2^2}\frac{J_1(\alpha_2 r)}{J_1(\alpha_2 c)} + \dots\right]$$

When these integrals are substituted in the stress equations, the stress curves of Fig. 5 are obtained showing the distribution 10 min after cooling has begun.

The maximum tension occurs at the surface where σ_x and σ_t are equal and at the time, $t = 0$. If we place $r = c$ and $t = 0$ in Equations [9] and [10], we find:

$$\text{max. } \sigma_x = \sigma_t = \frac{Ea T_1}{1-\mu}\sum_1^\infty \frac{4}{c^2}\frac{1}{\alpha_n^2}$$

---

[13] Watson, "Theory of Bessel's Functions."

Since we know that the value of the maximum stress at this point is $\frac{EaT_1}{1-\mu} = 28{,}800$, we may conclude that:

$$\sum_{1}^{\infty} \frac{1}{\alpha_n^2} = 25$$

Fig. 9 shows how this maximum value decreases with time so that the tension at the surface has decreased, after four minutes, to about one-half its value at the start.

Linear Heating. When the convex surface of the cylinder is increased in temperature at a constant rate the temperature is again given by a solution of Bessel's equation with the proper boundary conditions. It is:

$$T = mt - \frac{m}{8A}(c^2 - r^2) + \frac{2mc^2}{A} \sum_{1}^{\infty} e^{-\frac{A\alpha_n^2 t}{c^2}} \frac{J_0\left(\frac{\alpha_n r}{c}\right)}{\alpha_n^3 J_1(\alpha_n)}$$

When the heating has continued long enough for a steady state of temperatures to be reached, the last term of the above expression may be dropped. The stress equations for the steady state then become:

$$\sigma_r = \frac{Eam}{1-\mu} \frac{c^2 - r^2}{16A}$$

$$\sigma_t = \frac{Eam}{1-\mu} \frac{c^2 - 3r^2}{16A}$$

$$\sigma_z = \frac{Eam}{1-\mu} \frac{c^2 - 2r^2}{8A}$$

Fig. 6 shows the stress distribution and the temperature curve 20 min after heating begins, at which time the steady state has been reached. The cylinder is a long forging of 30 in. diameter whose surface is being increased in temperature at the rate of 4 deg per min.

Hollow Cylinder

When a long hollow cylinder is heated in such a way that the temperature is a function of the distance from the axis only, the stresses produced in that portion not near the ends, are given by:[14]

$$\sigma_r = \frac{Ea}{1-\mu}\left[\frac{r^2 - b^2}{r^2(c^2 - b^2)} \int_b^c Trdr - \frac{1}{r^2}\int_b^r Trdr\right] \ldots [12]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{r^2 + b^2}{r^2(c^2 - b^2)} \int_b^c Trdr + \frac{1}{r_2}\int_b^r Trdr - T\right] \ldots [13]$$

$$\sigma_z = \frac{Ea}{1-\mu}\left[\frac{2}{c^2 - b^2} \int_b^c Trdr - T\right] \ldots\ldots\ldots [14]$$

In the hollow cylinder as well as the solid, the axial stress is the sum of the radial and tangential. The value of the axial deformation, which is a constant, is $e_z = \frac{2}{c^2 - b^2}\int_b^c Trdr$.

Sudden Cooling. Suppose the cylinder to be heated to the uniform temperature T_1, and the inner and outer surfaces then kept at zero, as by immersion in a liquid. The temperature of any point is again given by a solution of Bessel's equation, but since the range of r does not now extend to the origin, Bessel's functions of the second kind are not excluded. The solution is:

$$T = \frac{\pi^2}{2} \sum_{1}^{\infty} \alpha_n^2 \left[\frac{J_0^2(\alpha_n b)}{J_0^2(\alpha_n b) - J_0^2(\alpha_n c)}\right] e^{-A\alpha_n^2 +} U_0(\alpha_n r) \int_b^c T_1 r U_0(\alpha_n r) dr \ldots\ldots [15]$$

where $U_0(\alpha r) = J_0(\alpha r)\, Y_0(\alpha c) - J_0(\alpha c) Y_0(\alpha r)$

α_n represents the real and positive roots of $U_0(\alpha b) = 0$, and

$Y_0(x)$ represents Bessel's function of the second kind,[15] and of order zero. It obeys the same laws in its mathematical treatment as $J_0(x)$, and its numerical values for various values of x are given in the tables of Watson.

The integral in Equation [15] has the following value:

$$\int rU_0(\alpha_n r)dr = \frac{1}{\alpha_n^2}\left(\frac{2}{\pi} + \alpha_n b F_n\right)$$

where $F_n = J_0(\alpha_n c)\, Y_1(\alpha_n b) - Y_0(\alpha_n c) J_1(\alpha_n b)$

Equation [15] may then be rewritten:

$$T = T_1 \frac{\pi^2}{2} \sum_{1}^{\infty} \left[\frac{J_0^2(\alpha_n b)}{J_0^2(\alpha_n b) - J_0^2(\alpha_n c)}\right] e^{-A\alpha_n^2 t} \times \left(\frac{2}{\pi} + \alpha_n b F_n\right) U_0(\alpha_n r)$$

The two variables in this expression are t and r. t appears only in the exponent of e, and r only in two terms of $U_0(\alpha_n r)$. All the other terms are constant and depend only on the form of the cylinder. Thus for all points on the temperature curve after the first it is only necessary to compute values of $U_2(\alpha_n r)$. The summation extends over the positive roots of $U_0(\alpha b) = 0$. This makes $U_0(\alpha b) = U_0(\alpha c) = 0$, which is necessary in order to reduce the expression for T to zero at $r = b$ and $r = c$.

Example 4. Assume a long steel cylinder of 10 in. outside radius and 5 in. inside. Let it be heated to 100 F throughout, and its surfaces, excluding the ends, then kept at zero.

The roots of the equation $U_0(\alpha_n b) = 0$, can be calculated as:[16]

$$\alpha_1 = 0.6264;\ \alpha_2 = 1.2547;\ \alpha_3 = 1.8837.$$

At the point $r = 8$ after the cooling has continued for 30 sec, the temperature is:

$$T = 494\left[\frac{0.0907}{0.0907 - 0.0445}\frac{1}{1.890}\left(\frac{2}{\pi} + 0.6264 \cdot 5 \cdot 0.1441\right)0.0763 + \ldots\right] = 494[0.1624 - 0.0043 + \ldots] = 78.1 \text{ F}$$

The following integrals will be needed in calculating stresses:

$$\int_b^c Trdr = T_1 \frac{\pi^2}{2} \sum_{1}^{\infty} e^{-A\alpha_n^2 t}\, V_n \left(\frac{2}{\pi} + \alpha_n b F_n\right) \times \int_b^c rU_0(\alpha_n r)dr$$

where $V_n = \frac{J_0^2(\alpha_n b)}{J_0^2(\alpha_n b) - J_0^2(\alpha_n c)}$

[15] Watson, p. 63.

[16] Gray and Mathews, "Bessel's Functions," p. 242.

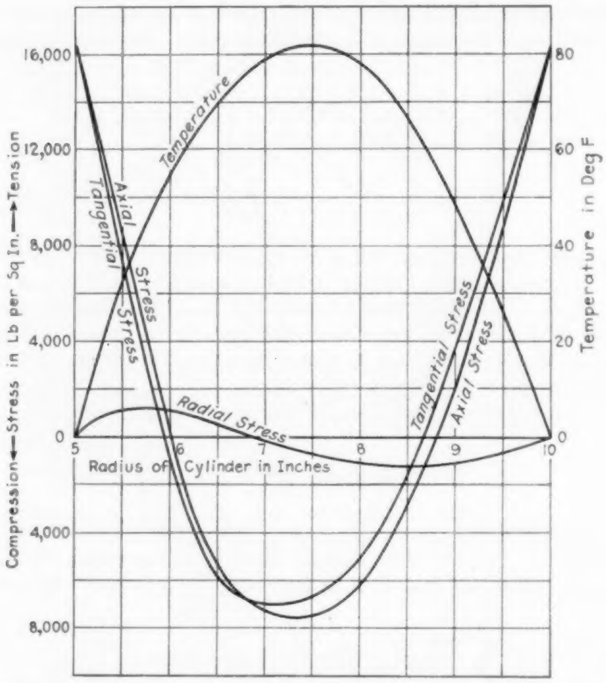

FIG. 7 TEMPERATURE AND STRESS DISTRIBUTION IN LONG HOLLOW CYLINDER OF 10 IN. OUTSIDE AND 5 IN. INSIDE RADIUS, 30 SECONDS AFTER BOTH SURFACES ARE SUDDENLY BROUGHT TO ZERO FROM AN INITIAL UNIFORM TEMPERATURE OF 100 F

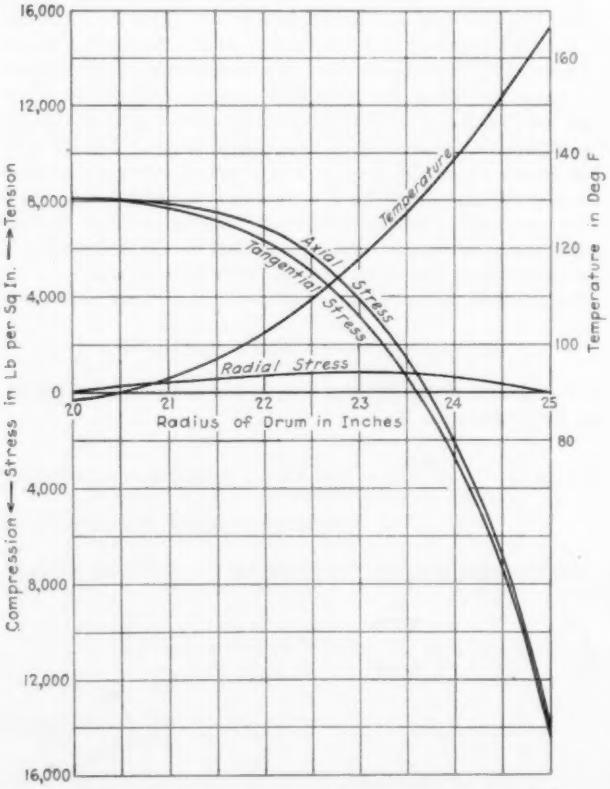

FIG. 8 TEMPERATURE AND STRESS DISTRIBUTION IN LONG STEEL DRUM OF 50 IN. OUTSIDE AND 40 IN. INSIDE DIAMETER, WHEN EXTERIOR SURFACE IS HEATED LINEARLY FROM 60 F TO 700 F IN ONE HOUR: CURVES SHOW CONDITION 10 MINUTES AFTER HEATING BEGINS

Integrating,

$$\int_b^c Trdr = T_1 \frac{\pi^2}{2} \sum_1^\infty \frac{1}{\alpha_n^2} e^{-A\alpha_n^2 t} V_n \left(\frac{2}{\pi} + \alpha_n b F_n\right)^2$$

$$= 494(4.30 + 0.0108 + \ldots) = 2130$$

$$\int_b^r Trdr = T_1 \frac{\pi^2}{2} \sum_1^\infty e^{-A\alpha_n^2 t} V_n \left(\frac{2}{\pi} + \alpha_n b F_n\right)$$

$$\left(\frac{Y_0(\alpha_n c)}{\alpha_n}\left[rJ_1(\alpha_n r) - bJ_1(\alpha_n b)\right]\right.$$

$$\left. - \frac{J_0(\alpha_n c)}{\alpha_n}\left[rY_1(\alpha_n r) - bY_1(\alpha_n b)\right]\right)$$

For $r = 8$, $\int_b^r Trdr = 1338$.

Fig. 7 shows the temperature and stress distribution one-half minute after the cooling has begun. Since the cooling takes place on both surfaces, the radial stress changes sign through the cross-section. Even with a thick cylinder such as has been taken in this example the radial stress is still quite small as compared with the other two.

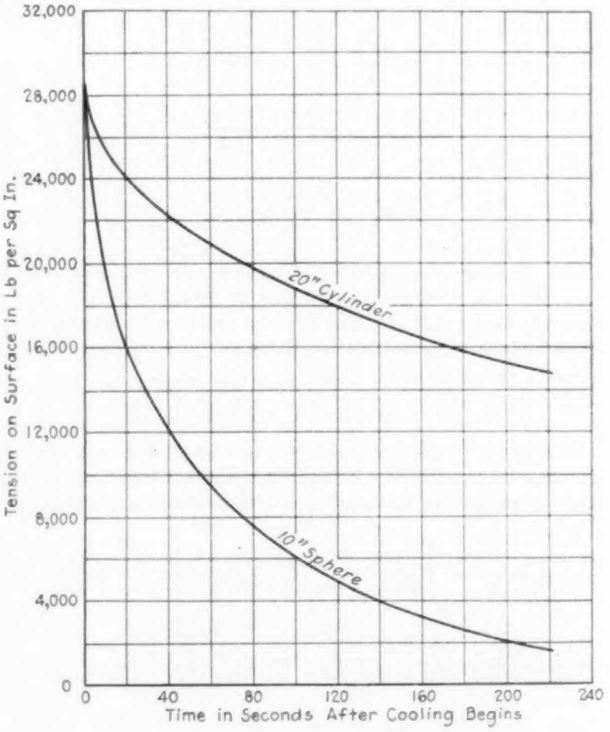

FIG. 9 TENSION ON SURFACE OF SPHERE OF FIG. 1 AND CYLINDER OF FIG. 5 AS TIME INCREASES AFTER SURFACES ARE SUDDENLY LOWERED 100 F IN TEMPERATURE

Linear Heating. For a long cylindrical tube heated linearly on the outside only, the temperature after a steady state has been reached is given by:

$$T = mt - \frac{m}{4A}(c^2 - r^2) + \frac{mb^2}{2A} \log \frac{c}{r}$$

For the same tube heated linearly on both surfaces, the equation becomes:

$$T = mt - \frac{mr^2}{4A} + \frac{m[b^2 \log (r/c) - c^2 \log (r/b)]}{4A \log(c/b)}$$

Substituting the first of these in Equations [12], [13], and [14],

$$\sigma_r = -\frac{Eam}{16A(1-\mu)}\left[r^2 - c^2 + \frac{b^2}{r^2}(c^2 - r^2) - 4\frac{b^2c^2}{r^2}\frac{b^2 - r^2}{c^2 - b^2}\log(c/b) - 4b^2 \log(r/b)\right]$$

$$\sigma_t = \frac{Eam}{16A(1-\mu)}\left[5b^2 - 3r^2 + \frac{c^2}{r^2}(r^2 + b^2) - 4\frac{b^2c^2}{r^2}\frac{b^2 + r^2}{c^2 - b^2}\,\mathrm{lgo}\,(c/b) + 4b^2 \log(r/b)\right]$$

$$\sigma_z = \frac{Eam}{8A(1-\mu)}\left[c^2 + 3b^2 - 2r^2 - 4\frac{b^2c^2}{c^2 - b^2}\log(c/b) + 4b^2 \log(r/b)\right]$$

when $r = c$,

$$\sigma_r = 0;\ \sigma_t = \sigma_z = \frac{Eam}{8A(1-\mu)}\left[3b^2 - c^2 - \frac{4b^4}{c^2 - b^2}\log(c/b)\right]$$

when $r = b$,

$$\sigma_r = 0;\ \sigma_t = \sigma_z = \frac{Eam}{8A(1-\mu)}\left[b^2 + c^2 - \frac{4b^2c^2}{c^2 - b^2}\log(c/b)\right]$$

For a very thick wall when b is small compared to c, these equations become:

$$\sigma_r = \frac{Eam}{16A(1-\mu)}\left(c^2 - r^2 - \frac{c^2b^2}{r^2}\right)$$

$$\sigma_t = \frac{Eam}{16A(1-\mu)}\left(c^2 - 3r^2 + \frac{c^2b^2}{r^2}\right)$$

$$\sigma_z = \frac{Eam}{8A(1-\mu)}(c^2 - 2r^2)$$

As in the case of the sphere, when there is a small cavity in the center of the cylinder the tangential stress at that cavity is twice the corresponding stress at the center of a solid cylinder heated linearly.

Fig. 8 shows the stress and temperature distribution in the drum of a turbine rotor when its exterior surface is heated linearly from 60 F to 700 F in one hour. The temperature curve corresponds to a time 10 min after the heating begins, at which time the steady state is established. The drum has an external diameter of 50 in. and internal of 40 in.

Appendix No. 1

The problem of the state of stress in a sphere of elastic material subjected to a temperature gradient in the direction of the radius was one of those solved by Duhamel[17] in 1838 in the first paper on thermal stresses. We may put this in a more modern form.

Let u be the radial displacement of any point in the sphere. On account of the symmetry of the temperature change there will be no other displacements. Then:

$$e_r = \frac{\partial u}{\partial r};\quad e_t = \frac{u}{r} \quad\ldots\ldots\ldots\ldots\ldots [16]$$

Hooke's law shows that:

$$e_r = \frac{1}{E}(\sigma_r - 2\mu\sigma_t) + aT$$

$$e_t = \frac{\sigma_t}{E}(1-\mu) - \frac{\mu}{E}\sigma_r + aT$$

Solving these for σ_r and σ_t:

$$\sigma_r = \frac{E}{1-2\mu}\left[\frac{1+\mu}{1-\mu}e_r + \frac{2\mu}{1+\mu}e_t - aT\right] \ldots\ldots [17]$$

$$\sigma_t = \frac{E}{1-2\mu}\left[\frac{\mu}{1+\mu}e_r + \frac{1}{1+\mu}e_t - aT\right] \ldots\ldots\ldots [18]$$

There will be but one equilibrium equation obtained by summing forces in the radial direction in Fig. 10. We may use the total differential since σ_r varies only with r, hence

$$\sigma_r - \sigma_t + \frac{r}{2}\frac{d\sigma_r}{dr} = 0 \ldots\ldots [19]$$

Differentiating [17] with respect to r,

$$\frac{d\sigma_r}{dr} = \frac{E}{1-2\mu}\left[\frac{1-\mu}{1+\mu}\frac{de_r}{dr} + \frac{2\mu}{1+\mu}\frac{de_t}{dr} - \frac{d}{dr}(aT)\right] \ldots [20]$$

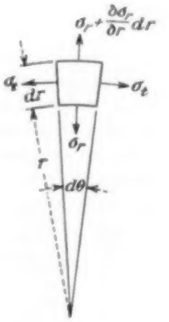

Fig. 10

Substituting [17], [18], and [20] in [19] after replacing e_r and e_t and their derivatives in terms of u from [16], gives

$$\frac{d^2u}{dr^2} + \frac{2}{r}\frac{du}{dr} - 2\frac{u}{r} = \frac{1+\mu}{1-\mu}\frac{d}{dr}(aT)$$

or we may write:

$$\frac{d}{dr}\left(\frac{du}{dr}\right) + 2\frac{d}{dr}\left(\frac{u}{r}\right) = \frac{1+\mu}{1-\mu}\frac{d}{dr}(aT)$$

Integrating,

$$\frac{du}{dr} + 2\frac{u}{r} = \frac{1+\mu}{1-\mu}aT + 3C_1$$

Multiply by r^2 and write

$$\frac{d}{dr}(ur^2) = \frac{1+\mu}{1-\mu}aTr^2 + 3C_1r^2$$

Integrating

$$u = \frac{1+\mu}{1-\mu}\frac{1}{r^2}\int_0^r aTr^2dr + C_1r + \frac{C_2}{r^2} \ldots\ldots\ldots [21]$$

When $r = 0$, $u = 0$, so $C_2 = 0$.

This value of u is then substituted in the Equations [16], which are then used to replace e_r and e_t in [17] and [18]:

$$\sigma_r = \frac{E}{1-2\mu}\left[C_1 - \frac{1-2\mu}{1-\mu}\frac{2}{r^3}\int_0^r aTr^2dr\right]$$

No external forces act on the surface and the radial stress must be zero here. Thus we write:

$$r = c,\ \sigma_r = 0,\ \text{and } C_1 = \frac{1-2\mu}{1-\mu}\frac{2}{c^3}\int_0^c aTr^2dr$$

---

[17] Mémoires divers savants, French Academy, vol. 5, 1838.

Then

$$\sigma_r = \frac{2Ea}{1-\mu}\left[\frac{1}{c^3}\int_0^c Tr^2dr - \frac{1}{r^3}\int_0^r Tr^2dr\right] \ldots\ldots [1]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{2}{c^3}\int_0^c Tr^2dr + \frac{1}{r^3}\int_0^r Tr^2dr - T\right] \ldots [2]$$

These equations are indeterminate when $r = 0$. If we multiply them by r^3 and then differentiate with respect to r, we arrive at expressions for σ_r and σ_t when $r = 0$, which are determinate:
For $r = 0$,

$$\sigma_r = \sigma_t = \frac{2Ea}{1-\mu}\left[\frac{1}{c^3}\int_0^c Tr^2dr - \frac{1}{3}T\right] \ldots\ldots\ldots [3]$$

Appendix No. 2

We may easily adapt the equations developed in Appendix No. 1 to the hollow sphere. The development outlined there as far as Equation [21] applies as well to the hollow as to the solid sphere, but the condition which reduces the constant to zero will not now obtain, and the lower limit for the integration will be b instead of zero. The two constants of integration may be evaluated by the fact that $\sigma_r = 0$, both when $r = b$ and when $r = c$. We have:

$$\sigma_r = \frac{E}{1-2\mu}\left[C_1 - \frac{1-2\mu}{1+\mu}\frac{2C_2}{r^3} - \frac{1-2\mu}{1-\mu}\frac{2}{r^3}\int_b^r aTr^2dr\right]$$

The constants are:

$$C_1 = \frac{1-2\mu}{1-\mu}\,\frac{2}{c^3-b^3}\int_b^c aTr^2dr$$

$$C_2 = \frac{1+\mu}{1-\mu}\,\frac{b^3}{c^3-b^3}\int_b^c aTr^2dr$$

so that finally

$$\sigma_r = \frac{2Ea}{1-\mu}\left[\frac{r^3-b^3}{r^3(c^3-b^3)}\int_b^c Tr^2dr - \frac{1}{r^3}\int_b^r Tr^2dr\right] \ldots [6]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{2r^3+b^3}{r^3(c^3-b^3)}\int_b^c Tr^2dr + \frac{1}{r^3}\int_b^r Tr^2dr - T\right] [7]$$

Appendix No. 3

As an example of the method of developing the differential equations of heat flow used in this paper, we may select the hollow sphere which is subjected to cooling on the external surface. If the initial temperature is uniform or a function of the radial coordinate, the temperature of any point after cooling begins is a function of its distance from the center and of the time. Thus any imaginary surface which is r distant from the center is an isothermal surface and the lines of heat flow are normal to it.

Fig. 11 shows such a surface of radius r within the sphere. It is a fundamental hypothesis for the theory of heat conduction that the rate at which heat crosses from the inside to the outside of an isothermal surface per unit area per unit time, is given by: $-K(\partial T/\partial n)$, where T is the temperature of the surface, K the coefficient of thermal conductivity of the material, and $\partial/\partial n$ indicates differentiation along the outward-drawn normal to the surface. The negative sign indicates that there must be a decrease in the temperature as the normal increases in order to establish flow in this direction. In this case $\partial/\partial n$ may be replaced by $\partial/\partial r$ since r is the normal to the isothermal surface and the partial derivative $\partial T/\partial r$ is called the temperature gradient. Then the heat per unit time flowing past the surface indicated toward the outside will be:

$$-4\pi r^2K\frac{\partial T}{\partial r}$$

Let us now consider the spherical shell of inner radius r and outer $r + dr$ in Fig. 11. A heat balance on this shell may be stated as follows:

Heat in — Heat out = Heat stored

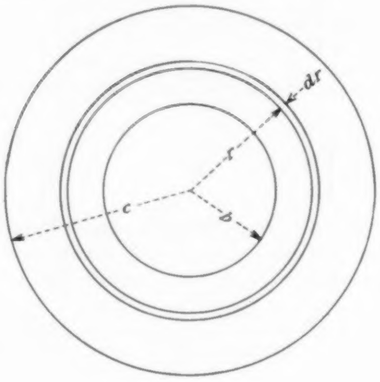

FIG. 11

The temperature of the outer surface of the shell will be:

$$T + \frac{\partial T}{\partial r}dr$$

The second term of this expression is the change in temperature along a distance dr when the rate of change is $\partial T/\partial r$. The heat flowing per unit time across this outer surface toward the outside is:

$$-4\pi(r+dr)^2K\frac{\partial}{\partial r}\left(T + \frac{\partial T}{\partial r}dr\right)$$

The heat stored is the product of four terms: the volume heated; its density; the specific heat of the material; and the change in temperature per unit time. This is given by:

$$4\pi r^2dr \cdot \rho \cdot s \cdot \frac{\partial T}{\partial t}$$

where ρ is the density and s the specific heat of the material.

Terms containing higher powers of dr than the first will vanish and have not been included in the above expression. When $\partial T/\partial t$ is negative, as in this example, the heat stored represents heat given up.

We may now write the heat-balance equation in symbols as:

$$-4\pi Kr^2\frac{\partial T}{\partial r} + 4\pi K(r+dr)^2\frac{\partial}{\partial r}\left(T + \frac{\partial T}{\partial r}dr\right) = 4\pi\rho sr^2\frac{\partial T}{\partial t}dr$$

By performing the indicated operations, discarding terms containing powers of dr higher than the first, and writing $K/\rho s$ as A, the coefficient of thermal diffusivity, we have:

$$A\left(r^2\frac{\partial^2 T}{\partial r^2} + 2\frac{\partial T}{\partial r}\right) = r\frac{\partial T}{\partial t}$$

or, changing the order and making a new variable, Tr, we can write:

$$\frac{\partial}{\partial t}(Tr) = A\,\frac{\partial^2}{\partial r^2}(Tr)\ldots\ldots\ldots\ldots\ldots\ldots[22]$$

This differential equation will now be solved for the special conditions applying to the sudden cooling of the convex surface. Let the sphere be originally at the uniform temperature T_1 and then its exterior is held at zero. The boundary conditions require, first, that there be no heat flow across the inner surface, that is, that the temperature gradient at that point is zero, which assumes a vacuum within the sphere. If there is a gas in this space, unless it is under high pressure, the amount of heat flowing across this surface would be very small. So we may assume that

$$\frac{\partial T}{\partial r}_{(r\,=\,b)} = 0\ldots\ldots\ldots\ldots\ldots\ldots[23]$$

The second condition requires that the outer surface is to be kept at zero, which gives

$$T = 0 \text{ when } r = c\ldots\ldots\ldots\ldots\ldots\ldots[24]$$

The initial condition requires that when $t = 0$, the temperature of the sphere is a constant:

$$T = T_1 \text{ when } t = 0\ldots\ldots\ldots\ldots\ldots\ldots[25]$$

Known solutions of [22] are:

$$Tr = \beta e^{-A\alpha^2 t}\sin\alpha r;\ \text{and}\ Tr = \beta e^{-A\alpha^2 t}\cos\alpha r$$

where α and β are constants to be determined. These solutions may be verified by substitution in Equation [22]. Since these are solutions their sum is also a solution, and we may write:

$$Tr = \beta e^{-A\alpha^2 t}(\sin\alpha r + \cos\alpha r)$$

We may modify this as follows. Let

$$Tr = \beta e^{-A\alpha^2 t}[\sin\alpha(r-b) + \alpha b\cos\alpha(r-b)]\ldots[26a]$$

The change in the angle or multiplication by the constant αb will not affect the solution of [22]. If we solve this for T and take the partial derivative with respect to r, we have:

$$\frac{\partial T}{\partial r} = \beta\left[\frac{\alpha e^{-A\alpha^2 t}}{r}\cos\alpha(r-b) - \frac{1}{r^2}e^{-A\alpha^2 t}\sin\alpha(r-b)\right.$$
$$\left. - \frac{\alpha^2 b}{rb}e^{-A\alpha^2 t}\sin\alpha(r-b) - \frac{\alpha b}{r^2}e^{-A\alpha^2 t}\cos\alpha(r-b)\right]$$

and when $r = b$, $\partial T/\partial r = 0$, so that Equation [23] is satisfied.

To satisfy [24], Equation [26a] must be zero when $r = c$, so that

$$\sin\alpha(c-b) + \alpha b\cos\alpha(c-b) = 0$$

or:

$$\tan\alpha(c-b) = -\alpha b$$

There will be a solution of this equation in both the second and fourth quadrants and the angle $\alpha(c-b)$ will increase approximately by multiples of π. To take care of these multiple solutions we may modify [26a] as follows: Let

$$Tr = \sum_{1}^{n}\beta_n e^{-A\alpha_n^2 t}[\sin\alpha_n(r-b) + \alpha_n b\cos\alpha_n(r-b)]\ldots[26]$$

where α_n is determined by

$$\tan\alpha_n(c-b) = -\alpha_n b\ldots\ldots\ldots\ldots\ldots\ldots[27]$$

and n has all positive integral values from 1 to n. α cannot be determined until we have numerical values for b and c.

The initial condition will determine the constants β_n. If we place $t = 0$, then $T = T_1$ and Equation [26] becomes:

$$T_1 r = \sum_{1}^{n}\beta_n\,[\sin\alpha_n(r-b) + \alpha_n b\cos\alpha_n(r-b)]\ldots[28]$$

Again when we have numerical values for b and c we may choose between them as many values of r as we like and obtain a corresponding number of simultaneous equations, each of which will yield a value of β.

In Example 2, $c = 5$ and $b = 2.5$. To determine α_1, Equation [27] becomes:

$$\tan 2.5\alpha_1 = -2.5\alpha_1$$

By trial we find that if $\alpha_1 = 0.811$, the equation becomes:

$$\tan 2.03 = -2.03$$

which is true. In the same way we obtain:

$$\alpha_2 = 1.965;\ \alpha_3 = 3.18$$

Three values will be found sufficient for ordinary calculations. We may then substitute these in Equation [28], using $r = 2.5$ and $T_1 = 100$. We have:

$$250 = \alpha_1 b\beta_1 + \alpha_2 b\beta_2 + \alpha_3 b\beta_3 + \ldots\ \alpha_n b\beta_n$$
$$= 2.03\beta_1 + 4.91\beta_2 + 7.95\beta_3 + \ldots$$

At the point $r = 3.5$, we have since $r - b = 1$,

$$350 = \beta_1(\sin\alpha_1 + \alpha_1 b\cos\alpha_1) + \beta_2(\sin\alpha_2 + \alpha_2 b\cos\alpha_2) + \ldots$$

In Example 2 the point $r = 4.5$ was also chosen and the corresponding values of β_n are found to be:

$$\beta_1 = 188;\ \beta_2 = -45.4;\ \beta_3 = 11.5$$

The curve represented by the right side of Equation [28] will coincide with rT_1 at the points $r = 2.5$, $r = 3.5$, and $r = 4.5$. A graph of the actual function shows that it approximates the required function, rT_1, for other values of r with sufficient accuracy.

Appendix No. 4

The stress equations applying to the thick cylindrical tube are given in several textbooks. For the solid cylinder we may begin with Equation (*f*) on page 552 of Timoshenko's "Strength of Materials," or

$$ur = \frac{1+\mu}{1-\mu}\int_0^r aTrdr + C_1 r^2 + C_2$$

In a solid cylinder when $r = 0$, $u = 0$, so $C_2 = 0$. From the consideration that $\sigma_r = 0$ when $r = c$, the value of C_1 is found as in the reference cited. Then

$$\sigma_r = \frac{Ea}{1-\mu}\left[\frac{1}{c^2}\int_0^c Trdr - \frac{1}{r^2}\int_0^r Trdr\right]\ldots\ldots[12]$$

$$\sigma_t = \frac{Ea}{1-\mu}\left[\frac{1}{c^2}\int_0^c Trdr + \frac{1}{r^2}\int_0^r Trdr - T\right]\ldots[13]$$

To find the axial stress σ_z we have the Equation (*d*), page 551, of Timoshenko's work, which we may write:

$$\sigma_z = \frac{E}{1+\mu}\left[e_z + \frac{\mu}{1-\mu}\,\frac{1-2\mu}{E}\,(\sigma_z+\sigma_r+\sigma_t) + \frac{3\mu}{1-2\mu}\,aT\right] - \frac{EaT}{1-2\mu}$$

By substituting the values of σ_r and σ_t,

$$\sigma_z = \frac{\mu}{1-\mu}\,\frac{2Ea}{c^2}\int^c Trdr + Ee_z - \frac{EaT}{1-\mu}$$

To evaluate e_z we note that: $\int_0^c \sigma_z dA = 0$, where $dA = 2\pi rdr$.

Substituting the above value of σ_z in this, we have:

$$e_z = \frac{2a}{c^2}\int_0^c Trdr \quad \text{and} \quad \sigma_z = \frac{Ea}{1-\mu}\left(\frac{2}{c^2}\int_0^c Trdr - T\right)$$

The axial stress is seen to be the sum of the radial and tangential stresses. Thus σ_z and σ_t are equal at the surface where the radial stress is zero.

Equations [12] and [13] are indeterminate when $r = 0$. As in the case of the sphere, if we multiply them by r^2 and differentiate with respect to r, we obtain: For $r = 0$:

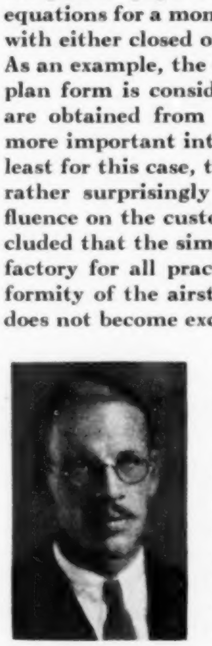
$$\sigma_r = \sigma_t = \frac{Ea}{1-\mu}\left[\frac{1}{c^2}\int_0^c Trdr - \frac{1}{2}\,T\right] \quad \ldots\ldots [14]$$

APM-54-19

On the Lift Distribution for a Wing of Arbitrary Plan Form in a Circular Wind Tunnel

By CLARK B. MILLIKAN,[1] PASADENA, CALIF.

Previous theories dealing with the interference of wind-tunnel boundaries on airfoil characteristics have in general neglected the distortion of the lift distribution along the span caused by the presence of the boundaries. In the present paper this effect is considered and the general equations for a monoplane wing in a circular wind tunnel, with either closed or open working section, are developed. As an example, the case of an untwisted wing of elliptical plan form is considered in detail, and numerical results are obtained from which curves are plotted giving the more important interference effects. It is found that, at least for this case, the distortion of the lift distribution is rather surprisingly small and has an unimportant influence on the customary interference factors. It is concluded that the simple Prandtl type of correction is satisfactory for all practical cases in which the lack of uniformity of the airstream or the size of the airfoil chord does not become excessive.



1 Introduction

THE author's interest in the present problem was aroused by a recent British report[2] describing wind-tunnel tests on a number of airfoils whose span was relatively large in comparison to the tunnel width. In this report it was concluded that when the airfoil span becomes as large as seven-eighths of the wind-tunnel width, the usual theoretical correction factors, which do not take into account distortion of the lift distribution, are no longer valid. This conclusion indicated that a more general investigation of wind-tunnel interference, taking into account the distortion of the lift distribution, might be of interest. In the following a working section of circular cross-section is assumed, both because of simplicity of the analysis and because the wind tunnel at the California Institute of Technology, with which the author has been much concerned, has that form.

2 The Image System and Its Associated Induced Velocities

The customary assumptions of Prandtl's "first-order" wing theory are made, namely, that all induced velocities are small compared to the basic velocity of flow and that the chord length is relatively small so that the wing may be approximated by a "lifting line." The wind-tunnel working section is idealized by assuming the model to be placed in an infinitely long cylindrical tube or jet whose axis is in the direction of the undisturbed flow, and the wing span is assumed to be symmetrically placed with respect to the axis, and the sweep-back to be zero, although otherwise the plan form and distribution of profile of the wing are arbitrary. The type of analysis originally introduced by Trefftz[3] is followed, in which the two-dimensional flow in a "retreating plane" far downstream from the airfoil and perpendicular to the tunnel axis is considered. Then since the trailing vortices are assumed to follow the undisturbed streamlines, they form a plane vortex sheet extending to infinity downstream from the airfoil. If the retreating plane is taken far enough behind the airfoil, then considerations of symmetry indicate that the velocities normal to the tunnel axis have exactly half the values in the plane through the wing which they have at corresponding points in the retreating plane. The symmetry conditions also indicate that the induced velocities parallel to the direction of the basic flow vanish at the wing itself. Since for the present purpose we are primarily interested in the induced velocities at the wing, the problem is reduced to that of determining the velocities in the two-dimensional flow in the retreating plane at the vortex sheet which gives the "wind shadow" of the wing.

This is exactly the same potential-flow problem as is treated in the case of a wing in an unbounded fluid, except that the usual boundary conditions at infinity are here replaced by conditions which must be satisfied at the circular boundary of the wind-tunnel stream. For a closed tunnel with solid walls this boundary condition obviously assumes the form that the circular boundary must be a streamline. For an open tunnel in which the airfoil is in a free jet the condition is that the pressure must be constant over the circular boundary of the jet. Prandtl[4] has shown that this condition is identical with the requirement that the circular boundary be an equipotential curve. The effects of the two types of wind tunnel may therefore be discussed in quite analogical manners through the use of the principle of superposition. It is only necessary to superimpose on the flow corresponding to the airfoil in an unbounded flow an additional potential flow which makes the circular wind-tunnel boundary a streamline for the closed tunnel or an equipotential curve for the open tunnel. In the retreating plane there is a distribution of vorticity along

the line determined by the wind shadow of the wing, and the unbounded flow is determined by this distribution of singularities and by the criterion that there be no other singularities in the entire plane. The superimposed flows which are necessary to satisfy our new boundary conditions require the addition of new singularities which must be outside the circular tunnel boundary. It is shown in the standard treatises on hydrodynamics[6] that if for every vortex in the wind shadow a vortex of opposite sign be placed at its image point with reference to the circular boundary, then the boundary will be a streamline of the resultant flow. Hence the superimposed flow for the closed-tunnel case is simply that corresponding to the distribution of image vortices in which each image vortex has a sign opposite to that of the original trailing vortex. Prandtl states that the superimposed flow for the open tunnel corresponds to exactly the same distribution of image vortices but with signs reversed. Since this arrangement of singularities has been less discussed than the previous one, it may be interesting to outline a simple proof of Prandtl's statement.

There is no circulation around the complete wind shadow, so that the distribution of vortices in it may be built up by the superposition of vortex pairs (two vortices with equal strength but opposite sign). Hence it is only necessary to prove that the circle is an equipotential curve for such a vortex pair with its images of the same signs. For a vortex of strength Γ the value of the potential at any point x,y is given by

$$\varphi(x,y) = \frac{\Gamma}{2\pi}\,\theta$$

where θ is the angle between the X-axis and the line joining the vortex to the point x,y. Hence if the circle has a radius R and the vortex pair is given by Γ at x_1, —Γ at x_2, while the images are Γ at ξ_1, —Γ at ξ_2, then for any point $P(x,y)$ on the circle (cf. Fig. 1) the complete potential is given by

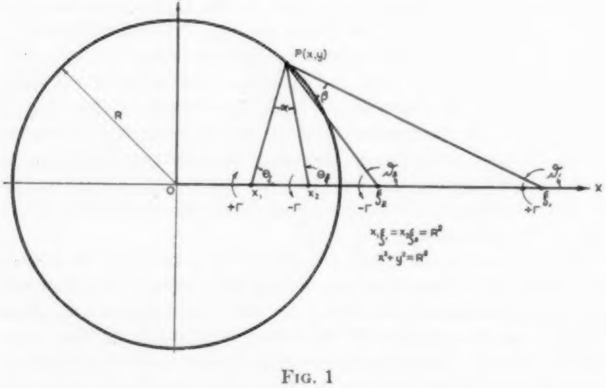

FIG. 1

$$\varphi\,(x,y) = \frac{\Gamma}{2\pi}\,(\theta_1 - \theta_2 + \vartheta_1 - \vartheta_2) = \frac{\Gamma}{2\pi}\,(\beta - \alpha)$$

where

$$x_1\xi_1 = x_2\xi_2 = R^2;\ x^2 + y^2 = R^2;\ \beta = \vartheta_1 - \vartheta_2;\ \alpha = \theta_2 - \theta_1$$

By simple applications of the cosine law to the triangles, x_1x_2P and $\xi_1\xi_2P$, it can immediately be shown that

$$\beta - \alpha = 0 \text{ for } x_1x_2 > 0;\ \beta - \alpha = \pi \text{ for } x_1x_2 < 0$$

Hence for such a distribution of vortices, φ = constant on the circle, and Prandtl's assertion is verified.

The calculations for the two types of wind tunnel may now be carried out simultaneously. In the following, the author will discuss explicitly the closed tunnel. The results can then be immediately applied to the open tunnel by changing the signs of all the image vortices.

Consider a wing span b with its center on the axis of the tunnel whose radius is $R = D/2$, and choose a coordinate system x,y in the plane of the wing or in the Trefftz retreating plane as indicated in Fig. 2. The lift is supposed to be in the direction of the positive Y-axis. In the wing shadow there is a distribution of vorticity whose strength per unit length along the span will be denoted by γ. Then at an element dx at a point x there will be a vortex of strength γdx. The image element will then be at $\xi = \dfrac{R^2}{x}$ and will have a length $d\xi = -\dfrac{R^2}{x^2}\,dx$. Place now at this element an image vortex of strength $\gamma' d\xi = \gamma dx$. Then, since dx and $d\xi$ have opposite signs, the original and image vortices will also have opposite signs, so that this gives the image system for a closed tunnel. For the complete system we have then a distribution of original vortices of strength γ per unit length along the X-axis from $-b/2$ to $+b/2$ and a similar distribution of image vortices of strength γ' per unit length from $x = -\infty$ to $x = -2R^2/b$ and from $x = +2R^2/b$ to $x = +\infty$, where

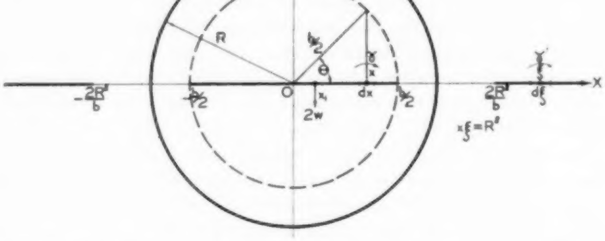

FIG. 2 THE TREFFTZ RETREATING PLANE FAR DOWNSTREAM FROM THE WING

$$\left.\begin{aligned} x\xi &= R^2 \\ \gamma dx &= \gamma' d\xi \end{aligned}\right\} \qquad [1]$$

We are interested in calculating the downwash $w(x_1)$ at an arbitrary point x_1 along the wing span. Then, as has already been mentioned, the downwash induced by the vortex singularities at the corresponding point x_1 in the retreating plane will be just $2w(x_1)$. It should be noted that the downwash is taken as positive in the direction of the negative Y-axis, i.e., opposite to the lift. It will be convenient to split this downwash into two parts, the first denoted by w_0 and giving that portion induced by the trailing vortices in the wing shadow, and the second denoted by w_1, giving the additional downwash induced by the complete system of image vortices. w_0 is exactly the downwash which would be present if the wing were in an unbounded flow, i.e., $R = \infty$, so that w_1 represents the interference velocities caused by the presence of the tunnel boundary. A new variable, θ, is now introduced, giving the position along the span where

$$x = \frac{b}{2}\cos\theta \qquad [2]$$

and the circulation around the wing, $\Gamma(x)$, expanded in a Fourier series of the form

---

[6] See, for instance, H. Lamb, "Hydrodynamics," fifth edition, p. 205.

$$\Gamma = 2Vb \sum_{n=1}^{\infty} B_n \sin n\theta \ldots\ldots\ldots\ldots\ldots [3]$$

where V is the flow velocity far upstream from the wing. Then the usual wing theory[6] gives for the "undisturbed" downwash w_0

$$\frac{w_0}{V} = \sum_{n=1}^{\infty} nB_n \frac{\sin n\theta}{\sin \theta} \ldots\ldots\ldots\ldots\ldots [4]$$

The task now is to find the downwash w_1 induced by the system of image vortices. Calling γ, γ' positive for clockwise rotation as indicated in Fig. 2,

$$2w_1(x_1) = -\frac{1}{2\pi}\int_{\frac{2R^2}{b}}^{\infty} \frac{\gamma' d\xi}{\xi - x_1} - \frac{1}{2\pi}\int_{-\infty}^{\frac{-2R^2}{b}} \frac{\gamma' d\xi}{\xi - x_1}$$

or, from [1]

$$2w_1(x_1) = \frac{1}{2\pi}\int_{-\frac{b}{2}}^{+\frac{b}{2}} \frac{\gamma dx}{\frac{R_2}{x} - x_1}$$

γ is connected with the circulation around the wing by the relation

$$\gamma = \frac{d\Gamma}{dx} = \frac{-2}{b \sin\theta}\frac{d\Gamma}{d\theta} = -4V \sum_{n=1}^{\infty} nB_n \frac{\cos n\theta}{\sin\theta}$$

so that the expression for w_1 may be transformed into

$$\frac{w_1(x_1)}{V} = -\frac{1}{4\pi}\frac{b^2}{R^2}\sum_{n=1}^{\infty} nB_n \int_0^{\pi} \frac{\cos n\theta \cos\theta}{1 - \frac{bx_1}{2R^2}\cos\theta}\, d\theta$$

Writing, for the moment, $bx_1/2R^2 = \epsilon$,

$$\int_0^{\pi} \frac{\cos n\theta \cos\theta}{1 - \frac{bx_1}{2R^2}\cos\theta}\, d\theta = \frac{1}{2}\int_0^{\pi}\frac{\cos (n-1)\theta}{1 - \epsilon\cos\theta}\, d\theta + \frac{1}{2}\int_0^{\pi}\frac{\cos (n+1)\theta}{1 - \epsilon\cos\theta}\, d\theta$$

A very simple contour integration leads to the result (for $\epsilon < 1$)

$$\int_0^{\pi} \frac{\cos a\theta}{1 - \epsilon\cos\theta}\, d\theta = \frac{\pi}{\sqrt{1-\epsilon^2}}\left(\frac{1-\sqrt{1-\epsilon^2}}{\epsilon}\right)$$

and using this, a little calculation gives

$$\frac{w_1(x_1)}{V} = \frac{-b^2}{4R^2\epsilon\sqrt{1-\epsilon^2}}\sum_{n=1}^{\infty} nB_n \left(\frac{1-\sqrt{1-\epsilon^2}}{\epsilon}\right)^n$$

Now letting θ correspond to x_1 in accordance with [2],

$$\epsilon = \frac{bx_1}{2R^2} = \frac{b^2}{4R^2}\cos\theta = A^2\cos\theta$$

where

$$A = \frac{b}{2R} = \frac{b}{D} \ldots\ldots\ldots\ldots\ldots\ldots\ldots [5]$$

Hence finally

$$\frac{w_1(\theta)}{V} = \frac{-1}{\cos\theta\sqrt{1-A^4\cos^2\theta}}\sum_{n=1}^{\infty} nB_n \times \left(\frac{1-\sqrt{1-A^4\cos^2\theta}}{A^2\cos\theta}\right)^n \ldots\ldots [6]$$

Equation [6] gives the additional downwash induced at all points along the wing span by the presence of the closed-tunnel boundary. For an open wind tunnel [6] is still valid if the sign be changed. In order to determine the circulation distribution, i.e., the B_n's, for a definite plan form and distribution of airfoil profiles this result must be combined with the two-dimensional theory of lift in quite the normal way [cf. footnote 6].

3 The Equations for a Monoplane Wing in a Circular Wind Tunnel

Let the lift per unit length of span be denoted by L', the effective angle of attack at any longitudinal section of the wing by α_e, the geometrical or apparent angle of attack by α, and the chord at any point along the span by t. Angles of attack are measured from the position of zero lift of the wing section under consideration. Then for every point along the span

$$\alpha = \alpha_e + \frac{w}{V} = \alpha_e + \frac{w_0}{V} + \frac{w_1}{V} \ldots\ldots\ldots\ldots [7]$$

The results of the two-dimensional theory of airfoil sections are now introduced by writing

$$L' = 2\pi\eta\alpha_e \frac{\rho}{2} V^2 t$$

where ρ is the fluid density and η is called the efficiency factor and is an empirical constant giving the fraction of the theoretical slope of the lift coefficient vs. α_e curve which is obtained experimentally. For all normal airfoil sections at reasonably high Reynolds numbers, η may be taken as approximately 0.90.

We have also the Kutta-Joukowsky law giving a second expression for L':

$$L' = \rho V \Gamma \ldots\ldots\ldots\ldots\ldots\ldots\ldots [8]$$

Equating these two expressions and using [7],

$$\alpha = \frac{\Gamma}{\pi\eta V t} + \frac{w_0}{V} + \frac{w_1}{V}$$

and introducing Equations [3], [4], and [6],

$$\alpha = \sum_{n=1}^{\infty} B_n \left[\frac{2b}{\pi\eta t}\sin n\theta + \frac{n}{\sin\theta}\sin n\theta - \frac{n}{\cos\theta\sqrt{1-A^4\cos^2\theta}}\left(\frac{1-\sqrt{1-A^4\cos^2\theta}}{A^2\cos\theta}\right)^n\right] \ldots . [9]$$

It is convenient to introduce the chord at the center of the wing, $t_0 = t\left(\theta = \frac{\pi}{2}\right)$, and to write

$$\mu = \frac{2b}{\pi\eta t_0},\ \beta_n = \frac{B_n}{B_1} \ldots\ldots\ldots\ldots\ldots [10]$$

---

[6] H. Glauert, "Aerofoil and Airscrew Theory" (1926), p. 139.

Then [9] may be written in the form

$$\alpha \sin \theta = B_1 \sum_{n=1}^{\infty} \beta_n \left(\mu \frac{\sin \theta}{t/t_0} + n \right) \sin n\theta - \sigma(\theta) \quad \text{..[11]}$$

where

$$\sigma(\theta) = \pm \frac{B_1 \sin \theta}{\cos \theta \sqrt{1 - A^4 \cos^2 \theta}} \sum_{n=1}^{\infty} n\beta_n \times \left(\frac{1 - \sqrt{1 - A^4 \cos^2 \theta}}{A^2 \cos \theta} \right)^n \quad \text{.....[12]}$$

Equation [11] serves to determine the coefficients B_n when the plan form of the wing (t/t_0), the distribution of profile (α), and the ratio of span to tunnel diameter (A) are given. The plus sign in [12] corresponds to a closed-working-section tunnel and the minus sign to an open tunnel. It should be noted that in the limit $A = 0$, corresponding to a wind tunnel of infinite diameter, the factor $\sigma(\theta) = 0$ and [11] reduces to the standard equation for a monoplane wing in an unbounded flow.

The most obvious method of proceeding with the determination of the coefficients β_n from [11] is to express $\sigma(\theta)$ as a Fourier series

$$\sigma(\theta) = B_1 \sum_{n=1}^{\infty} \gamma_n \sin n\theta$$

Equations [11] and [12] now assume the form

$$\left.\begin{aligned} \alpha \sin \theta &= B_1 \sum_{n=1}^{\infty} \left[\left(\mu \frac{\sin \theta}{t/t_0} + n \right) \beta_n - \gamma_n \right] \sin n\theta \\ \gamma_n &= \pm \frac{2}{\pi} \sum_{m=1}^{\infty} m\beta_m \int_0^{\pi} \left(\frac{1 - \sqrt{1 - A^4 \cos^2 \varphi}}{A^2 \cos \varphi} \right)^m \\ &\qquad \times \frac{\sin n\varphi \sin \varphi}{\cos \varphi \sqrt{1 - A^4 \cos^2 \varphi}} d\varphi \end{aligned}\right\} \quad [13]$$

where the plus sign corresponds to a closed tunnel and the minus to an open tunnel.

Before discussing the solution of [13] to give the coefficients β_n, it will be convenient to derive the form of the final results in which we are interested. In the present investigation it is desired to determine primarily three wind-tunnel interference effects. The first is the distortion to the lift distribution over the span, the second is the change in total lift coefficient or angle of attack, and the third is change in total drag coefficient. For this purpose a given wing will be considered in two conditions, first in the wind tunnel with a given total lift coefficient (no subscript), and second in a free stream, $A = 0$, with the same total lift coefficient (subscript *f*). The interference factors are then defined by

$$\Delta\alpha = \alpha_F - \alpha, \ \Delta C_D = C_{DF} - C_D, \text{ where } C_{LF} = C_L \quad \text{..[14]}$$

Now, using [3] and [8], we have

$$C_L = \frac{1}{\rho/2\, V^2 S} \int_{-b/2}^{b/2} L' dx = \frac{2b^2}{S} \sum_{n=1}^{\infty} B_n \int_0^{\pi} \sin n\theta \sin \theta d\theta$$

or

$$C_L = \pi M B_1 \quad \text{....................[15]}$$

where

$$S = \text{wing area}; \quad M = \frac{b^2}{S} = \text{aspect ratio} \quad \text{......[16]}$$

Hence B_1 will have the same value for the wing in the wind tunnel and in the free stream, since in our comparison we take $C_{LF} = C_L$. The expression for $\Delta\alpha$ may now be written

$$\Delta\alpha = \alpha(A = 0) - \alpha(A) = \alpha(\gamma_n = 0) - \alpha \quad \text{......[17]}$$

The fundamental expression for total drag coefficient is

$$C_D = \frac{D}{\frac{\rho}{2} V^2 S} \quad \text{where} \quad D = \rho \int_{-b/2}^{b/2} \Gamma w dx$$

But $w = w_0 + w_1$, and from [6] and [12]

$$\frac{w_1}{V} = \frac{-\sigma}{\sin \theta} = -B_1 \sum_{n=1}^{\infty} \gamma_n \frac{\sin n\theta}{\sin \theta}$$

A little calculation now gives

$$C_D = \frac{2b^2}{S} B_1^2 \int_0^{\pi} \left[\sum_{n=1}^{\infty} \beta_n \sin n\theta \sum_{m=1}^{\infty} (m\beta_m - \gamma_m) \sin m\theta \right] d\theta$$

or

$$C_D = \frac{C_L^2}{\pi M} \sum_{n=1}^{\infty} (n\beta_n^2 - \beta_n \gamma_n)$$

Hence

$$\Delta C_D = \frac{C_L^2}{\pi M} \sum_{n=1}^{\infty} \left[n\beta_n^2(A = 0) - (n\beta_n^2 - \beta_n\gamma_n) \right] \quad \text{..[18]}$$

Finally the free stream and actual lift distributions are given by

$$L_F' = 2\rho V^2 b B_1 \sum_{n=1}^{\infty} \beta_n(A = 0) \sin n\theta; \quad L' = 2\rho V^2 b B_1 \sum_{n=1}^{\infty} \beta_n \sin n\theta \quad \text{........[19]}$$

Equations [17], [18], and [19] give all of the interference effects with which we are concerned, in terms of the coefficients β_n and γ_n.

4 OTHER EXPRESSIONS FOR THE COEFFICIENTS γ_n

The evaluation of the integral in the expression for γ_n in [13] appears to be very difficult for arbitrary values of A. We therefore adopt the expedient of expanding the integrand as a power series in A and so obtaining approximate values of γ_n. In carrying out this calculation considerations are restricted to cases in which the lift distribution is symmetrical about the center line of the wing. This covers all practically interesting cases except those in which the effect of aileron displacements is sought for. The restriction mentioned implies that only odd coefficients $\beta_1, \beta_3, \beta_5$, etc., appear, i.e., $\beta_2 = \beta_4 = \beta_6 = \ldots..$etc. $= 0$. Similarly the image vortices will have a symmetrical arrangement so that $\gamma_2 = \gamma_4 = \gamma_6 = \ldots..$etc. $= 0$. Hence in Equations [13] the summation indices n and m may be replaced by indices of the form

$$n, m = 2k - 1 \quad \text{.................[20]}$$

Using this notation the expansion of [12] gives

$$\sigma = A^2 \sin\theta \cdot B_1\left[\frac{1}{2} + \frac{3}{8}(1 + \beta_3)(A^2\cos\theta)^2 + \frac{5}{32}(2 + 3\beta_3 + \beta_5)(A^2\cos\theta)^4 + \frac{7}{128}(5 + 9\beta_3 + 5\beta_5 + \beta_7)(A^2\cos\theta)^6 + \ldots\right]$$

Transforming this to the Fourier-series form given in [13], a little calculation gives for the first four Fourier coefficients:

$$\left.\begin{aligned}
\gamma_1 &= \pm A^2\left[\frac{1}{2} + \frac{3}{32}(1+\beta_3)A^4 + 2\cdot\frac{5}{512}(2+3\beta_3+\beta_5)A^8 + 5\cdot\frac{7}{8192}(5+9\beta_3+5\beta_5+\beta_7)A^{12} + \ldots\ldots\right]\\
\gamma_3 &= \pm A^2\left[\frac{3}{32}(1+\beta_3)A^4 + 3\cdot\frac{5}{512}(2+3\beta_3+\beta_5)A^8 + 9\cdot\frac{7}{8192}(5+9\beta_3+5\beta_5+\beta_7)A^{12} + \ldots\ldots\right]\\
\gamma_5 &= \pm A^2\left[1\cdot\frac{5}{512}(2+3\beta_3+\beta_5)A^8 + 5\cdot\frac{7}{8192}(5+9\beta_3+5\beta_5+\beta_7)A^{12} + \ldots\ldots\right]\\
\gamma_7 &= \pm A^2\left[1\cdot\frac{7}{8192}(5+9\beta_3+5\beta_5+\beta_7)A^{12} + \ldots\ldots\right]
\end{aligned}\right\}\ldots[21]$$

where the plus and minus signs refer as usual to the closed and open tunnel conditions.

The curious symmetry which appears in these expressions renders it easy to write down additional terms after a little experience, but the complexity of the calculations makes it difficult to give a definite formula for any arbitrary term. It may be noted that if A be put equal to 1, then the numerical coefficients of β_1, β_3, β_5, etc., form a matrix symmetrical about the diagonal.

The expansion given by [21] leads to a satisfactory solution of the wind-tunnel interference problem when A does not approach unity too closely. In the limiting case $A = 1$ the integral of [13] can be evaluated directly and expressed as a definite function of m and n. For large values of n the integration becomes a little tedious, but there are no difficulties in principle for arbitrary values of the indices. The same property which was noted at the end of the last paragraph is found to hold also in this case, namely, the coefficients of β_1, β_3, β_5, etc., form a diagonally symmetrical matrix. The numerical results for the first few terms are as follows:

$$\left.\begin{aligned}
\gamma_1 &= \pm(0.727 + 0.367\beta_3 + 0.238\beta_5 + 0.177\beta_7 + 0.139\beta_9 + \ldots\ldots)\\
\gamma_3 &= \pm(0.367 + 0.681\beta_3 + 0.569\beta_5 + 0.461\beta_7 + 0.379\beta_9 + \ldots\ldots)\\
\gamma_5 &= \pm(0.238 + 0.569\beta_3 + 0.652\beta_5 + 0.608\beta_7 + 0.542\beta_9 + \ldots\ldots)\\
\gamma_7 &= \pm(0.177 + 0.461\beta_3 + 0.608\beta_5 + \ldots\ldots)\\
\gamma_9 &= \pm(0.139 + 0.379\beta_3 + 0.542\beta_5 + \ldots\ldots)
\end{aligned}\right\}\ldots[22]$$

5 APPLICATION TO AN UNTWISTED WING OF ELLIPTICAL PLAN FORM

The solution of Equation [13] is particularly simple for an untwisted wing of elliptical plan form, so that this case is chosen for the working out of a numerical example. For such a wing

$$\alpha = \text{constant}, \quad t/t_0 = \sin\theta, \quad \beta_{2k} = \gamma_{2k} = 0$$

Hence [13] gives at once

$$\beta_{2k-1}(\mu + 2k - 1) - \gamma_{2k-1} = \frac{2\alpha}{\pi B_1}\int_0^{\pi} \sin\theta \sin(2k-1)\theta d\theta$$

or

$$\left.\begin{aligned}
\alpha &= B_1(1 + \mu + \gamma_1)\\
\beta_{2k-1} &= \frac{\gamma_{2k-1}}{2k - 1 + \mu} \qquad (k > 1)
\end{aligned}\right\}\ldots\ldots[23]$$

To get free-stream conditions we must put $A = 0$, i.e., $\gamma_{2k-1} = 0$. Hence

$$\alpha_F = B_1(1 + \mu), \quad (\beta_{2k-1})_F = 0 \qquad (k > 1)$$

and [17] and [18] together with [15] give

$$\Delta\alpha = B_1\gamma_1 = \frac{C_L}{\pi M}\gamma_1$$

$$\Delta C_D = \frac{C_L^2}{\pi M}\left[\gamma_1 + \sum_{k=2}^{\infty}\left\{\gamma_{2k-1} - (2k-1)\beta_{2k-1}\right\}\beta_{2k-1}\right]$$

In order to compare our results with those given by Prandtl, which are based on the assumption of an elliptical lift distribution,[4] it will be convenient to rewrite these expressions in a little different form. Denoting the cross-sectional area of the wind tunnel by C so that

$$\pi M = \pi\frac{b^2}{S} = \frac{\pi R^2}{S}4\left(\frac{b}{2R}\right)^2 = 4\frac{C}{S}A^2$$

and writing

$$\Delta\alpha = \delta_\alpha\frac{S}{C}C_L, \qquad \Delta C_D = \delta_D\frac{S}{C}C_L^2 \ldots\ldots\ldots [24]$$

then

$$\delta_\alpha = \frac{\gamma_1}{4A^2},$$

$$\delta_D = \frac{1}{4A^2}\left[\gamma_1 + \sum_{k=2}^{\infty}\left\{\gamma_{2k-1} - (2k-1)\beta_{2k-1}\right\}\beta_{2k-1}\right]\ldots[25]$$

Prandtl's results may be expressed in the form:[4,7]

$$\left.\begin{aligned}
&\delta_\alpha = \delta_D = \delta_P, \quad \beta_{2k-1} = 0 \quad (k > 1)\\
&\text{and}\\
&\delta_P = \frac{1}{8}\left(1 + \frac{3}{16}A^4 + \frac{5}{64}A^8 + \frac{175}{4096}A^{12} + \ldots\ldots\right)
\end{aligned}\right\}\ldots[26]$$

The simultaneous solution of the sets of linear Equations [21] or [22] and [23] may quite easily be carried out to any desired

---

[7] L. Prandtl, etc., "Ergebnisse der Aerodynamischen Versuchstanstalt zu Göttingen," 2 Lieferung (1923), p. 17.

approximation. The expansion in powers of A, neglecting terms of degree higher than 14 in A, gives for a closed wind tunnel:

$$\left.\begin{aligned}
\delta_\alpha &= \frac{1}{8}\Bigg[1 + \frac{3}{16}A^4 + \frac{5}{64}A^8 + \frac{175}{4096}A^{12} + \ldots\ldots\ldots \\
&\qquad + \frac{9}{512(3+\mu)}A^{10}\left(1 + \frac{5}{4}A^4 + \ldots\ldots\ldots\right)\Bigg] \\
\delta_D &= \frac{1}{8}\Bigg[1 + \frac{3}{16}A^4 + \frac{5}{64}A^8 + \frac{175}{4096}A^{12} + \ldots\ldots\ldots \\
&\qquad + \frac{9(3+2\mu)}{512(3+\mu)^2}A^{10}\left(1 + \frac{5}{4}A^4 + \ldots\ldots\ldots\right)\Bigg] \\
L' &= 2\rho V^2 bB_1\Bigg[\sin\theta + \frac{3}{32(3+\mu)}A^6\Bigg\{1 + \frac{5}{8}A^4 + \frac{105}{256}A^8 \\
&\qquad + \ldots\ldots + \frac{3}{32(3+\mu)}A^6 + \ldots\ldots\Bigg\}\sin 3\theta \\
&\qquad + \frac{5}{256(5+\mu)}A^{10}\left\{1 + \frac{35}{32}A^4 + \ldots\ldots\right\}\sin 5\theta \\
&\qquad + \frac{35}{8192(7+\mu)}A^{14}\sin 7\theta + \ldots\ldots\Bigg]
\end{aligned}\right\} .[27]$$

It will be observed that δ_α and δ_D differ from Prandtl's value and from one another only in terms of the tenth degree or higher in A, while the distortion of the lift distribution contains terms of the sixth degree. The secondary series in parentheses would appear to diverge for values of A near to unity, but there is a reason to believe that the numerical coefficients of the first few terms only increase and that the coefficients later decrease with increasing degree of A, so as to make the series actually convergent even for $A \longrightarrow 1$. Putting $\mu = 3$, corresponding to an aspect ratio of about 5.5 [27] gives:

$$\left.\begin{aligned}
\delta_\alpha &= \frac{1}{8}\,[1 + 0.188A^4 + 0.078A^8 + 0.043A^{12} + \ldots\ldots\ldots \\
&\qquad + 0.003A^{10}(1 + 1.250A^4 + \ldots\ldots\ldots)] \\
\delta_D &= \frac{1}{8}\,[1 + 0.188A^4 + 0.078A^8 + 0.043A^{12} + \ldots\ldots\ldots \\
&\qquad + 0.004A^{10}(1 + 1.250A^4 + \ldots\ldots\ldots)] \\
\beta_3 &= 0.016A^6\,(1 + 0.625A^4 + 0.410A^8 + \ldots\ldots\ldots \\
&\qquad + 0.016A^6 + \ldots\ldots\ldots) \\
\beta_5 &= 0.0024A^{10}\,(1 + 1.094A^4 + \ldots\ldots\ldots) \\
\beta_7 &= 0.0004A^{14}(1 + \ldots\ldots\ldots).
\end{aligned}\right\} .[28]$$

In the limiting case $A = 1$ the calculations have been carried out for $\mu = 3$, using the approximation indicated in [22]. The result is

$$\left.\begin{aligned}
&\delta_\alpha = 0.192 \qquad\qquad \delta_D = 0.198 \\
&L' = 2\rho V^2 bB_1\,[\sin\theta + 0.076\sin 3\theta + 0.041\sin 5\theta \\
&\qquad + 0.024\sin 7\theta + 0.017\sin 9\theta + \ldots\ldots\ldots]
\end{aligned}\right\} .[29]$$

Decreasing the degree of approximation by one step, i.e., neglecting β_9 and γ_9, caused no noticeable change in the above values of δ_α and δ_D, while neglecting β_7 and γ_7 in addition decreased both about one-half per cent.

The numerical expressions have also been worked out for the open-throat wind-tunnel case. The expansion in powers of A gives

$$\left.\begin{aligned}
\delta_\alpha &= -\frac{1}{8}\,[1 + 0.188A^4 + 0.078A^8 + 0.043A^{12} + \ldots\ldots \\
&\qquad - 0.003A^{10}\,(1 + 1.250A^4 + \ldots\ldots\ldots)] \\
\delta_D &= -\frac{1}{8}\,[1 + 0.188A^4 + 0.078A^8 + 0.043A^{12} + \ldots\ldots \\
&\qquad - 0.004A^{10}\,(1 + 1.250A^4 + \ldots\ldots\ldots)] \\
\beta_3 &= -0.016A^6\,(1 + 0.625A^4 + 0.410A^8 + \ldots\ldots\ldots \\
&\qquad - 0.016A^6 + \ldots\ldots\ldots) \\
\beta_5 &= -0.0024A^{10}\,(1 + 1.094A^4 + \ldots\ldots\ldots) \\
\beta_7 &= -0.0004A^{14}\,(1 + \ldots\ldots\ldots)
\end{aligned}\right\} .[30]$$

The limiting case $A = 1$ leads to the expressions:

$$\left.\begin{aligned}
&\delta_\alpha = -0.175 \qquad\qquad \delta_D = -0.172 \\
&L' = 2\rho V^2 bB_1\,[\sin\theta - 0.052\sin 3\theta - 0.023\sin 5\theta \\
&\qquad - 0.014\sin 7\theta - 0.009\sin 9\theta - \ldots\ldots\ldots]
\end{aligned}\right\} .[31]$$

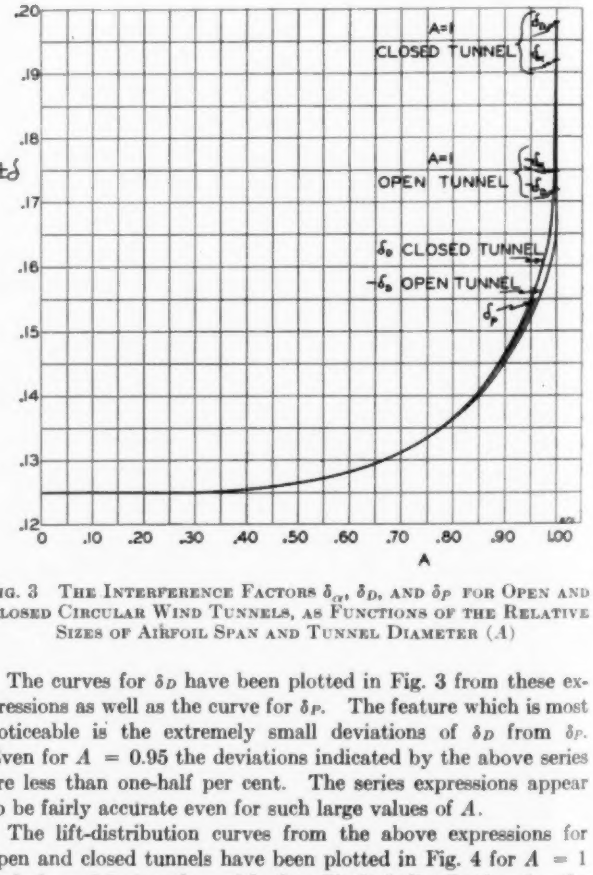

Fig. 3 The Interference Factors δ_α, δ_D, and δ_P for Open and Closed Circular Wind Tunnels, as Functions of the Relative Sizes of Airfoil Span and Tunnel Diameter (A)

The curves for δ_D have been plotted in Fig. 3 from these expressions as well as the curve for δ_P. The feature which is most noticeable is the extremely small deviations of δ_D from δ_P. Even for $A = 0.95$ the deviations indicated by the above series are less than one-half per cent. The series expressions appear to be fairly accurate even for such large values of A.

The lift-distribution curves from the above expressions for open and closed tunnels have been plotted in Fig. 4 for $A = 1$ and $A = 0.9$, together with the elliptical distribution for the airfoil in a free stream $A = 0$. Even in the extreme case $A = 1$ the distortion of the lift-distribution curve is not violent, while for $A = 0.9$ it is so slight as to be of no practical consequence.

6 Discussion of Results

The most interesting result of the foregoing numerical investigation is the surprisingly small distortion in the lift distribution caused by the wind-tunnel interference. In view of this very small effect for elliptical wings, it appears very unlikely that other normal plan forms (e.g., rectangular, tapered) will suffer markedly larger distortions until *A* approaches very near to unity. Also it seems very probable that for wind tunnels with rectangular, elliptical, or other usual cross-sections the distortion will be of the same order as that found here, as long as the wing tips are a reasonable distance from the tunnel boundaries. In closed tunnels there is always a boundary layer which disturbs the uniformity of flow near the walls, and in open tunnels the region near the jet boundary is much disturbed. Hence it is generally unsafe from this point of view to test a model whose span is much over nine-tenths of the wind-tunnel breadth. Hence one may conclude that for tests in circular wind tunnels with a wing plan form similar to an ellipse, if the wing is restricted to the region of uniform velocity, the simple Prandtl correction factors may safely be used and the lift-distribution distortion may be neglected. This conclusion can probably be extended with reasonable certainty to other wind-tunnel cross-sections and wing plan forms. Hence it would seem that the explanation for the discrepancies to which reference is made in the introduction must be sought in some other direction.

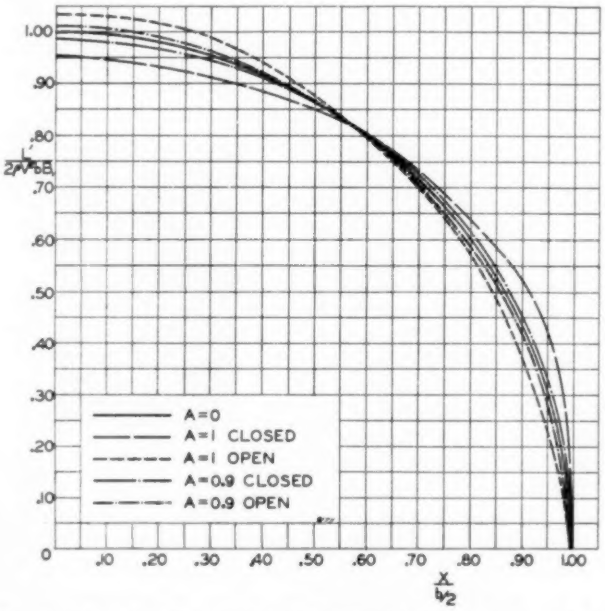

Fig. 4 The Lift Distribution Over the Semi-Span of an Untwisted Elliptical Wing in Open and Closed Circular Wind Tunnels for Various Values of *A*

It should be pointed out explicitly that the effects of streamline curvature due to tunnel walls or of deflection of the jet in the case of open tunnels have not been considered in the present work. Both of these effects vary with the ratio of wing chord to tunnel dimensions, and not with the ratio of span to tunnel dimension.

In conclusion, it may be mentioned that the investigation of other plan forms may be carried out, using the results of the present analysis, by exactly the same methods as have been used for a wing in an unbounded fluid by Glauert[4] or more recently by Lotz.[5]

APM-54-20

Design of Spring Gears for Exhaust-Turbine Installations

By J. ORMONDROYD[1] and T. C. KUCHLER,[2] PHILADELPHIA, PA.

J. Ormondroyd

The paper outlines the necessity for flexibility in the coupling linkage of a turbine with a reciprocating engine driving the same shaft. A résumé of the history of the problem is given. The conditions which must be fulfilled for satisfactory operation and the details of the calculation to fulfil these conditions are discussed. For simplicity the design chosen relies on propeller damping to hold the torque oscillations within safe limits. Tests with and without flexibility in the turbine gearing are described. It is shown that the problem depends on the vibration characteristics of the system and that a solution can be made if the drawings of the rotating parts and a few engine indicator cards at different speeds are available.

T. C. Kuchler

THE exhaust turbine for raising the efficiency of existing reciprocating-engined ships is gaining increased notice in marine circles. The combination of the exhaust turbine and the reciprocating engine driving a single propeller shaft gives rise to peculiar mechanical difficulties in the gearing which connects the turbine to the propeller shaft. This paper deals with a solution of this problem.

The steamship *Susan V. Luckenbach* is a cargo vessel of 12,000-ton displacement which was originally equipped with a triple-expansion reciprocating engine which delivered 2600 i.hp. at 77 r.p.m. and having a speed of about 12 knots. Competition required a greater speed for the same operating cost. Having the engine available, this was best accomplished by the installation of an exhaust turbine.

The exhaust-turbine installation consists of a 1000-hp. turbine taking steam from the engine at 19 in. vacuum and exhausting to the condenser at 29 in. vacuum. The power developed by this turbine is transmitted to the propeller shaft through a gear of double-reduction flexible-frame type.

To make the maneuvering easier, the turbine is directly connected to the propeller shaft at all times, and a control is installed to maneuver the turbine automatically with the engine by the use of high-pressure steam.

This turbine, shown in Fig. 1, is designed to utilize either low- or high-pressure steam. The ahead blading consists of four pairs of rows of reaction blading in which either low-pressure exhaust steam or high-pressure steam expanded through a nozzle is used. The astern blading consists of two moving and one stationary row of impulse blades in which only high-pressure steam is used.

The reduction gearing as originally installed is shown in Fig. 2. It was designed to carry the load of 1000 hp. developed by the turbine with a speed reduction from 3600 r.p.m. of the turbine to 84 r.p.m. of the propeller shaft. The gears were made strong enough to carry the full engine torque to which they might be subjected if reversing should be done with the engine alone. The gearing is of the double-reduction flexible-frame type, the pinions and gears being double helical with standard involute teeth. The entire gear train—which consists of a high-speed (or first reduction) pinion, high-speed (or first reduction) gear, with low-speed (or second reduction) pinion mounted on the same shaft, and low-speed (or second reduction) gear—is arranged in a horizontal plane and carried in a single housing. The connection between the turbine and the high-speed pinion is by means of a pin-type coupling and a flexible drive shaft. This drive shaft extends through the pinion and is fastened to it at the end remote from the turbine. The arrangement gives a shaft of considerable length which provides the necessary flexibility to permit the flexible frame to function without restraint. The permissible rocking of the frames insures good tooth alignment, even though the housing is distorted due to weaving of the ship or the main shaft drops due to wear of the engine main bearings.

The result of this installation was to increase the indicated shaft horsepower of the ship from 3000 hp. developed by the engine to 4000 hp. developed by the combination of the engine and turbine with the same fuel consumption. This added horsepower increases the speed of the ship about 2 knots.

The original trials of the installation showed very fine results, with the exception of a violent bumping in the gears. This was at first thought to be due to uneven load distribution in the three engine cylinders. The load distribution was improved without changing the gear bumping. Reducing bearing clearances and backlash had no effect on the gear impacts.

Torsiograph readings were taken during the trials to determine

[1] Experimental Engineering Division, South Philadelphia Works, Westinghouse Elec. & Mfg. Co. Mr. Ormondroyd received the degree of A.B. from the University of Pennsylvania in 1920. Since then he has been with his present company as engineer. For two years his duties related to electric-heating engineering and from 1924 to 1930 to railway-motor engineering. In 1927 he was made engineer in charge of instruction in the Westinghouse Mechanical Design School. In 1930 he became manager of the company's Experimental Division.

[2] Research Engineer, Engine Division, South Philadelphia Works, Westinghouse Elec. & Mfg. Co. Jun. A.S.M.E. Mr. Kuchler was graduated in 1926 from the Swiss Federal College of Science, as a pupil of Dr. A. Stodola. From 1926 to 1928 he was employed by Sulzer Bros., Winterthur, Switzerland, as a draftsman in the marine Diesel engine department. He was been connected with the Westinghouse Company since 1928, and has been engaged in research and development in connection with high-speed oil engines.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

the variable engine torque. The results from these readings showed quite convincingly that the bumping was caused by this variable torque.

Consideration of the design of a flexible gear drive resulted in the design of a low-speed gear driving the propeller shaft through springs, the variation in torque being taken up by the springs.

This spring-gear wheel is shown in Fig. 3. The gear wheel center, two spiders, and one of the 12 spring assemblies are shown in Fig. 4. The gear wheel is free to rotate on the gear-wheel center, having two bronze bushings at the ends which bear on the journals at the ends of the gear-wheel center. The springs are supported by two internal stops which are used to limit their deflection and hold them in place. There are hardened pins fitted into the ends of the stops which are used as a support point for the spring assembly in the gear wheel and spiders. The spiders are bolted directly to the ends of the gear-wheel center.

The load is transmitted from the gear wheel through the springs to the spider, which in turn drives the gear-wheel shaft. The springs take the load in compression in either direction of rotation as they are always in contact at the semicircular notches in the gear wheel at one end and with the semicircular notches in the spider at the other. Under no load the spring stresses are zero with this arrangement.

Guard plates are attached to the gear wheel to prevent the spring assemblies from coming out in case a spring should be broken. Openings are provided in the gear-housing cover to allow easy and quick spring replacement.

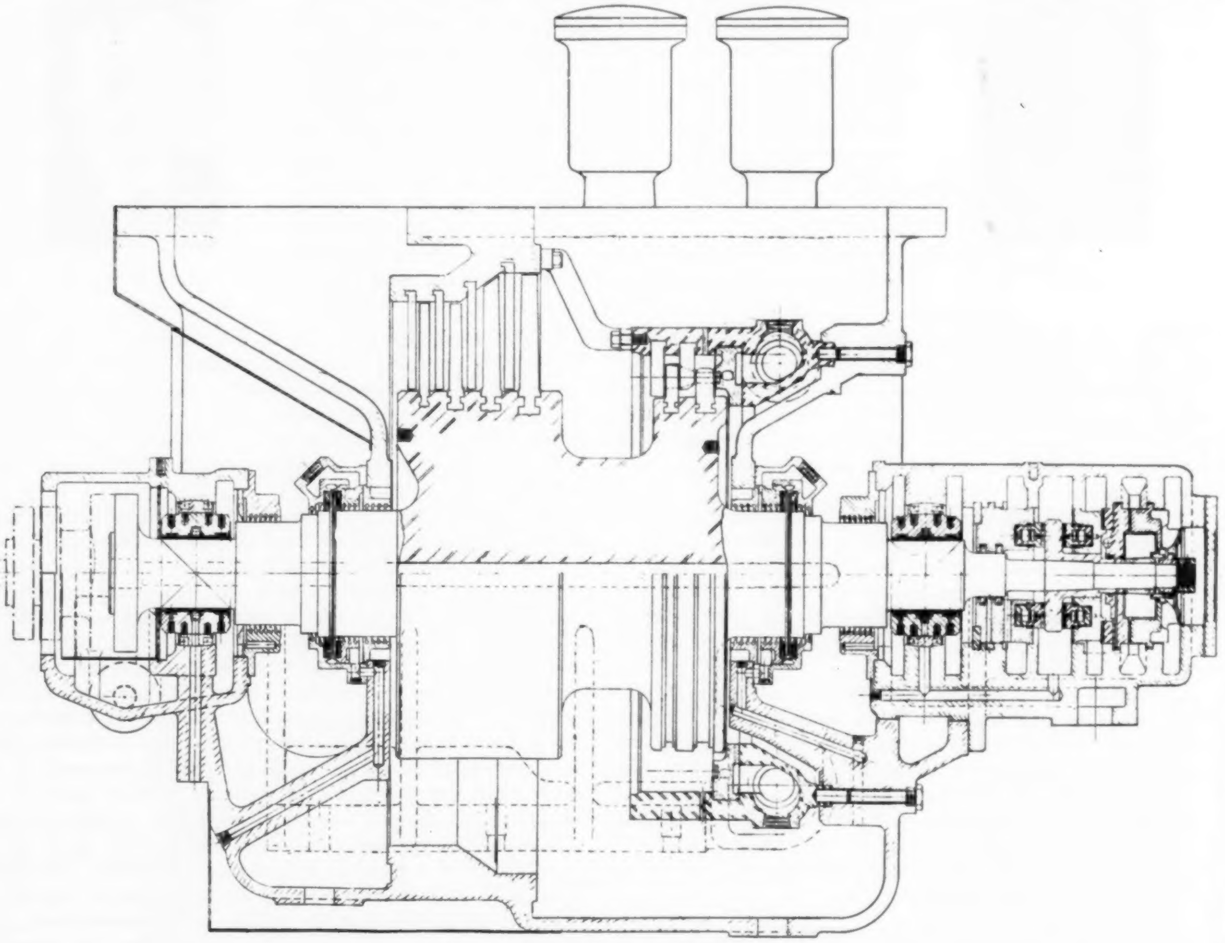

FIG. 1 LOW-PRESSURE TURBINE

The turbine and gear installation in the ship is shown in Fig. 5. The ship has been in service about one year with the spring gear, and the operation is very satisfactory.

HISTORY OF THE SPRING GEAR

As early as 1906 Sir Charles Parsons had taken out patents, not only covering the combination of steam engine and exhaust turbine by means of gearing, but also flexible gears to be used in the unit. He realized that the variable-torque characteristic of the steam engine and the steady-torque characteristic of the turbine necessitated some elastic linkage between the two when used in combination. At full load the steam-engine torque variation may be as much as 60 per cent of the average torque, and this variation may occur several times in one revolution.

This leads to severe bumping in the gears and large impact forces on the gear teeth and housing. Parsons indicated a preference for the flexibility in the high-speed pinion shaft. In 1929 Parsons took out another patent covering the combination of flexibility and friction damping in the first reduction gear wheel. In spite of their early appreciation of the advantages to be gained by the combination of exhaust-turbine and triple-expansion steam engine, the Parsons company equipped its first ship this year.[3] The equipment on the *Kingswood* embodies the flexibility and damping described in the 1929 patent.

The well-known Bauer-Wach engine-exhaust turbine system employs a Föttinger hydraulic coupling between the turbine and the high-speed pinion. The chief purpose of the coupling is to provide a means of disconnecting the turbine from the propeller shaft during maneuvering. Its use involves a loss of 2 to 3 per cent of turbine efficiency in transmission. Incidentally it is supposed to give enough slip to keep the shocks arising from variable torque within safe limits. The main gear in the Bauer-Wach system is connected to the propeller shaft by means of a comparatively flexible quillshaft. The expressed purpose of this shaft is to take care of crankshaft misalignment caused by engine bearing wear.

The Brown Boveri Company has recently designed an exhaust-turbine drive incorporating a flexible, hydraulically damped coupling between the second reduction-gear wheel and the propeller shaft.[4] The slow-speed gear is mounted on the quillshaft, to which the flexible coupling is attached. The coupling is a separate device external to the gear itself. So far the Brown Boveri Company has not made an installation.

In 1929 the Westinghouse Company provided the exhaust turbine and gears, as described, for the *Susan V. Luckenbach.* The second reduction-gear wheel had flexibility introduced into it as shown in Fig. 3. The rim is free to rotate around its center, the connection between the rim and the center being made through tangentially placed coil springs.

Quantitative Design Requirements

While the necessity of flexibility has been recognized extensively, no quantitative discussion of design details ever has been published.

The fundamental requirements demanded of any flexibility introduced into the gear system are:

1 To keep the variation in torque in the gears less than the average torque transmitted by them
2 To keep the variation in torque as small as possible
3 To accomplish the first requirements with safe working stresses in the springs.

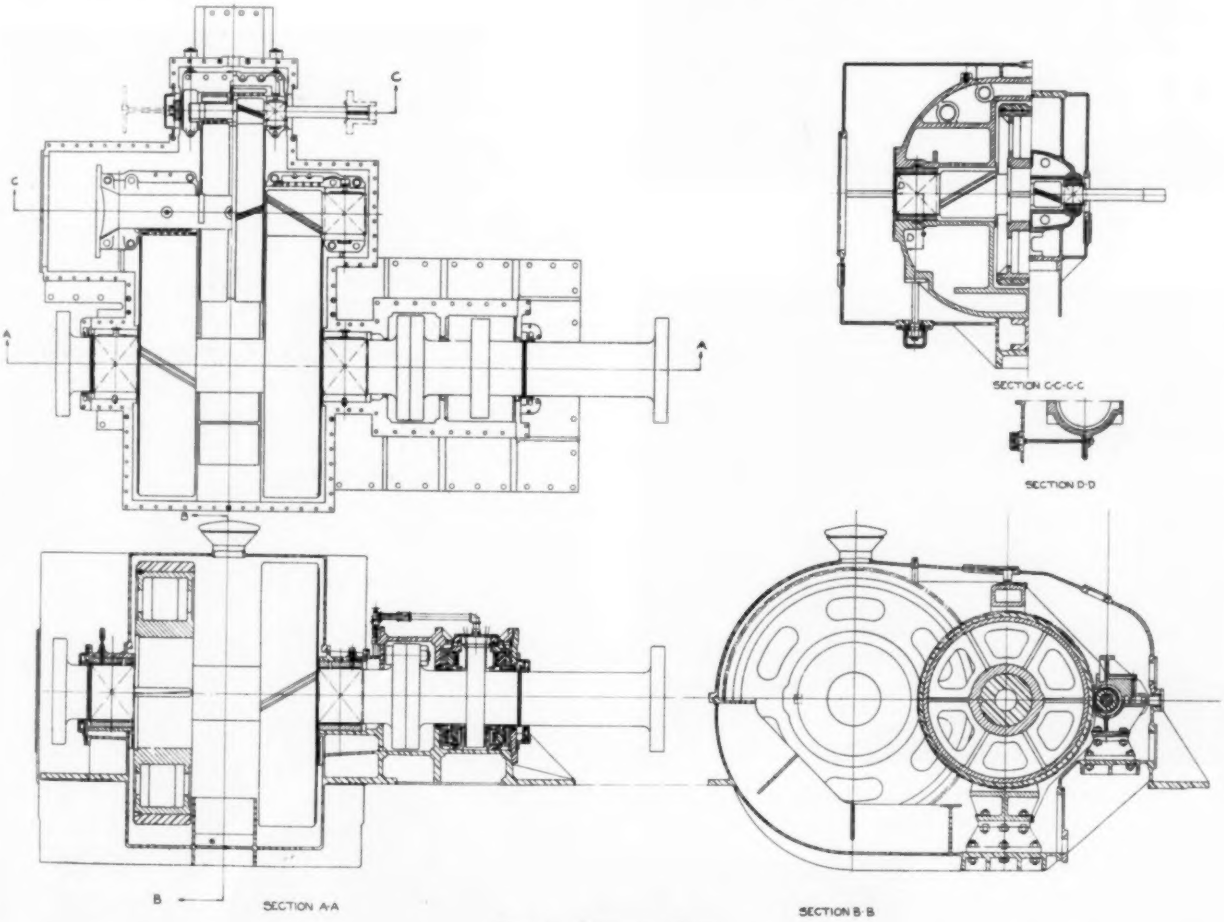

Fig. 2 Original Gear

These conditions can be met by practical flexibilities at the usual running speeds of the engines, but not at very low speed maneuvering. Since, in freight steamers, maneuvering covers such a small percentage of the working time of the engines, the failure to satisfy the fundamental requirements under those conditions is not serious.

The worst variation in torque in the gears will be encountered when the engine-turbine-propeller system is running at a torsional critical speed; therefore, the requirements of the flexibility, stated specifically, are:

4 To keep the variation in torque in the gears less than the average torque transmitted by the gears and as small as possible in the worst torsional critical speed which

---

[4] Brown Boveri Review.

may be encountered in or near the usual running range of the engine.

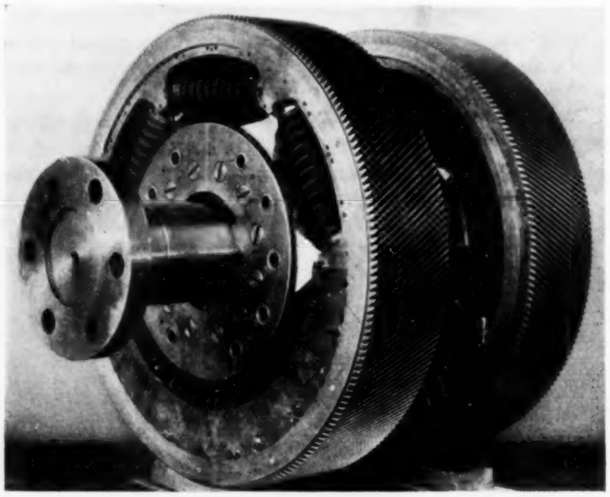

FIG. 3 SECOND REDUCTION SPRING GEAR

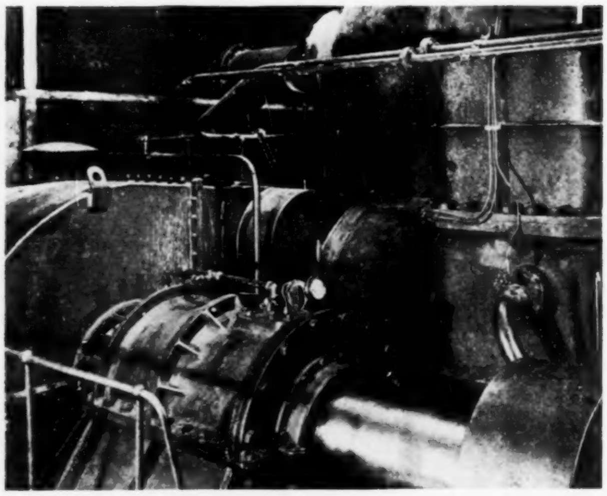

FIG. 5 EXHAUST-TURBINE AND REDUCTION-GEAR INSTALLATION IN SHIP

POSITION OF FLEXIBILITY IN SYSTEM

Before making a study of the torsional critical speeds of the system, it will be well to indicate the reasons for placing the flexibility in the low-speed gear. For practical reasons it was decided to incorporate the flexibility on the gear wheels; the only question to be settled was whether the springs should be in the first reduction gear or the slow-speed gear. With flexibility in the gearing, the turbine mass will not vibrate because of its tremendous inertia and the springs will have deflections corresponding to the vibration of the engine-propeller-shaft system. The conditions which determine the position of the springs are as follows:

1 For a given amplitude of vibration in the crankshaft, the transmitted torque must be the least possible

2 For the same given motion, the stresses in the springs must be the least possible.

Assume that coil springs, tangentially placed, are used at some radius R_2 in the low-speed gear or at R_1 in the first reduction gear. Let the pitch-line radii of the low-speed gear, low-speed pinion, and first reduction gear be r_2, r_3, and r_1, respectively. Let the number of springs used, the diameter of spring wire, mean diameter of spring coil, and number of turns of wire per spring be n, d, D, and N, respectively. Assume that the pro-

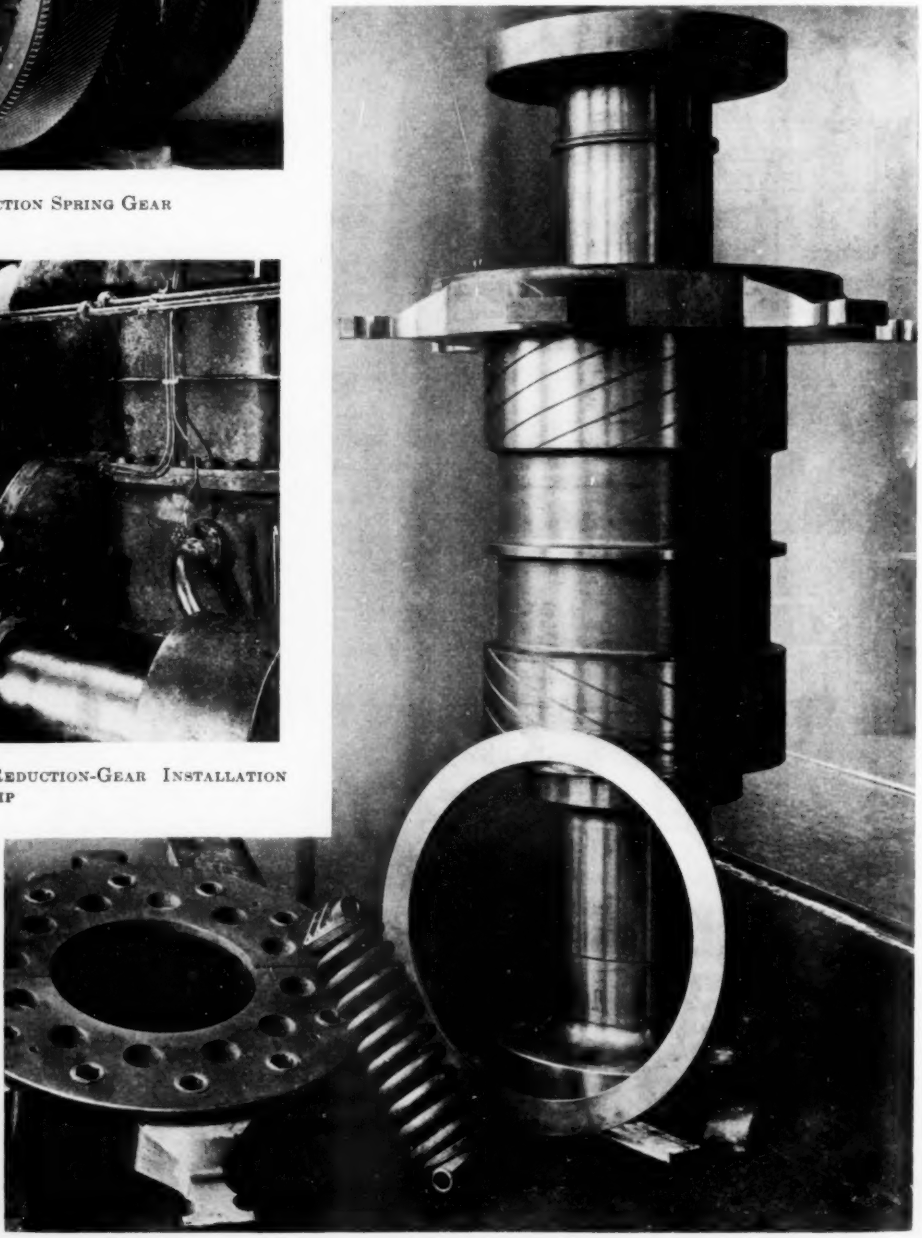

FIG. 4 SPRING-GEAR PARTS

peller shaft moves through an angle α. G is the modulus of elasticity in shear.

For geometrically similar spring systems, the following relations will hold: $n_1 = n_2$; $G_1 = G_2$; $R_1 = \frac{r_1}{r_2} R_2$; $d_1 = \frac{r_1}{r_2} d_2$; $D_1 = \frac{r_1}{r_2} D_2$; $\alpha_1 = \frac{r_2}{r_3} \alpha_2$, where the subscripts 1 and 2 refer to the first and second reduction gears, respectively.

Let T stand for torque transmitted and S stand for the stress arising in the springs for the motion α. Then:

$$T_2 = \frac{n_2 G_2}{8 N_2} \frac{R_2^2 d_2^4}{D_2^3} \alpha_2 \ldots\ldots\ldots\ldots [1]$$

FIG. 6b FLYWHEELS AND SPRING CONSTANTS, ACTUAL SYSTEM

$$T_1 = \frac{r_2}{r_3} \left(\frac{r_1}{r_2} \right)^3 \frac{n_2 G_2}{8 N_2} \frac{R_2^2 d_2^4}{D_2^3} \alpha_2 \ldots\ldots\ldots\ldots [2]$$

or

$$T_1 = \frac{r_2}{r_3} \left(\frac{r_1}{r_2} \right)^3 T_2 \ldots\ldots\ldots\ldots [3]$$

$$S_2 = \frac{G_2}{\pi N_2} \frac{R_2 d_2}{D_2^2} \alpha_2 \ldots\ldots\ldots\ldots [4]$$

$$S_1 = \frac{r_2}{r_3} \frac{G_2}{\pi N_2} \frac{R_2 d_2}{D_2^2} \alpha_2 \ldots\ldots\ldots\ldots [5]$$

$$S_1 = \frac{r_2}{r_3} S_2 \ldots\ldots\ldots\ldots [6]$$

In the gears proposed for the ship, $r_2/r_3 = 5.8$ and $r_1/r_2 = 0.679$; therefore, $T_1 = 1.8\ T_2$ and $S_1 = 5.8\ S_2$.

This indicates clearly that the springs should be placed between the center and the rim of the low-speed gear. All calculations, therefore, are based on springs in this position.

FIG. 6d FLYWHEELS AND SPRING CONSTANTS, SYSTEM REDUCED TO PROPELLER SPEED

TORSIONAL CRITICAL SPEEDS

The method used in calculating the natural frequency of the systems and the relative configuration of the parts of the system at resonance is that of Holzer.[5] The methods of reducing the reciprocating parts and rotating parts including the propeller to equivalent flywheels is well known. These methods also can be found treated in detail.[6]

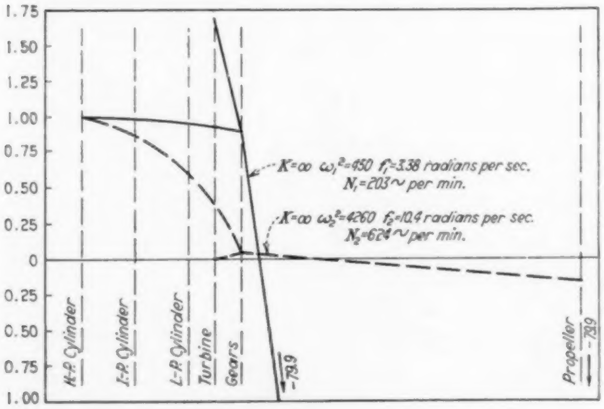

FIG. 7 NORMAL ELASTIC CURVES, NO SPRINGS IN GEARS

Fig. 6*a* shows the equivalent flywheels and spring constants in the original installation without the exhaust turbine, and Fig. 6*b* shows the equivalent flywheels and spring constants of the engine-exhaust turbine-propeller system installed on the *Susan V. Luckenbach*. Fig. 6*c* shows the latter system with all flywheels and springs reduced to equivalent values for rotation at propeller-shaft speed. Fig. 6*d* shows the system with flexibility introduced into the slow-speed gear. All calculations refer to the systems shown in Figs. 6*c* and 6*d*. The first reduction has a gear ratio $n_1 = 7.39$; the second reduction has a gear ratio $n_2 = 5.8$. The overall gear reduction between turbine and gear shaft is $n = 42.8$.

Holzer's numerical method of calculating natural frequencies and normal elastic curves is usually published as applying to systems having all the flywheels on one shaft; while here there is a branched system. The branch contains one flywheel (the turbine rotor), in Fig. 6*c*, and two flywheels, in Fig. 6*d*. However, the system shown in Fig. 6*d* can be considered to have a branch containing one body only when K is small as compared to the torsional stiffness between the turbine and the gearing.

For systems having flywheels in a branch attached to the main-line system by a flexibility, the principle which permits the use of Holzer's method is as follows:

In cases of branched systems the end of the branch spring which is attached to the main system must have the same amplitude as the main system at that point.

For the motion at the point where the branch system is attached to the main system, the amplitude of torsional vibration at resonance is α_4 (using the amplitude of the high-pressure cylinder flywheel as α_1), and the unknown amplitude of the branch flywheel is α_b. The maximum inertia torque of the branch flywheel is $I_b\alpha_b\omega^2$, where ω^2 is the trial value chosen for the particular calculation at hand. The twist in the branch-system spring to balance this inertia torque is $I_b\alpha_b\omega^2/K_b$. Therefore, the following relationship must exist according to the principle enunciated:

$$\alpha_b - \frac{I_b}{K_b}\omega^2\alpha_b = \alpha_4 \quad [7]$$

or

$$\alpha_b = \frac{\alpha_4}{1 - \dfrac{\omega^2}{\omega_b^2}} \quad [8]$$

where

$$\omega_b^2 = \frac{K_b}{I_b} \quad [9]$$

Equation [8] gives α_b its proper magnitude and sign.

Table 1 shows the calculations of the single-noded vibration of the engine and propeller without the exhaust turbine, the single- and two-noded vibrations of the engine-exhaust turbine-propeller system with no flexibility, and the single- and two-noded vibration of the engine-exhaust turbine-propeller system with $K = 16 \times 10^6$. The calculated values of ω^2 are higher than the actual, since damping, neglected flexibilities, and clearances in the system all tend to lower the natural frequencies.

Fig. 7 shows the normal elastic curves for the first and second modes of motion of the system without springs in the gears. Fig. 8 shows the elastic curves for the same system with values of $K = 0$, 16×10^6, 100×10^6, 300×10^6. Only the second mode of motion is shown for all values of K except $K = 16 \times 10^6$, for which both the first and second modes of motion are shown.

Considering the propeller as the chief source of damping in the system, Fig. 7 indicates that the first mode of motion will never appear in an actual installation without springs in the gears. Any violent bumping in the gear teeth must be caused in this case by the second mode of motion, where the propeller damping is very small. Assuming the propeller damping to be proportional to the velocity of the vibration, the energy absorption is proportional to the square of the amplitude. The ratio of energy absorption in the first and second modes is of the order of 300,000 ÷ 1, or even approaching 1,000,000 ÷ 1; for vibration energy inputs of the same order of magnitude. Fig. 8 indicates, on the same basis of reasoning, that the first mode of motion will not be the most troublesome, since the propeller damping in the first mode is about four times as effective as in the second mode of motion when flexibility exists in the gears.

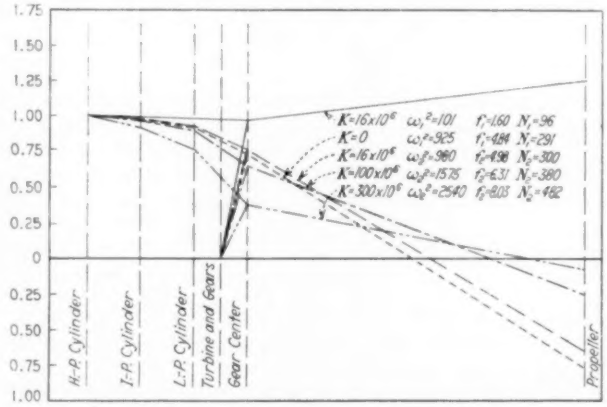

FIG. 8 NORMAL ELASTIC CURVES, SPRINGS IN GEARS

The figures in the fifth row, fourth column, of the last four sections of Table 1 indicate the torque transmitted to the gearing by the vibration per radian amplitude at the high-pressure cylinder. Fig. 9 shows the relationship between the value of the spring constant K and the vibration torque transmitted to the gearing per radian amplitude at the high-pressure cylinder. This curve clearly indicates that the springs should be made as flexible as possible—a conclusion which seems obvious. Fig. 8 leads to the same conclusion, as it shows the propeller amplitude to approach a maximum value as K decreases, indicating an increase in propeller damping as the flexibility increases.

ACTUAL AMPLITUDES AT RESONANCE

The procedure of design based on the conclusions drawn is to make a spring system with nominal load (maximum turbine torque) stresses as high as consistent with known properties of the spring steel used. This gives a first trial spring constant K, which in turn permits the natural frequencies and the normal elastic curve to be calculated. The next step is to calculate approximately the actual amplitudes at the worst critical speed in the running range. This can be done on the assumption that the propeller supplies all the damping. This assumption not only makes the calculation easier, but it is on the safe side, since all the damping arising from hysteresis on the twisted elements and other causes will make the actual amplitude smaller than calculated.

The vibration is caused by the harmonic torques arising from the varying steam pressure in the cylinder and the inertia and weight effects of the reciprocating parts. The harmonic torques caused by weight and inertia can be calculable from the steam-engine dimensions and materials. The harmonic steam torques can be estimated from theoretical indicator cards or, if it is a case of rejuvenating an old ship, from actual engine indicator cards taken before the turbine is applied. The cards will be somewhat different before and after the application of the turbine, but for approximate calculations they will be sufficiently similar.

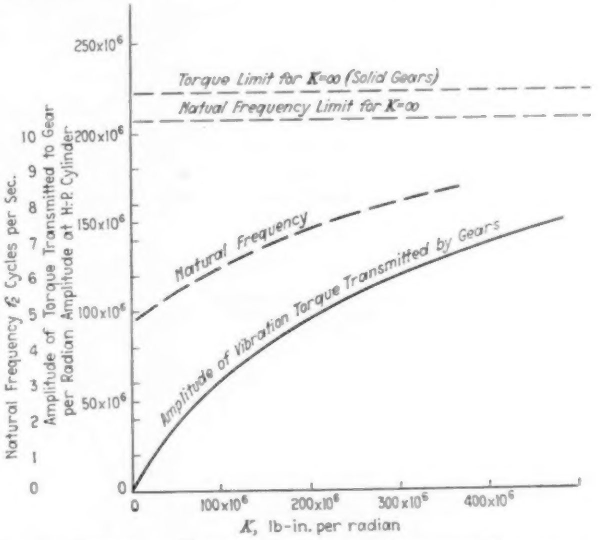

FIG. 9 EFFECT OF VARIOUS SPRINGS ON VIBRATION TORQUE AND NATURAL FREQUENCY

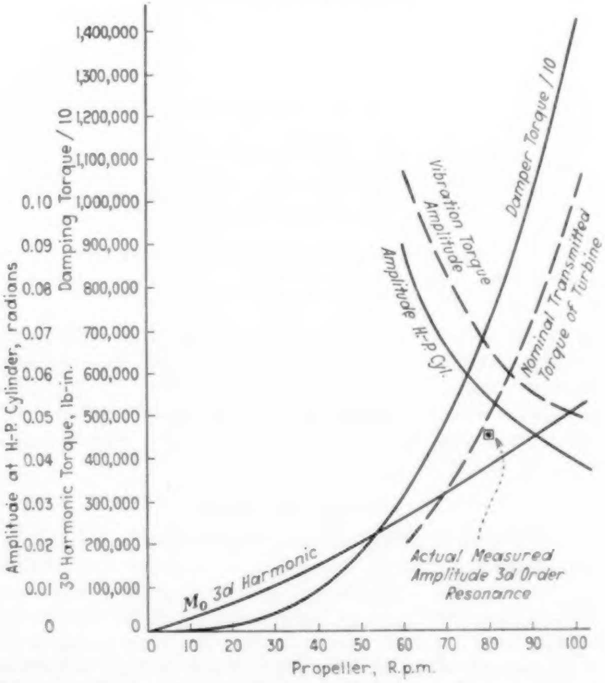

FIG. 10 GRAPHIC CALCULATION OF VIBRATION AMPLITUDE AND TORQUE

For calculation purposes we will use $K = 16 \times 10^6$. From Table 1 the natural frequency of the second mode of motion with $K = 16 \times 10^6$ lb-in. per radian is 5 cycles per sec. or 300 cycles per min. Under this condition the speeds at which resonance may occur are given in Table 2.

TABLE 2

Harmonic	Resonance speed, r.p.m.
1	300
2	150
3	100
4	75
5	60
6	50

In any triple steam engine the first three harmonics will have large amplitudes, while the others will be small. Since the engines of the *Susan V. Luckenbach* operated between 70 and 90 r.p.m., the first two harmonics were not to be feared, even if the calculated critical speed were too high. But the third harmonic might actually occur in the running range. The analysis of several indicator cards taken on the original triple-expansion engine gives the amplitude of the third harmonic as shown in Fig. 10.

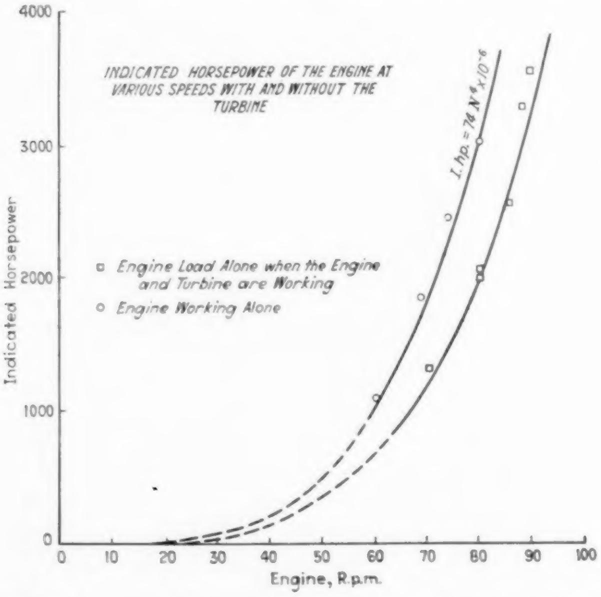

FIG. 11 INDICATED HORSEPOWER VERSUS PROPELLER REVOLUTIONS PER MINUTE
(For steamship *Susan V. Luckenbach*.)

PROPELLER DAMPING

The analysis of several published curves showing the relationship between indicated horsepower and propeller revolutions per minute with three-bladed propellers on battleships and cruisers shows that the i.hp. varies as the r.p.m. raised to powers varying from 3 to 3.75. On a slow-speed freighter, such as the ship equipped, where the lines of the ship are not as fine as those of a cruiser or battleship and a four-bladed propeller is used, the i.hp. probably varies nearly as the fourth power of the r.p.m. Analysis of the curves shown in Fig. 11 shows this assumption to be correct. This ship was known to turn 77 r.p.m. with 2600 i.hp. before the turbines were added.

$$H = KN^4 \quad \text{[10]}$$

$$K = \frac{2600}{(77)^4} = 74 \times 10^{-6} \quad \text{[11]}$$

where

H = indicated horsepower
N = propeller revolutions per minute.

The shaft horsepower H_1 is then

$$H_1 = \eta KN^4 \quad \text{[12]}$$

where η is the mechanical efficiency of the driving engine.

For small vibrations the damping will be a linear function of the vibratory velocity, and the relationship between the damping constant and propeller r.p.m. can be obtained from the H-N curves in Fig. 11.

$$C = \frac{dT}{d\omega} \quad \text{[13]}$$

where

T = shaft torque
ω = angular velocity of propeller
C = damping constant

$$T = \frac{33{,}000 \times 12 \times \eta KN^4}{2\pi N} \quad \text{[14]}$$

$$\omega = \frac{2\pi N}{60} \qquad N = \frac{60}{2\pi}\omega \quad \text{[15]}$$

$$T = \frac{33{,}000 \times 12}{2\pi}\left(\frac{60}{2\pi}\right)^3 \eta K\omega^3 \quad \text{[16]}$$

$$\frac{dT}{d\omega} = 3 \cdot \frac{33{,}000 \times 12}{2\pi}\left(\frac{60}{2\pi}\right)^3 \eta K\omega^2 \quad \text{[17]}$$

$$C = 3 \cdot \frac{33{,}000 \times 12}{2\pi}\left(\frac{60}{2\pi}\right) \eta KN^2 \quad \text{[18]}$$

$$C = 1{,}808{,}000 \ \eta KN^2 \quad \text{[19]}$$

For the combination of the engine and turbine the overall mechanical efficiency is about 81 per cent. Therefore:

$$C = 1.808 \times 10^6 \times 0.81 \times 74 \times 10^{-6} N^2 = 108.5 \ N^2 \ \text{lb-in. per radian per second} \quad \text{[20]}$$

ENERGY METHOD OF CALCULATING AMPLITUDE

The amplitude can now be calculated by equating the energy put into the vibration by the harmonic torque to the energy dissipated by damping.

The energy input per cycle of motion, assuming a motion

$$\alpha = \alpha_1 \sin \omega t \quad \text{[21]}$$

and a harmonic exciting torque

$$M = M_o \sin (\omega t + \varphi) \quad \text{[22]}$$

is

$$W/\sim \ = \pi M_o \alpha_1 \sin \varphi \quad \text{[23]}$$

At resonance $\varphi = 90$ deg., so that the input is:

$$W = \pi \ M_o \alpha_1 \quad \text{[24]}$$

The energy output per cycle of a sinusoidally vibrating body acted upon by a linear damping is

$$W_2 = C \int^{\frac{2\pi}{\omega}} \left(\frac{d\alpha}{dt}\right)^2 dt = \pi C\beta^2\alpha^2{}_1\omega_c \quad \text{[25]}$$

where

α_1 = amplitude at the high-pressure cylinder
α_p = amplitude at the propeller
β = α_p/α_1
ω_c = angular velocity of vibration at resonance.

TABLE 3

	Without springs		With $K = 16 \times 10^6$ lb-in. per radian			
	Calculated	Measured	Calculated at 80	Measured	Calculated at 60	Measured
Order	6	6	3	3	4	4
R.p.m.	104	74	100	80	75	60
Amplitude at high-pressure cylinder radian	...	0.0115	0.053	0.043	0.02	0.008
Amplitude T_v lb-in.	...	2.55×10^6	0.654×10^6	0.523×10^6	0.243×10^6	0.097×10^6
Amplitude T_t lb-in.	...	0.43×10^6	0.512×10^6	0.512×10^6	0.230×10^6	0.230×10^6
Ratio T_v/T_t	...	6	1.26	1.02	1.06	0.42

Equating W_1 and W_2, the amplitude α_1 is:

$$\alpha_1 = \frac{M_o}{\beta^2 C\omega_e} \qquad [26]$$

For resonance with the third harmonic the vibration has a frequency of $3N$ cycles per minute; therefore,

$$\omega_e = 2\pi \frac{3N}{60} = \frac{\pi}{10} N \text{ radians per sec} \qquad [27]$$

Assuming that β remains constant, even when the critical speed varies $\beta = 0.64$ and $\beta^2 = 0.41$, from Table 1, the last figure in the fifth column.

$$\beta^2 C\omega_e = \beta^2 \times 108.5\ N^2 \times \frac{\pi}{10} N = 14\ N^3 \qquad [28]$$

Fig. 10 shows the plotted points of the third harmonic torque taken from analysis of steam pressure, weight, and inertia torques on the triple-expansion engine originally in the ship and the damping torque, both as functions of r.p.m. From Fig. 9 the torque transmitted by the vibration is:

$$T_v = \frac{12.17 \times 10^6\ M_o}{\beta^2 C\omega} \qquad [29]$$

By dividing the corresponding values of the input and output curves, T_v is obtained and plotted. The turbine torque T_t is plotted on Fig. 10, based on the assumption that the turbine puts out one-third of the indicated horsepower at an efficiency of about 70 per cent.

$$T_t = \frac{0.33 \times 0.70 \times 74 \times 10^{-6} N^4 \times 33000 \times 12}{2\pi N} = 1.07\ N^3 \qquad [30]$$

T_v and T_t cross at 83 r.p.m. Actually other damping will make them cross at some lower speed. That is to say, if the third order critical speed occurs at any speed above 80, the first condition for a spring drive will be satisfied.

TEST RESULTS

Torsiograms were taken on the installation in the ship without and with springs in the low-speed gear. The results are given in Table 3.

The calculated T_v/T_t at 100 r.p.m. for the third order vibration was 0.5 and the calculated T_v/T_t at 75 r.p.m. for the fourth order vibration is 0.36.

Without the springs the unit was practically inoperative because of the violent and dangerous impacts in the gear unit. With the springs the unit is safely operative and has made voyages totaling a distance close to 75,000 miles since installation. There is a slight bump at 80 r.p.m., as the measurements indicate there should be; but the ship operates most of the time between 85 and 89 r.p.m., where the gears remain completely in contact in one direction. The improvement made by the spring gear in T_v/T_t is 6 to 1, as shown by measurement. The improvement was even greater than this, since the effects of other harmonics beside the sixth were neglected in computing the vibration torque in the gear without springs.

The unit could be improved in two ways:

1 By decreasing K to some value less than 16×10^6 lb-in. per radian, the slight bump at 80 r.p.m. could be completely removed

2 By adding some definite friction or hydraulic damping to the spring gear.

The cheaper and simpler solution is to depend on propeller damping and to omit artificial damping from the gear wheel, as was done in this installation.

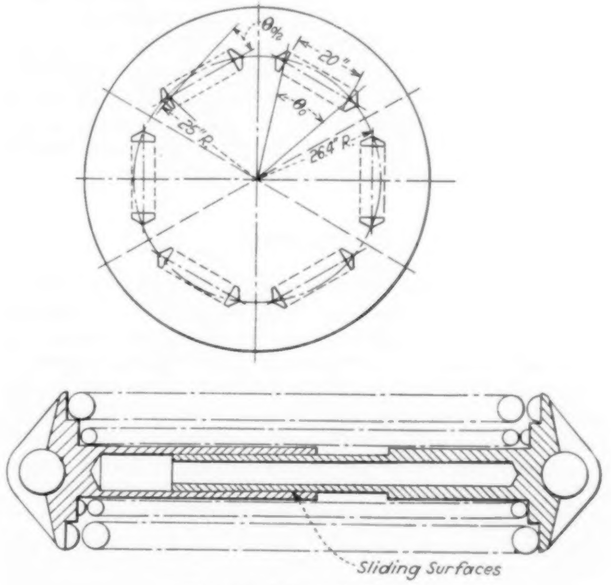

FIG. 12 SPRING DETAILS

	Outer spring coil	Inner spring coil
Diameter of wire, in.	$1^1/_4$	$^{11}/_{16}$
Mean diameter of coil, in.	$5^1/_2$	3

Actual max. stress per in. defl., lb. per sq. in.	17,500	18,150

SPRING-DESIGN DETAILS

Twelve springs, six on each side of the low-speed gear, were used. The details are shown in Fig. 12. The entire gear was made as a large type C Nuttall coupling, as shown in Fig. 3. The torsional spring constant of the spring system shown in Fig. 12 is:

$$K_1 = nKR^2 \cos^2 \left(\frac{\theta_0 - \theta}{2}\right) \text{ lb-in. per radian} \qquad [31]$$

With $\theta_0 = 44.5$ deg., the average value of K_1 for deflection θ up to 0.1 radian is:

$$K_1 = 0.875\ nKR^2 \qquad [32]$$

where

n = number springs
K = linear spring of each nest of springs
R = radius to center line of spring at the end of the spring.

Since $n = 12$, $K = 2355$ lb-in., and $R = 25$ in., $K_1 = 16 \times 10^6$ lb-in. per radian. At 80 r.p.m. the deflection of the spring gear caused by the turbine torque is 0.035 radian; the amplitude of vibration is also equal to 0.035 radian (at the gear), giving a total maximum deflection of 0.07 radian (1.65 in spring deflection), which corresponds to a maximum stress of about 32,000 lb. per sq. in. in each spring. This stress is the true maximum stress at the outer fiber on the inside of the coil. It is composed of static stress of 16,000 lb. per sq. in. and a variable stress which has an amplitude of 16,000 lb. per sq. in. These stresses are very conservative for the spring steel used.

The spring stops limit the maximum travel to 3 in., with a corresponding maximum stress of 53,500 lb. per sq. in.

CONCLUSION

It has been shown that it is possible to predict the suitability of any chosen gear flexibility if the drawings of the rotating parts for calculating the critical speeds and indicator cards (theoretical or actual) at two or three speeds are available.

The calculation made in designing the springs for the ship installation were in some error because the natural frequencies were calculated too high by some 20 per cent. This can be attributed to lack of experience in calculating such marine installations, and in nowise vitiates the value of the method to those practiced in the art of calculating such things.

Discussion

Hans Bauer.[7] For purposes of discussion this paper may be considered under two headings: first, the application of exhaust turbines in reciprocating-engined steamships, and second, the mathematical theory of oscillations in elastic rotating systems.

Concerning the first classification, the writer is able to offer observations based upon the successful operation of over 200 vessels equipped with exhaust turbines constructed according to the Bauer-Wach system and aggregating approximately 1,000,000 hp. In that system, two single-reduction gears are connected by a Vulcan hydraulic coupling, the latter being interposed between the high-speed gear shaft and the low-speed pinion shaft. The hydraulic coupling serves both to absorb shocks and vibration and as a clutch to disconnect the turbine and high-speed gear from the engine and low-speed gear when maneuvering, or at other times when it is desired to run on the engine alone.

Reversing is best performed when the exhaust turbine is disconnected, since it is practically impossible to synchronize the admission of steam to turbine and reciprocator as required for maneuvering, quite apart from the complicated design that it necessitates. Therefore, if the turbine is kept continually coupled to the engine, the gear teeth and the whole system are repeatedly subjected to reversal of stresses of unknown magnitudes. It may be claimed that this can be overcome by using the turbine alone when maneuvering. To do so, however, restricts the maneuvering power to that available from the turbine, and there are still torque variations due to dragging the engine. The much simpler method is to disconnect the turbine and use the engine for maneuvering.

That the hydraulic coupling provides complete protection of the turbine and gear system against torsional shocks or vibrations originating in the engine and propeller system may be seen from torsiographs which have been published from time to time. This result is considered ample justification for a slippage which, be it noted, constitutes about one-half of 1 per cent of the total power.

To introduce springs into an oscillating system is to invite trouble from vibration. By proper proportioning of one to the other the period may be controlled, but the tendency to oscillate remains and will be felt at some frequency. The authors admit that it is impossible to design a spring coupling to damp out torsional vibrations at all speeds, and they should not be satisfied if they have succeeded in doing this in or near the usual running range of the engine, since, as all marine engineers know, a marine engine may be called upon to run at any speed up to the maximum, according to weather conditions, load, etc., and if torsional vibration occur even for only a short period, it may be detrimental to the gearing. Conditions in an oscillating system like the above linked by a flexible and elastic member will be much more difficult to determine, and almost impossible to control, if the propeller is momentarily lifted out of the water in a seaway.

It is not quite clear what the authors mean by "propeller damping." The degree of propeller damping must necessarily be different under different draft and weather conditions. The propeller cannot prevent resonance as between the turbine system and the engine system. Springs interposed between the two systems obviate the extreme stresses due to short-period oscillations, but are not effective—in fact, they constitute a source of danger when the frequency of the impressed forces approaches the natural frequency of oscillation of the spring-coupled system.

A hydraulic coupling, on the other hand, not being elastic, does not transmit any torsional oscillations.

The authors are to be commended for having gathered and analyzed mathematical researches relating to torsional vibration and the design of spring couplings. To criticize a detail, however, it does not seem advisable to the writer to base designs on stresses as high as 32,000 lb. per sq. in. in spring steel, since the springs may at times be compressed to the maximum travel when, as stated by the authors, the stress would be raised to 52,500 lb. per sq. in. This may occur frequently, as, for example, with a racing propeller in rough weather, or, again, in maneuvering.

R. Eksergian.[8] The authors are to be congratulated on an excellent technical investigation of a complicated problem. An outstanding feature of the presentation is the clearness in picturing the phenomena with skilful approximations.

The normal elastic curves in Fig. 8 show very clearly the advantage of elasticity at the coupling in producing large amplitudes for the propeller damping, which, from Equation [26], shows corresponding reduction in the amplitude of vibration caused by a given disturbing moment.

The writer has been further impressed with the advantage of reducing the elasticities and inertias to a common shaft coordinate. In this way a much clearer picture of the relative inertias and elasticities of the system is obtained. The turbine rotor of only 2120 lb-in.-sec.^{2} polar moment of inertia when reduced to the propeller-shaft coordinate and thereby increased by the square of the products of the gear ratio becomes 3,900,000 lb-in.-sec.^{2} Thus the turbine becomes practically the pivot point of the system. Likewise the turbine spindle, which is fairly flexible in itself, becomes extremely stiff when multiplied by the square of the products of the gear ratio and reduced to the propeller shaft.

The authors' analysis for thus placing the flexibility in the main gear is very interesting. The ratios stated for geometrical spring systems appear obvious except the last one. A little consideration, however, will show that $\alpha_1 = (r_2/r_3)\alpha_2$ is correct if the amplitude at the propeller-shaft junction is to remain the same. We have the two cases shown by Fig. 13.

If the amplitudes α_D at the junction of the propeller shaft remain the same for the two cases, then, with the assumption of the negligible amplitude of the reduced turbine mass due to its enormous value, the authors show that on the basis of a geometrical-similarity comparison, the stresses and torques transmitted are considerably increased when the spring system is placed in the high-speed gear. On the other hand, referring to Fig. 8, the amplitudes at the propeller-shaft junction on the basis of unit amplitude at the engine decrease with increased stiffness of the spring system. But the decreased amplitude at the propeller, however, for the stiffer spring system may result because of the consequent decreased damping at resonance, in possibly larger actual amplitudes for the system under the exerting engine torque. Therefore α_D for the stiffer spring, as in Case 1, may be further augmented as compared with α_D in Case II, which would appear even more to favor the authors' conclusions.

---

[7] 11 Broadway, New York, N. Y.

[8] Consultant, Eng. Dept., E. I. du Pont de Nemours & Co. Wilmington, Del. Mem. A.S.M.E.

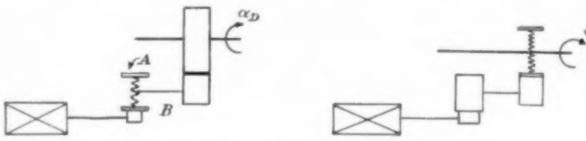

FIG. 13

CASE I

$$\alpha_D = \alpha_c$$
$$\alpha_c r_2 = \alpha_B r_3$$
$$\alpha_B - \alpha_4 = \alpha_1$$
$$\text{If } \alpha_4 = 0,\ \alpha_B = \alpha_1$$
$$\therefore\ \alpha_D = \alpha_1 \frac{r_3}{r_2}$$

CASE II

$$\alpha_D - \alpha_c = \alpha_2$$
$$\alpha_c r_2 = \alpha_B r_3$$
$$\alpha_B = \alpha_4 = 0$$
$$\text{If } \alpha_c = 0,\ \alpha_D = \alpha_2$$
$$\therefore\ \alpha_2 = \alpha_1 \frac{r_3}{r_2}$$

Another point of view in addition to the authors' proof of a condition of inherent high stresses, etc. in the secondary gear is on the basis of the dynamics of the system by a comparison of the elastic constants of the springs for the two cases.

If T is the torque transmitted and ϕ the corresponding relative angular displacement between the spider and gear rim, then the elastic or spring constant is

$$K = \frac{T}{\phi} = \frac{nPR}{\dfrac{8NPD^3}{d^4GR}} = \frac{nR^2d^4G}{8nD^3}$$

Using the authors' geometrical-similarity assumption and noting that the reduced spring constant of the secondary gear is $K_1' = K_1\,(r_2/r_3)^2$, we have the ratio of the elastic constants

$$\frac{K_1'}{K_2} = \frac{n_1R_1^2d_1^4G_1}{8N_1D_1^3}\left(\frac{r_2}{r_3}\right)^2 \Bigg/ \frac{n_2R_2^2d_2^4G_2}{8N_2D_2^3} = \left(\frac{r_1}{r_2}\right)^3\left(\frac{r_2}{r_3}\right)^2$$

The greater the flexibility, the *smaller* the spring constant; therefore, if the ratio C_1'/C_2 is greater than unity, the greatest flexibility is obtained by placing the springs in the primary or low-speed gear. If, on the other hand, the factor $(r_2/r_1)^3 > (r_2/r_3)^2$, the greatest flexibility is obtained in the secondary gear. For this latter condition to be realized, assuming the gear ratio $r_2/r_3 = 5.8$, then $r_1/r_2 < 0.31$, which from constructional limitations alone it is impossible to obtain. With the practical value of $r_1/r_2 = 0.679$, the ratio of the spring constants is $K'_1/K_2 = 10.5$. This shows, when considering the flexibilities of the system, the considerable advantage in placing the springs in the low-speed gear.

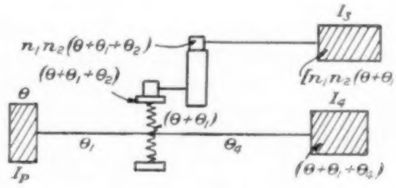
The actual torques transmitted for the two cases are: $K_2\,\alpha_{D2}$ with spring in low-speed gear, and $K_1\,(r_2/r_3)\,\alpha_D$ with spring in high-speed gear. Hence the torques transmitted for the two cases are

$$\frac{T_1}{T_2} = \frac{K_1\left(\dfrac{r_2}{r_3}\right)\alpha_{D1}}{K_2\alpha_{D2}} = \frac{\left[K'_1\Big/\left(\dfrac{r_2}{r_3}\right)^2\right]\dfrac{r_2}{r_3}\,\alpha_{D1}}{K_2\alpha_{D2}} = \left(\frac{r_1}{r_2}\right)^3\frac{r_2}{r_3}$$

which agrees with the author's conclusions, provided $\alpha_{D1} = \alpha_{D2}$.

In estimating the modes of oscillation corresponding to the natural frequencies of the system, the authors have shown that the problem is concerned with the second mode of oscillation. The reduced dynamical system shown in Fig. 6 has five degrees of freedom, and by using the Holzer method the two lower frequencies can be accurately estimated by trial solutions.

By further combinations of the inertias and elasticities we can reduce the system to one of two degrees of freedom, which would be in fair agreement with the first mode and approximately accurate for the second mode when compared with the system of five degrees of freedom. Such a resolution, however, may be of interest.



I_3
$n_1n_2(\theta+\theta_1+\theta_2)$
$(\theta+\theta_1+\theta_2)$
$[n_1n_2(\theta+\theta_1+\theta_2)+\phi_3]$
θ
I_4
$(\theta+\theta_1)$
θ_1
θ_4
I_p
$(\theta+\theta_1+\theta_4)$

FIG. 14

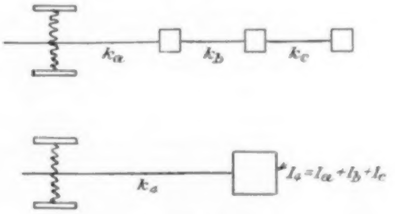


FIG. 15

The approximate two-degree system is shown in Fig. 14. The inertias of the gearing when reduced to the line shaft are small compared with the inertia of the turbine. Therefore they may be neglected or added to the turbine inertia I_3. The inertia of the propeller is I_p, and that of the engine, I_4.

To approximate the elastic constant of the engine shaft to the gearing, if k_a, k_b, and k_c are the elastic constants shown in Fig. 15 between the gearing and engine masses I_a, I_b, and I_c,

$$\frac{1}{k_4} = \frac{\dfrac{I_a}{k_a} + \left(\dfrac{1}{k_a} + \dfrac{1}{k_b}\right)I_b + \left(\dfrac{1}{k_a} + \dfrac{1}{k_b} + \dfrac{1}{k_c}\right)I_c}{I_a + I_b + I_c}$$

Now considering the system shown in Fig. 14, we have for the kinetic and potential energies,

$$T = {}^1/_2\, I_p\theta'^2 + {}^1/_2\, I_3\,(n_1n_2(\theta' + \theta_1' + \theta_2') + \phi_3')^2 + {}^1/_2\, I_4\,(\theta' + \theta_1' + \theta_4')^2$$

$$V = {}^1/_2\, k_1\theta_1^2 + {}^1/_2\, k_2\theta_2^2 + {}^1/_2\, k_3\phi_3^2 + {}^1/_2\, k_4\theta_4^2$$

where θ' and ϕ' are the first derivatives of θ and ϕ with respect to time.

The momentum corresponding to the coordinate θ is a constant, which we may take equal to zero, i.e.,

$$I_p\theta' + I_3\,(n_1n_2\,(\theta' + \theta_1' + \theta'_2) + \phi_3')n_1n_2 + I_4\,(\theta' + \theta'_1 + \theta'_4) = \theta$$

from which we can eliminate the coordinate θ in the expression of the kinetic energy. Or we may differentiate directly, so that,

$$(I_p + (n_1n_2)^2\,I_3 + I_4)\theta'' = -\,n_1n_2I_3(n_1n_2(\theta_1'' + \theta_2'') + \phi_3'') - I_4\,(\theta_1'' + \theta_4'')\ldots\ldots[33]$$

from which we can express the second derivative ϕ'' in terms of θ_1'', θ_2'', θ_4'', and θ_3''.

The equations of motion corresponding to the coordinates θ_2 and θ_3 are,

$$\frac{d}{dt}\left(\frac{\theta T}{\partial \theta'_2}\right) = n_1n_2I_3\,[n_1n_2(\theta'' + \theta_1'' + \theta_2'') + \phi_3''] = -k_2\theta_2 \quad [34]$$

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \phi_3'}\right) = I_3\,[n_1n_2(\theta'' + \theta_1'' + \theta_2'') + \phi_3''] = -k_3\phi_3 \quad [35]$$

which, on combining, give

$$k_2\theta_2 = n_1n_2k_3\phi_3, \qquad \therefore\ \theta_2 = \frac{n_1n_2k_3}{k_2}\phi_3$$

that is, the torque of the elastic gear balances the reduced inertia torque of the turbine shaft. This provides additional elimination of the coordinates.

The two remaining equations are,

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \theta_1'}\right) = nn_2I_3\,[n_1n_2(\theta'' + \theta_1'' + \theta_2'') + \phi_3''] + I_4\,(\theta'' + \theta_1'' + \theta_4'') = -k_1\theta_1 \quad [36]$$

$$\frac{d}{dt}\left(\frac{\partial T}{\partial \theta'_4}\right) = I_4\,(\theta'' + \theta_1'' + \theta_4'') = -k_4\theta_4 \quad [37]$$

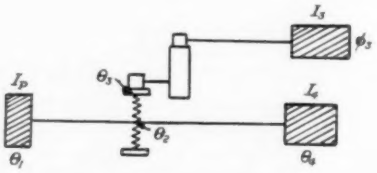

FIG. 16

Combining [34] and [37] with [36], we note that

$$k_1\theta_1 = k_2\theta_2 + k_4\theta_4$$

which we should anticipate immediately from the condition of equilibrium at the coupling. Therefore

$$\theta_1 = \frac{k_2}{k_1}\theta_2 + \frac{k_4}{k_1}\theta_4 = n_1n_2\frac{k_3}{k_1}\phi_3 + \frac{k_4}{k_1}\theta_4$$

On substituting the values of θ_1'' and θ_2'' in terms of ϕ_3'' and θ_4'' in [33], we have

$$\theta'' = -A\phi_3'' - B\theta_4''$$

where

$$A = \frac{n_1n_2\left[\left((n_1n_2)^2\left(\frac{k_3}{k_1} + \frac{k_3}{k_2}\right) + 1\right)I_3 + \frac{k_3}{k_1}I_4\right]}{I_p + (n_1n_2)^2 I_3 + I_4}$$

$$B = \frac{(n_1n_2)^2\frac{k_4}{k_1}I_3 + \left(1 + \frac{k_4}{k_1}\right)I_4}{I_p + (n_1n_2)^2 I_3 + I_4}$$

Substituting the values of θ'', θ_1'', and θ_2'' in terms of ϕ_3'' and θ_4'' in Equations [35] and [37], we obtain

$$\left[1 + (n_1n_2)^2\left(\frac{k_3}{k_2} + \frac{k_3}{k_1}\right) - n_1n_2A\right]I_3\phi_3'' + n_1n_2\left(\frac{k_4}{k_1} - B\right)I_3\theta_4'' + k_3\phi_3 = 0$$

$$\left(n_1n_2\frac{k_3}{k_1} - A\right)I_4\phi_3'' + \left(1 + \frac{k_4}{k_1} - B\right)I_4\theta_4'' + k_4\theta_4 = 0$$

The frequencies are obtained from the solution of the determinate

$$\begin{vmatrix} k_3 - \omega^2\left[1 + (n_1n_2)^2\left(\frac{k_3}{k_2} + \frac{k_3}{k_1}\right) - n_1n_2A\right]I_3, & -\omega^2 n_1n_2\left(\frac{k_4}{k_1} - B\right)I_3, \\ -\omega^2\left(n_1n_2\frac{k_3}{k_1} - A\right)I_4, & k_4 - \omega^2\left(1 + \frac{k_4}{k_1} - B\right)I_4 \end{vmatrix} = 0$$

On substituting for the numerical values given by the authors for the actual installation, a good check is found with the frequency values obtained by them. A closer approximation would be obtained by including the inertias of the gearing with an additional degree of freedom.

The determinate, however, is of use for comparing different spring constants and in approximating the frequencies for similar installations.

In order to calculate the ratio of the amplitudes a different system of coordinates is used as shown in Fig. 16. The equations of motion, with these coordinates are

$$I_4\theta_4'' = k_4(\theta_4 - \theta_2)$$

$$I_3\phi_3'' = -k_3\ (\phi_3 - n_1n_2\theta_3)$$

$$I_p\,\theta_1'' = k_1\ (\theta_2 - \theta_1)$$

and

$$k_2\,(\theta_3 - \theta_2) + k_4\,(\theta_1 - \theta_2) - k_1\,(\theta_2 - \theta_1) = 0$$

$$-k_2(\theta_3 - \theta_2) + n_1n_2k_3\ (\phi_3 - n_1n_2\theta_3) = 0$$

If we assume the amplitude at the engine equal to unity, then

$$\theta_2 = \frac{k_4 - I_4\omega^2}{k_4}, \qquad \theta_1 = \frac{k_1\,(k_4 - I_4\omega^2)}{k_4\,(k_1 - I_p\omega^2)}$$

$$\theta_3 = \left(\frac{k_1 + k_2 + k_4}{k_2}\right)\theta_2 - \frac{k_1}{k_2}\theta_1 - \frac{k_4}{k_2}$$

$$\phi_3 = \left(\frac{k_2 + (n_1n_2)^2 k_3}{n_1n_2k_3}\right)\theta_3 - \frac{k_2}{n_1n_2k_3}\theta_2 = \frac{n_1n_2k_3\theta_3}{k_3 - \omega_2I_3}$$

The last equation could also be used for calculating the frequencies.

HEINRICH HOLZER.[9] To find out the best way of coupling an exhaust turbine of steady-torque characteristic to a reciprocating engine of variable-torque characteristic we may start by considering the fact that vibration in the turbine shafting can arise only from the coupling linkage. Therefore, if the point of the engine shafting at which the turbine branch is attached has no vibratory motion itself, the whole turbine branch will remain without vibrations.

The turbine branch should be attached to the main system at a point where a node of the vibration of the main system occurs. In general the vibration of the propeller system will consist of harmonic components of different periods and phases, and a coupling point without any vibratory motion will not be available. In this case we must of course be content to couple the two systems at one of the nodes of the main harmonic component. At the coupling point the amplitudes of both the main shaft and the turbine branch are not only the same, but also the harmonic coupling torques are equal but of different signs, representing the action—and reaction—torque. By means of these harmonic coupling torques both the main shaft and the turbine branch can be treated as free systems independent of each other. At the turbine branch the harmonic coupling torque is the only exciting torque determining completely the vibratory motion of the turbine-gearing system. Now it is well known that of all vibratory states of a given system, the natural or free vibrations of the system demand the smallest exciting torques down to zero, if there is no damping in the system. The effect of the reciprocating engine on the turbine branch, represented by the harmonic coupling torque, will therefore be eliminated when the turbine-gearing system is tuned to the frequency of the main component vibration of the engine-propeller system. When, for instance, the plant is ordinarily running between 85 and 89 r.p.m. and the main vibration is of third order, we may tune the turbine-gearing system to the free frequency of $3 \times 87 = 261$ cycles per min., if there is not critical speed in or near the working range; we may tune it to $3 \times 80 = 240$ cycles per min. if there is a heavy critical speed of the third order at 80 r.p.m. The flexibility of the springs coupling the low-speed gear to the propeller shaft is therefore of little or no account, though it is never wrong to make the springs as flexible as possible. When running at the speed to which the turbine-gearing system is tuned, there will be no vibration torque whatever in the gearing nor in the springs connecting the low-speed gear to the propeller shaft.

---

[9] Consultant on Vibration and Strength Problems, Schwabach, Germany.

Of course, the best solution is to tune the turbine branch to the best running conditions and at the same time attach it to the propeller shaft at the point of least amplitude of vibration.

Frank M. Lewis.[10] The paper directs attention to the dynamic problems which arise when reciprocating machinery is used in conjunction with geared transmission. As the authors state, it is necessary that a positive torque be always maintained at the gear faces of such an installation. The irregular torque of the reciprocating machinery can start oscillations in the system which may cause the torque at the gear teeth to pass through negative loops. The pounding thus caused results in rapid deterioration of the gears. It is very difficult to insure this condition of positive torque without the introduction of a considerable amount of elasticity at an appropriate point in the system. In all the installations with which the writer is familiar, elasticity in some form was introduced—hydraulic, electrical, or in the form of mechanical springs. In the installation described springs have been used and the writer believes that the authors have effected a very satisfactory solution of the problem.

Propeller damping coefficients are deduced from the so-called propeller characteristics. The damping coefficient is essentially the slope of the torque–angular-velocity curve. It is this slope which the authors deduce in their Equations [10] to [19]. However, the writer is not quite in agreement with their results. The curve they give is based on an assumption that the ship's speed increases as the revolutions increase, while the slip increases only slightly. The condition of a vibrating propeller differs widely from this, however. Here the ship's speed remains constant while the slip is varying widely as the propeller vibrates. A torque–angular-velocity curve for this condition would have a much steeper slope than the one corresponding to Fig. 11, with a consequent higher damping coefficient. The writer deduced a method of calculating propeller damping coefficients based on these latter assumptions in 1925. While he has no data relative to the propeller dealt with in the paper, the method would probably give a damping coefficient 50 per cent to 75 per cent higher than the one calculated by the authors.

Any check of propeller damping coefficients by direct experiment is a very difficult matter. The best that can be done is to make torsiograph measurements on actual ships where all conditions and exciting forces are known. It is not an easy matter to make tests under such satisfactory conditions that reliable information will result.

In regard to the inertia effect of the water, our knowledge of propellers is also very inadequate, even more so than in regard to the damping effects. It is usual to make a purely arbitrary allowance of some 10 to 25 per cent of the propeller inertia, according to the taste of the calculator. The writer has made many torsional vibration investigations on ships, but has never been able to obtain a sufficiently comprehensive set of observations to permit an accurate calculation of either the inertia or damping effects of the water.

C. Richard Soderberg.[11] On page 8 there is an attempt to determine the damping properties of a ship propeller from the speed-horsepower curve. Now, a speed-horsepower curve such as the one shown in Fig. 11 is based on a steady state of motion, that is, the speed is assumed to be constant for each horsepower reading. This is so important that great care has to be taken in guarding against speed variations during the test. In view of this, it does not appear permissible to draw conclusions of the damping properties from this curve. For the damping phenomenon we are interested in the behavior of the propeller under cyclic variations of the speed; the speed-horsepower curve is entirely unrelated to this phenomenon.

Just what ought to be the correct relation for the damping resistance is difficult to say, but it is probable that it will depend upon the velocity of the oscillation $d\alpha/dt$ as well as on the mean speed of rotation N. The comparatively satisfactory agreement of tested and calculated amplitudes must be regarded as accidental.

O. G. Tietjens.[12] In this paper an attempt has been made to derive the damping constant for small torsional vibrations of a propeller shaft from a curve representing the indicated horsepower as a function of the revolutions per minute of the propeller. Leaving the question open for a moment as to whether the curve shown in Fig. 11 of the paper is the right one or not, it may be of interest to explain in general how the propeller supplies the damping, or in what manner the amount of energy that corresponds to the damping is being dissipated by the propeller.

If we consider the performance of a propeller-blade element having the peripheral speed u and the axial speed w, Fig. 17, we see that the relative speed of the blade element with respect to the water will be $v = \sqrt{(u^2 + w^2)}$. Each blade element has a certain angle of attack α with respect to the relative velocity v. The torsional vibration of the propeller shaft produces a periodic

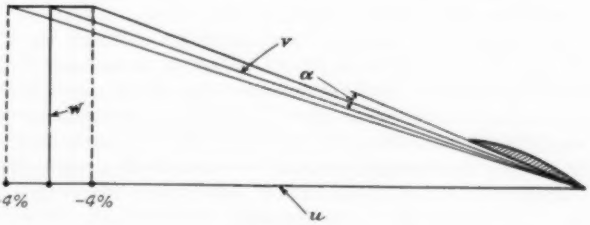

Fig. 17

(The variation of the peripheral speed u of a blade element caused by torsional vibration of the propeller increases and decreases periodically the angle of attack of the blade element.)

increase and decrease in the peripheral speed u of each blade element. The amplitude of this variation in u is about ±4 per cent in the actual case dealt with in the paper. Therefore, since the axial velocity w remains constant during this periodic variation of the peripheral speed, we see from Fig. 17 that the torsional vibration of a propeller shaft produces a similar variation in the angle of attack of each blade element. These changes of the angle of attack are combined with a small variation of the relative velocity v as shown in Fig. 17. However, the variation of the angle of attack is the much more important factor.

On the other hand, an increase in the angle of attack of a blade element means an increase of the lift of this element, and a decrease in the angle of attack means a decrease of the lift. However, we know[13] that an increase in the lift generates behind the blade element a vortex which rotates in a counterclockwise direction if the blade element moves from the right to the left, and we know that a decrease of the angle of attack causes a vortex which rotates in a clockwise direction. Therefore we see that the torsional vibration of the propeller shaft gives rise to a periodic generation of vortices as shown in Fig. 18. The kinetic energy of these vortices produced per unit time corresponds to the work of damping done by the propeller.[14]

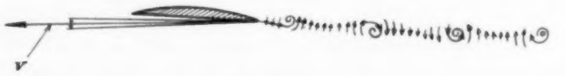

FIG. 18

(The kinetic energy of the vortex path produced per unit time corresponds to the work of damping done by the propeller.)

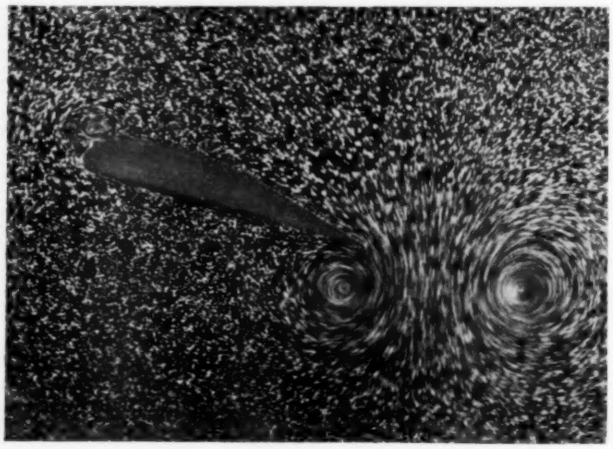

FIG. 19

(Showing two vortices which are generated behind a blade section by a variation in lift of this blade.)

Fig. 19 shows a picture of a wing section with two vortices generated by a variation in lift. The vortex at the right corresponds to an increase of the lift from zero to a certain amount; the vortex close to the trailing edge of the wing section corresponds to a decrease of the lift to zero. Due to the fact, however, that for the propeller-blade elements the variation in lift caused by the torsional vibration is much smaller than that corresponding to Fig. 19, the vortices for the propeller blades will also be much smaller than shown in this figure.

However, it is important to realize that a certain time is required to enable these vortices to reach the size that corresponds to the amount of variation in the angle of attack. If the frequency of the torsional vibration of the shaft, and therefore the frequency of the variation of the angle of attack, becomes too high, say, 100 cycles per second, the time for developing the vortices will be too short and very little or no energy will be dissipated. For very high frequencies, therefore, the propeller will supply no damping at all. In this case the tangent to the curve in Fig. 11 should be a horizontal line and $C = dT/d\omega = 0$. For a smaller frequency of variation the angle of attack C has a certain finite value. Therefore it is seen that the damping constant must be considered an unknown function of the frequency f, or

$$C = \frac{dT}{d\omega} = F(f)$$

However, even if we make the assumption that the frequency of the torsional vibration of the shaft is small enough to guarantee the generation of the vortices to their full size, it is further necessary to take into account a certain relation between the hydrodynamical forces and the frequency. This relation depends on the expression $\pi l/tv$, where l is the width of the blade, v the relative velocity of the blade element, and t the time of one cycle. The smaller the above expression, the less does the lift of a blade element, and therefore also the thrust as well as the torque, depend on the frequency. However, according to a theory developed by W. Birnbaum,[15] even for

$$\frac{\pi l}{tv} = 0.15$$

the amount of the variation in the lift, and therefore also in the torque, is about 20 per cent smaller than that based on the assumption of a steady flow, i.e., for lim $1/t = 0$. Assuming the data given in the paper, i.e., a blade width of about 2 ft., a frequency of 4 cycles per second, and a relative velocity of 4200 ft. per min. or 70 ft. per sec., we obtain approximately

$$\frac{\pi l}{tv} = 0.3$$

which makes it evident that the performance of a propeller with such a variation of its angle of attack will be different from that taking place under steady-flow conditions.

However, even if we have a sufficiently low frequency, or high velocity v, so that the above expression becomes small enough to justify the assumption of steady flow around the blades, the calculation of the damping constant should be based on a curve which gives the indicated horsepower as a function of the propeller revolutions for *constant* ship speed instead of the curve of Fig. 11 of the paper which gives the indicated horsepower as a function of the propeller r.p.m. where the ship speed varies with the r.p.m. As also mentioned by Professor Lewis, this has to be taken into account since the ship speed remains constant while the peripheral speed of each blade element varies due to the torsional vibration of the propeller shaft.

The curve for constant ship speed, however, is steeper and has a larger tangent than the curve of Fig. 11 at points of corresponding values of propeller revolutions. This can easily be seen from Fig. 17 if we realize that with increasing r.p.m. the increase in the angle of attack, and hence the increase in the torque, would be smaller if the speed of the ship, and therefore the axial velocity w increases with increasing propeller revolutions.

If we could make the assumption that the performance of the vibrating blade can be approximated by the performance of the blade in steady flow, we could then obtain the above-mentioned curve of indicated horsepower as a function of propeller revolutions for constant ship speed if the r.p.m. is suddenly increased or decreased and the indicated horsepower is then determined before the ship has had time to change its speed.

[14] It may be mentioned that these vortices have nothing to do with the so-called Kármán vortex path.

[15] W. Birnbaum, "Das ebene Problem des schlagenden Fluegels," *Zeit. f. Angew. Math. u. Mech.*, 1924, p. 277.

However, since we do not know in what manner the damping depends on the frequency, or more generally, on the term $\pi l/tv$, the derivation of the damping constant from a curve similar to Fig. 11 does not appear to be based on sound physical principles.

These remarks should not be considered as a criticism of this interesting paper as a whole, but as referring only to that part of it which deals with the theoretical derivation of the damping constant.

Authors' Closure

The primary purpose of the Vulcan coupling in the Bauer-Wach exhaust turbine is to permit the disengagement of the low-pressure turbine during maneuvering. Incidentally, it may minimize vibrational effects. All the published studies of this coupling concern themselves with its steady-state operation at constant rotational speed on both sides of the coupling. The Vulcan coupling must have distinct reactions to vibratory motion. There must be a loss of energy associated with oscillatory relative motion between the parts; and there is a torque between the driving and driven members that depends on their relative displacement. This elastic torque would be analogous to the synchronizing torque found in synchronous electrical machinery.

No quantitative values of these damping and elastic torques are known when the coupling is applied. The application may be effective against the vibration or it may not; that depends on the relationship of the vibratory properties of the coupling to the rest of the system.

As a damping device the Vulcan coupling is in its best position on the high-speed shaft. As an elastic device it might as well be torsionally rigid in this position. Without quantitative knowledge of its damping properties, reference must be made to experience. If it is a universally effective protective device against vibration, the gear teeth in all the 200 Bauer-Wach installations will only be worn or wire-edged on the driving side. If it is not, signs of pounding will appear on both sides of the teeth. The authors have been informed that such pounding and wear on both sides of the gear teeth is in evidence in some installations where the Vulcan coupling is used.

The spring gear described in the paper eliminated signs of pounding on both sides of the gear teeth.

It must be remembered that gear-tooth pounding and ultimate breakage are usually fatigue effects. Destructive effects require time and the repeated action of millions of blows. If these blows can be eliminated from the speed range where the ship runs 95 per cent of the time, the number of blows has been reduced to such an extent that other factors become more important in the ultimate life of the equipment. It is also understood that the Bauer-Wach system must be disconnected at lower speeds on account of pounding in the gear teeth.

Propeller damping is a very real thing. It is so effective that the one-noded vibration has practically no amplitude even at resonance. The purpose of a spring coupling is to keep amplitudes of stress harmless even in the event of resonance. Experience shows that it accomplishes this end.

The working spring stresses amount to 16,000 lb. per sq. in. static with an oscillating stress with 16,000 lb. per sq. in. amplitude; these stresses are well within the limit of safety of the material used as one year's continuous service amply proves. The maximum stress of 52,500 lb. per sq. in. occurs at low speeds and is not repeated often. It is also within the limits of safety for the material.

Dr. Eksergian's mathematical treatment reducing the complicated system to one of a few degrees of freedom is very interesting. It can be very useful in calculating the values of the natural frequencies after the numerical data on inertias and spring constants have been obtained.

Mr. Holzer's contention that the whole problem of oscillatory gear stresses could be eliminated by placing the gearing at a node in the elastic system is entirely correct. If the second reduction gear could have been placed at the node of the two-noded mode of motion, the gears would need no elasticity to protect them. Unfortunately insurance regulations and considerations other than torsional vibration determine the masses of the steam engine and propeller and the size of the main propeller shaft. The properties of most ship installations are such as to put the important node somewhere in the propeller-shaft alley far aft of the available engine-room space. These practical reasons are determining factors, especially when the exhaust turbine is installed in a ship originally designed to operate only with a multiple-expansion steam engine.

Dr. Holzer's statement that tuning the turbine and gear system would entirely eliminate any gear-torque reactions at those speeds where the harmonic frequencies were in resonance with the tuned frequency of the branch system, is correct. However, unless this tuned frequency is exactly equal to the 2-noded natural frequency of the system, it does not offer any great advantage since the maximum force in the gear teeth grows very rapidly as the 2-noded frequency recedes in either direction from the tuned frequency of the branch system. Practically, this means that the natural frequency of the branch system would have to be adjustable since it is almost impossible to calculate within limits of 5 to 10 per cent of the actual value of the 2-noded critical speed of one of these installations.

In the case of the *Susan V. Luckenbach* the 2-noded natural frequency is somewhere in the order of 4 cycles per second, which would require a flexibility between the turbine and gearing about 50 times as great as that of the present pinion shaft. Such a flexible coupling would certainly require more space than is used at present between the turbine and the gearing. The spring gear as actually used takes up no more space than an installation which has no flexibility in it. In the engine room of a ship, space is at a great premium.

With adjustable flexibility in the turbine coupling, Dr. Holzer's scheme is not only theoretically correct, but probably would offer actual practical advantages. Without adjustability and with complete dependability on design calculations, we feel that the spring gear used by us in the *Susan V. Luckenbach* probably gives a better practical answer.

The spring gear as used is not only a theoretical cure for a difficult problem, but it works.

Messrs. Lewis, Soderberg, and Tietjens have attacked the authors' method of calculating the propeller damping. The authors cannot defend the method used on physical grounds and can only add their desires to those of the discussors for a good theoretical and experimental method for determining the actual values for propeller damping. They cannot agree with Mr. Soderberg that the method is completely valueless, however.

First of all, the damping constant found by the authors' method agrees in form with those found by Frahm and Lewis:

$$\text{Lewis: } C = \left(1 - S\right)\frac{\dfrac{\partial T}{\partial s}}{T}\,\frac{T}{\omega}$$

$$\text{Frahm: } C = r\,\frac{T}{\omega}$$

$$\text{Ormondroyd and Kuchler: } C = \left(n - 1\right)\frac{T}{\omega}$$

where T = propeller torque (steady rotation)
ω = angular velocity of propeller (steady rotation)
S = slip of propeller
r = Frahm's constant
n = exponent of N (r.p.m.) in expression for propeller torque (steady rotation).

The disagreement between these methods concerns only the value of the constant, which in the authors' method is 3. Lewis, in his paper cited on page 5, gives a method for calculating this constant from propeller-model tests and based on good physical reasoning. Using data published by Porter[16] based on the Lewis method, this constant should be about 3.7 for the propeller in question, although Porter's data refer to three-bladed propellers and the propeller in the authors' case has four blades. Frahm's constant as published by Porter in the same paper was 3.8.

General considerations indicate that the damping constant found by the authors' method will always be too small. This leads to the prediction of larger amplitudes than actually exist, which is on the safe side as far as design prediction is concerned.

The method proposed by Lewis is the best available, although Tietjens indicates that the problem is even more complicated than indicated by Lewis. What is really needed for a large class of ship-machinery vibration problems is an experimental study of propeller damping effects.

Distribution of Pressure Concentrated on a Small Surface

By MICHAEL A. SADOWSKY,[1] MINNEAPOLIS, MINN.

In this paper the author discusses mathematically problems concerning the pressures and deformations that arise when a very rigid die or punch is pressed against a comparatively elastic material, and also in the case where column footings rest on an elastic soil foundation. The author considers (1) the case where the axial section of the die is given and the resulting distribution of pressure along the curved contact surface is required; and (2) where the distribution of pressure over the contact surface is prescribed and the proper curvature of the surface to give such a distribution of pressure is required. Solutions of each of these cases are given for two types of die; namely, when the die is a body of revolution, and when it has a rectangular cross-section the dimension of which perpendicular to the plane of the figure is either very large or very small.

THE present paper deals with the problem of pressures and deformations arising when a very rigid die, or punch, is pressed against a comparatively elastic material. Such a problem arises in the case of various punching machines and also in the case of column footings resting on an elastic soil foundation. In such cases it is reasonable to assume that the die is absolutely rigid in comparison with the body of material with which it comes in contact. This assumption has been made in each of the cases considered.

Two problems of particular interest arise (see Fig. 1):

1 When the axial section of the die is given (curve ABC), and the resulting distribution of pressure along the surface ABC is required.

2 When the distribution of pressure along the curve ABC is prescribed, and the proper shape of the curve to give such a distribution of pressure is required.

The first problem may be easily solved if the curve ABC is a straight line, and the second, if the pressure distribution along the curve is uniform. Only these two special cases of the above problems have been solved in the present paper.

Solutions for each of the above-mentioned problems are given for two types of die, namely:

(a) When the die or punch is a body of revolution (e.g., a cylinder), and,

(b) When it has a rectangular cross-section the dimension of which perpendicular to the plane of the figure is either very large or very small (i.e., a two-dimensional problem).

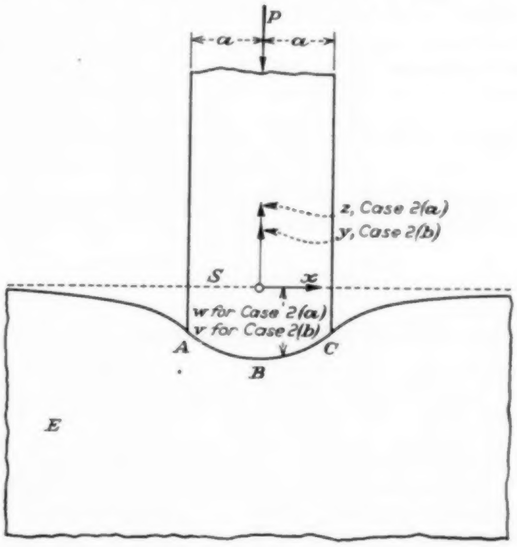

FIG. 1

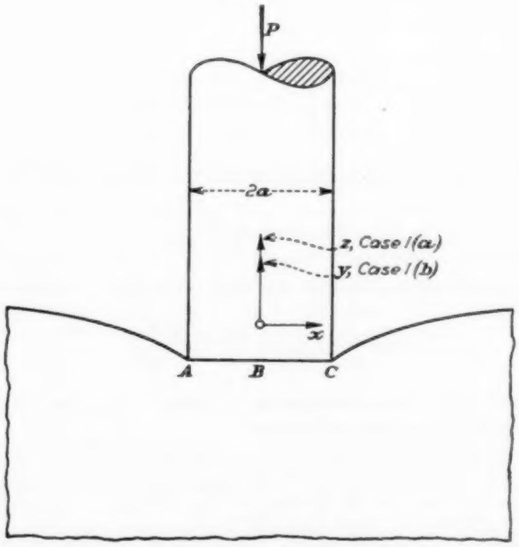

FIG. 2

SUMMARY OF RESULTS

1—DISTRIBUTION OF PRESSURE WHEN ABC IS A STRAIGHT LINE (FIG. 2)

Case 1(a). The die (punch) is a body of revolution, and the

[1] Dr. Sadowsky was born in Dorpat (Esthonia, formerly Russia) on March 1, 1902. He left Russia before the revolution and lived for six years in Finland. In 1922 he went to Berlin, Germany; in 1926 he was graduated at the Technische Hochschule, Berlin; and in 1927 he took the degree of Dr.-Ing. there. Later he became a Privatdozent for Mathematics of the faculty at the Technische Hochschule. After six years of teaching experience in Berlin, he came to this country, in 1931, going to the University of Minnesota, where he gives general mathematical courses and organizes a mathematical laboratory for teaching practical (applied) mathematics.

Presented at the National Applied Mechanics Meeting, New Haven, Conn., June 23–25, 1932, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

pressing surface *ABC* is plane. Then the pressure (p) depends on the distance (x) from the center B, and is given by the equation:

$$p_x = \frac{P}{2\pi a} \frac{1}{\sqrt{a^2 - x^2}} \quad \ldots\ldots [1]$$

At the boundary ($x = a$) the pressure becomes infinite; at the center ($x = 0$) it is equal to $P/2\pi a^2$.

Case 1(b). Two-dimensional problem.[2] *ABC*, Fig. 2, is a straight line, and the pressure at any point is then given by the equation:

$$p_x = \frac{P}{\pi} \frac{1}{\sqrt{a^2 - x^2}} \quad \ldots\ldots [2]$$

in which P is the load per unit length in the direction perpendicular to the plane of the figure. At the edges $x = \pm a$ the pressure becomes infinite. At the center ($x = 0$) it is equal to $P/\pi a$.

2—SHAPE OF SURFACE *ABC* FOR A UNIFORM DISTRIBUTION OF PRESSURE (p) (FIG. 1)

Case 2(a) (*Fig. 1*). The die (Fig. 1) is a body of revolution. the distribution of pressure is uniform, i.e.,

$$p_x = \frac{P}{\pi a^2} = \text{const.} = p \quad \ldots\ldots [3]$$

The curve *ABC* is then given by the equation:

$$w_{(x,0,0)} = -\frac{4(1-\sigma^2)}{\pi}\frac{ap}{E}\int_0^{\frac{\pi}{2}} \sqrt{1 - \left(\frac{x}{a}\right)^2 \sin^2 \varphi}\, d\varphi \ldots [4]$$

in which σ is Poisson's ratio. The elliptic integral of the second kind occurring here is represented by the notation $E(x/a, \pi/2)$. Its numerical values as a function of x/a may be found in mathematical tables.[3]

The curve *ABC* is like that shown in Fig. 1. Replacing it by a circle through the points A, B, and C, it is found that the radius R of this circle is

$$R = \frac{aE}{4\left(1 - \frac{2}{\pi}\right)(1 - \sigma^2)p} \quad \ldots\ldots [5]$$

The radius of curvature of the curve *ABC* at point B is

$$R_{x=0} = \frac{aE}{(1-\sigma^2)p} \quad \ldots\ldots [6]$$

The difference of ordinates of the curve *ABC* at A and at B is:

$$w_{(a,0,0)} - w_{(0,0,0)} = \frac{2(\pi - 2)(1 - \sigma^2)ap}{\pi E} \quad \ldots\ldots [7]$$

Case 2(b). Two-dimensional problem. Assuming in Fig. 1 a uniform distribution of pressure,

$$p_x = \frac{P}{2a} = \text{const.} = p \quad \ldots\ldots [8]$$

in which P is the load per unit length in the direction perpendicular to the plane of the figure. The necessary shape of the curve *ABC* is then given by the equation

$$v_{(x,0)} - v_{(0,0)} = \frac{paK}{\pi G}\left(\log\left|1 - \frac{x^2}{a^2}\right| + \frac{x}{a}\log\left|\frac{a+x}{a-x}\right|\right) \ldots [9]$$

which can be used for all values of x except $x = \pm a$. For $x = \pm a$,

$$v_{(\pm a,0)} - v_{(0,0)} = \frac{2\log 2paK}{\pi G} \quad \ldots\ldots [10]$$

The constant K which occurs in Equations [9] and [10] has the value

$$K = 1 - \sigma \quad \ldots\ldots [11]$$

in the case of *plane deformation*, i.e., when the dimension of the punch and of the body in the direction perpendicular to the plane of the figure is very large.

In the case of *plane stress distribution*, i.e., when the dimensions of the punch and of the body in the direction perpendicular to the plane of the figure are small, the value of K is given by equation:

$$K = \frac{1}{1 + \sigma} \quad \ldots\ldots [12]$$

Poisson's ratio σ is about 0.3, and the difference between Equations [11] and [12], being a quantity of the second order, is small, and the dimension in the direction perpendicular to the plane of the figure does not substantially affect the shape of the curve *ABC*.

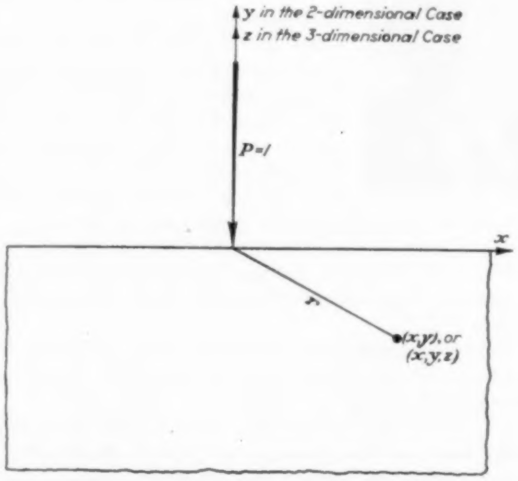

FIG. 3

Fig. 1 shows approximately the shape of the curve *ABC*. The circle passing through points A, B, and C has the radius

$$R = \frac{a\pi G}{4\log 2pK} \quad \ldots\ldots [13]$$

The radius of curvature of *ABC* at B is

$$R_{(x=0)} = \frac{a\pi G}{2pK} \quad \ldots\ldots [14]$$

Replacing the curve *ABC* by a circle the radius of which is equal to the average of the values given by Equations [13] and [14], a distribution of pressure approaching uniform distribution may be obtained.

---

[2] The solution is the same for the case of plane deformation and for plane stress.

Appendix

MATHEMATICAL TREATMENT OF THE PROBLEM AND DERIVATION OF THE RESULTS

THE TWO-DIMENSIONAL PROBLEM

If a single force, the magnitude of which is unity, acts, as shown in Fig. 3, upon an elastic semi-infinite plane, the displacement $v_{(x,y)}$ in the y-direction of a point x,y of this semi-infinite plane is given by the equation

$$v_{(x,y)} = \frac{1}{2\pi G}\left[K \log (x^2 + y^2) - \frac{y^2}{x^2 + y^2}\right] \ldots\ldots [15]$$

where

$$K = \begin{cases} 1 - \sigma, \text{ in the case of plane deformation} \\ \dfrac{1}{1+\sigma}, \text{ in the case of plane stress distribution} \end{cases} \ldots\ldots\ldots [16]$$

Equations [15] and [16] may be found in books on elasticity[4] and their systematic derivation in some special papers.[5]

If a uniform load of the intensity p is distributed on $-a \leqq x \leqq a$, the vertical component of the displacement can be obtained from Equation [15] by integration, or

$$v_{(x,y)} = \frac{p}{2\pi G}\int_{-a}^{a}\left[K \log \left\{ (x-\xi)^2 + y^2 \right\} - \frac{y^2}{(x-\xi)^2 + y^2}\right] d\xi \ldots\ldots [17]$$

where y is negative as seen from Fig. 1.

To determine the displacement $v_{(x,0)}$ on the boundary $y = 0$, we have to determine the limit

$$v_{(x,0)} = \underset{y \longrightarrow 0-0}{\text{limit}}\; v_{(x,y)} = \underset{y \longrightarrow 0-0}{\text{limit}} \text{ of right-hand member of [17]} \ldots [18]$$

Now, as $\log 0 = \infty$, the convergency of the integral [17] is not uniform for the process [18], when $-a \leqq x \leqq a$, and so it is necessary to determine carefully if it is allowable to change the sequence of the ξ-integration and the $y \longrightarrow 0 - 0$ limitation in [18]. This can be done, as is shown by the formula

$$\lim_{c \longrightarrow 0} \int^{b} \log\,(z^2 + c^2)dz = \int_0^b \log\,(z^2)dz \ldots . [19]$$

The proof of Equation [19] is very easy, as it is known that $\int_0^b \log z dz$ is integrable. The result of the limit operation [18] is then

$$v_{(x,0)} = \frac{pK}{\pi G}\int_{-a}^{a} \log \left| x - \xi \right| d\xi \ldots\ldots\ldots [20]$$

[The second term of the right-hand member of [17] when integrated gives $-y \tan^{-1} \dfrac{\xi - x}{y}\Big|_{\xi = -a}^{\xi =}$ the absolute value of which is equal to or less than $\pi|y|$, which $\longrightarrow$ 0 with y.] The integral in Equation [20] can be evaluated, giving

$$v_{(x,0)} - v_{(0,0)} = \frac{paK}{\pi G}\left[\log \left| 1 - \frac{x^2}{a^2} \right| + \frac{x}{a} \log \left| \frac{a+x}{a-x} \right| \right] \ldots [21]$$

This expression can be used for all values of x except $x = \pm a$. For $x = \pm a$ we have:

$$v_{(\pm a,0)} - v_{(0,0)} = \frac{2 \log 2paK}{\pi G} \ldots\ldots\ldots [22]$$

The following table gives numerical values of Equation [21] for various values of the ratio x/a.

x/a	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1	2	3	10
$v_{(x,0)} - v_{(0,0)} =$	0	0.0100	0.0403	0.0914	0.1646	0.2616	0.3855	0.5409	0.7361	0.9893	1.3863	3.2958	4.16	6.60

By using the table, the shape of the die producing uniform pressure distribution can be drawn. Thus a solution of the problem of case 2(*b*) is obtained. Let us consider now the problem of 1(*b*) and determine the distribution of pressures p when the section *ABC* of the punch is a straight line. In order to solve this problem we have to take Equation [15] and perform an integration over the loaded length *ABC*. The equation from which the distribution of pressures $p(\xi)$ is obtained is:

$$\text{constant} = \int_{-a}^{a} p(\xi) \log \left| x - \xi \right| d\xi \ldots\ldots [23]$$

The right-hand member of this equation represents $v_{(x,0)}$ along *ABC* (see Equation [20]), and has to be constant because *ABC* is a straight line. The absolute value of this constant has no physical meaning, because the solution of an elastic problem always admits an additional displacement of the whole system, and so it cannot be stated that this constant represents the real displacement of the punch. However, this constant is not needed for the determination of the pressures, as will be immediately shown. The pressure $p(x)$ is no longer constant as in Equation [20], but is variable, and so it is seen that [23] is an integral equation, the use of which will determine the unknown function $p(x)$.

To solve this integral equation we can say that [23] represents an equation of the potential theory of two dimensions, the kernel $\log|x - \xi|$ being the logarithmic potential and $p_{(x)}$ the unknown density of charge. As the left-hand member of Equation [23] is a constant, the distance $-a \leqq x \leqq a$ must have a constant potential, and as there is no pressure for $|x| > a$, the density of charge has to be zero for $|x| > a$. The problem can then be solved at once by conformal mapping. Let us take a circle of unit radius in an auxiliary plane of the complex variable ψ, and make it a line of a constant potential. Then we know that the charge distribution along the boundary of this circle is uniform. If we use the conformal mapping, given by

$$\zeta = \frac{a}{2}\left(\psi + \frac{1}{\psi}\right)$$

where the ζ-plane corresponds to the xy-plane of our elastic problem, the circle will be transformed to the loaded distance $-a \leqq x \leqq a$, and the distribution of the charge $p_{(x)}$ will be given by the absolute value of the derivative $d\psi/d\zeta$ determined at the corresponding point, multiplied by the density of the distribution in the auxiliary plane ψ. As this last density is constant, $p_{(x)}$ will be directly proportional to

$$\left|\frac{d\psi}{d\zeta}\right|$$

[5] See author's papers in *Sitzungsberichte der Berliner Mahtematischen Gesellschaft*, vol. 28, pp. 86–99; and in *Zeitschrift für Angewandte Mathematik und Mechanik*, Berlin, 1927, vol. 7.

This quantity can be evaluated by a simple differentiation, which will be omitted here; the result is

$$p_{(x)} \alpha \frac{1}{\sqrt{a^2 - x^2}}$$

In order to determine the factor of proportionality, use will be made of the relation

$$P = \int_{-a}^{a} p_{(x)} dx$$

which is obvious. Then the final result is:

$$p_{(x)} = \frac{P}{\pi\sqrt{a^2 - x^2}} \dots\dots\dots\dots\dots\dots [24]$$

Equation [24] solves the proposed problem 1(*b*). An extension of the method described here, applicable in the case of other shapes of punches, has been given in a paper by the author.[5]

The Three-Dimensional Problem

Let us consider now the three-dimensional problem. The method of the calculation will be essentially the same as in the two-dimensional case, the only difference being that the function theory and conformal mapping are not applicable for the solution of the three-dimensional potential problems. If a single vertical force, the magnitude of which is unity, acts as shown in Fig. 3 upon an elastic semi-infinite body $z \leqq 0$, the vertical displacement $w_{(x,y,z)}$ of a point (x,y,z) in the elastic body is given by the known formula of Somigliana, namely:

$$w = -\frac{1}{4\pi G}\left[\frac{z^2}{r^3} + 2(1 - \sigma)\frac{1}{r}\right] \dots\dots\dots [25]$$

where

$$r^2 = x^2 + y^2 + z^2$$

If there is a uniformly distributed load, the intensity of which is p, the displacement $w_{(x,y,0)}$ of a point $(x,y,0)$ of the surface $(z = 0)$ can be obtained from Equation [25] by integration and by performing the limiting process $(z \longrightarrow 0 - 0)$. The result is

$$w_{(x,y,0)} = -\frac{p(1 - \sigma)}{2\pi G} \int\int \frac{dF}{r} \dots\dots\dots [26]$$

where

$$r^2 = (x - \xi)^2 + (y - \eta)^2 \text{ and } w_{(x,y,0)} = \lim_{z \longrightarrow 0 - 0} w_{(x,y,z)}$$

The region of the integration is the loaded region, and *dF* denotes its differential.

Referring to the limit process $z \longrightarrow 0 - 0$, see the corresponding portion of the two-dimensional case, Equations [18] and [19].

If the region of integration is a circle of radius a, the integration may be performed by using polar coordinates and the result will be Equation [4].

If the distribution of pressure is non-uniform, but corresponding to a plane circular pressing surface of the punch (*ABC* a straight line), the pressure $p_{(x)}$ for $(y = 0)$ has to be determined from the integral equation

$$\text{constant} = \int\int \frac{p dF}{r} \dots\dots\dots\dots [27]$$

which corresponds to Equation [23] of the two-dimensional case. If we interpret [27] as an equation of the potential theory, $p(x)$ is the charge-distribution function when the circular disk, the radius of which is a, has a constant potential. This problem is solved by the potential theory,[6] and Equation [1] in its solution.

The Use of Models in Aerodynamics and Hydrodynamics

By O. G. TIETJENS,[1] EAST PITTSBURGH, PA.

In the present paper the author endeavors to present in a simple manner the various laws of similarity and to indicate the ways in which they may be applied to model-testing practice. After explaining the principles of mechanical similarity, he describes different methods of deriving its laws, following which he discusses the functions of Reynolds', Froude's, and Mach's numbers. The closing section of the paper deals with special applications of the laws set forth to fluid resistance, propellers and fans, cavitation in ship propellers, hydraulic turbines and pumps, flow through pipes and channels, and to fluid problems related to acoustic velocity.

MODEL testing is probably of greater importance in those fields of engineering which are based on aerodynamics and hydrodynamics than in any of the others. This is mainly due to the fact that the applications of the general differential equation in hydrodynamics still offer insurmountable difficulties even in comparatively simple cases.

In considering, for instance, the design of an electrical machine, say, of a turbo-generator, it is known that the theory of electrodynamics can be readily applied for obtaining the electrical data necessary for the design. However, it is out of the question to apply the theory of hydrodynamics in a similar way for calculating the air flow through the machine for purposes of ventilation. The electrodynamic field, the copper losses, the iron losses, and many other details of such a machine can be determined theoretically with a fair degree of exactness, whereas the determination of the pressure drop of the cooling air through the machine and any details of the air flow through the various ducts must be based entirely on experiments.

In carrying out experiments concerning aerodynamical or hydrodynamical problems it is very often of considerable advantage to make them with small-scale models. This is true not only from an economical standpoint, but also because small-scale models are usually simplified to such an extent that the essential features of the problem are brought out more clearly. In addition, it is generally much easier to make systematic changes in models than in full-sized structures, not to mention the considerable saving in time. Therefore, particularly in research work where systematic investigations are carried on, tests with small-scale models will be found most advantageous.

On the contrary, however, in some cases, it is better to use models of a larger scale than the prototype. If, for instance, the flow of steam between small turbine blades is to be investigated, it will be more suitable to use models of turbine blades which are five to ten times larger in size. Or, if the performance of the wing of an insect is to be studied, it can be done advantageously by testing a wing one hundred times larger, and of geometrically similar shape, in thick oil instead of in air.

The purpose of testing models is, generally speaking, to apply the results obtained therefrom to full-scale practice. These results may be of a more or less general character, giving information regarding the kind of flow, the shape of streamlines, etc., or they may consist of numerical data which provide the desired information for the full-scale structure.

In order to insure that the results obtained by model tests can be applied to full-scale practice, certain so-called laws of mechanical similarity must be observed. Conversely, these laws will furnish the rules according to which the desired information for the full-sized structure can be obtained from the model test data.

It is the aim of this paper to present in a simple manner these various laws of mechanical similarity, and to indicate the ways in which they may be applied to model-testing practice. Details of practice in aerodynamical and hydrodynamical experimental work have been purposely avoided, although particulars regarding the more important experimental equipment for model testing such as wind tunnels and water tanks would be of interest, as would also be a description of one of the larger laboratories for aerodynamic and hydrodynamic research work.

I—PRINCIPLES OF MECHANICAL SIMILARITY

Considering, for instance, the flow of a gas or of water around two bodies, the question arises when and under what conditions the flow around one body will be mechanically similar to the flow around the other. Similarity in the mechanical sense implies not only geometrical similarity but also similarity with respect to the forces in question, or dynamical similarity. The flow around two bodies can be similar only if the shapes of the two bodies are geometrically similar. This condition is necessary but by no means sufficient.

Considering a particular case, e.g., the flow around two cylinders of different sizes—which involves the necessary condition of geometrical similarity—it will be found, in general, that the streamlines around these two cylinders are not similar, which means that there is no similarity in the kinematical and dynamical sense.

This is shown in Figs. 1 and 2, which are photographs showing streamlines of water flowing around a thin wire. It is quite obvious from the appearance of the streamlines that there is no mechanical similarity in the two cases, although the shapes of the bodies are similar. The different streamline formations shown are due to the water impinging on the cylinders at different velocities. In Fig. 1 the velocity is extremely low (about 6 in. per min for a wire of about $^1/_{32}$ in. diameter), while in Fig. 2

[1] Westinghouse Elec. & Mfg. Co. Mem. A.S.M.E. Dr. Tietjens was educated in Germany at the University of Göttingen, where he studied mechanics, hydrodynamics, and aerodynamics under Dr. L. Prandtl. In 1922 he received the degree of Ph.D., after which he was for five years an assistant to Dr. Prandtl. Since January, 1929, he has been connected with the Westinghouse Company, where he is in charge of hydrodynamics and aerodynamics.

Contributed by the Applied Mechanics Division and presented at the Semi-Annual Meeting of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS, Bigwin Inn, Lake of Bays, Ontario, Canada, June 27–July 1, 1932.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

it is considerably higher (about 1000 ft per min for the same wire).

Similar configurations of streamlines would indicate that the direction of the velocity is the same at corresponding points with respect to the bodies in consideration.

However, the velocity direction at any point of the flow is entirely determined by the *ratio of the forces* acting on a fluid particle at this point. One can say, therefore, that the conditions of mechanical similarity are fulfilled if the ratio of the forces acting on a fluid particle is the same at points similarly situated with respect to the bodies.

For a body moving in air or in water, provided it is completely immersed, the inertia and the viscosity forces are the only ones which have to be taken into account. Therefore mechanical similarity can then be expected if at points similarly located with respect to the bodies the ratios of the inertia forces to the viscosity forces are the same.

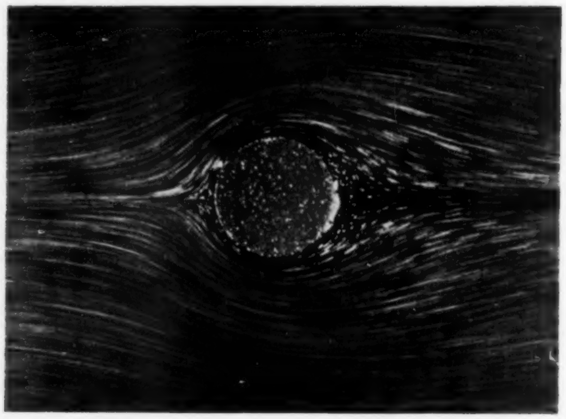

Fig. 1 Streamlines Around a Cylinder of Circular Cross-Section; $R = dV/\nu = 2$

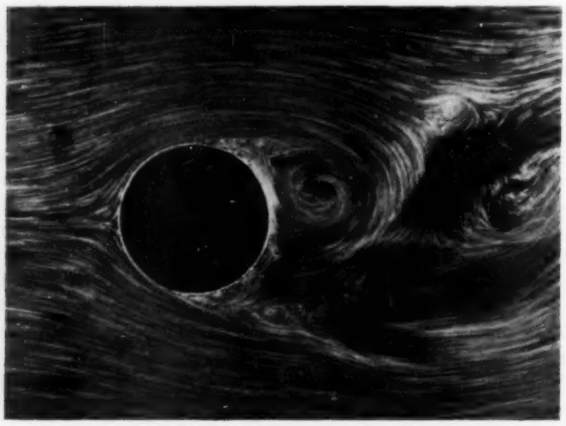

Fig. 2 Streamlines Around a Cylinder of Circular Cross-Section; $R = dV/\nu = 4000$

In considering water waves produced by a ship or by a seaplane hull, those forces which have to be taken into account are the inertia forces and the force of gravity. A model of a ship will therefore produce the same shape of waves as the full-sized ship if the ratio of inertia force to force of gravity is the same at similarly located points with respect to the model and the full-sized ship.

The various laws of mechanical similarity are merely concise expressions of the above-stated fact that mechanical similarity always exists if the ratio of those forces which govern the flow is the same at similarly located points.

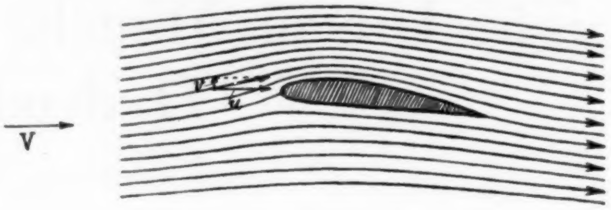

Fig. 3 Flow Around an Airfoil Section

II—DIFFERENT METHODS OF DERIVING THE VARIOUS LAWS OF MECHANICAL SIMILARITY

(a) Ratio of Forces

The manner in which the different forces acting on a single fluid particle will vary if the geometrical dimensions, the unit of time, and the physical constants of the fluid change, may now be investigated.

Consider, as an example, the flow around an airplane wing. The question arises: In what manner do the forces acting on a single air particle vary if the size of the wing changes but in other respects it remains geometrically similar to the original wing? And in what manner do the forces acting on the air particles vary if the speed of the wing changes? Finally, how do these forces vary by a change of the physical constants of the air such as specific weight and viscosity?

The relation between a change in dimensions, a change in the unit of time, and a change in the physical constants on the one hand and the variation of the forces acting on the air particles due to this change on the other, may be derived for the three most important forces, namely:

1 Inertia forces
2 Viscosity forces
3 Gravity forces.

1 The inertia force acting on a single fluid particle is equal to the product of the mass of the particle times its acceleration. If u, v, w are the components of the velocity at any point in the x, y, z directions, respectively, and if ρ denotes the mass density or the mass per unit volume, the x-component of the inertia force per unit volume for a steady flow is (Ref. 17, vol. I)

$$\rho\left(u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} + w\frac{\partial u}{\partial z}\right) \ldots\ldots\ldots\ldots\ldots [1]$$

From this expression it is seen that the inertia force is proportional to the mass density of the fluid.

Taking into consideration that the acceleration of any fluid particle must be independent of the arbitrary choice of the length and velocity units applied, new units for length and velocity can be introduced in [1] without changing this expression.

Considering again as an example the flow around an airfoil section as shown in Fig. 3, the velocity of the air wing itself, denoted by V, may be introduced as the unit of velocity, which leads to:

$$u = Vu'$$
$$v = Vv'$$
$$w = Vw'$$

where u', v', w' are dimensionless figures.

By taking the width L of the plane for the unit of length, the following equations are obtained:

$$x = Lx'$$
$$y = Ly'$$
$$z = Lz'$$

where x', y', z' are also dimensionless figures.

By introducing u', v', w', and x', y', z' in [1], this expression becomes

$$\rho \frac{V^2}{L}\left(u'\frac{\partial u'}{\partial x'} + v'\frac{\partial u'}{\partial y'} + w'\frac{\partial u'}{\partial z'}\right)\ldots\ldots\ldots\ldots[2]$$

Assuming two similar airfoil sections of different size as shown in Fig. 4, and assuming that the flows around both air wings are similar, which means that the streamlines are geometrically similar, then it is seen from expression [2] that at corresponding points P_1 and P_2 the inertia forces are proportional to $\rho_1 V_1^2/L_1$ and $\rho_2 V_2^2/L_2$, respectively, or generally proportional to $\rho V^2/L$.

2 The force due to the internal friction or viscosity of the fluid[2] is, per unit volume, equal to (Ref. 17, vol. II)

$$\mu\left(\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2}\right)\ldots\ldots\ldots\ldots\ldots\ldots[3]$$

if only one component of this force, for instance, the x-component, is considered.

By substituting the above-mentioned dimensionless variables u', x', y', and z' in [3] it becomes:

$$\mu \frac{V}{L^2}\left(\frac{\partial^2 u'}{\partial x'^2} + \frac{\partial^2 u'}{\partial y'^2} + \frac{\partial^2 u'}{\partial z'^2}\right)\ldots\ldots\ldots\ldots\ldots[4]$$

from which it is seen that the viscosity forces at corresponding points, for instance, P_1 and P_2 in Fig. 4, are proportional to $\mu_1 V_1/L_1^2$ and $\mu_2 V_2/L_2^2$, respectively, or generally proportional to $\mu V/L^2$.

It has been stated before and can be shown by the general differential equation of hydrodynamics that within any liquid, for instance, water, and in any gas, with not too high velocities (lower than about one-fifth of the acoustic velocity), the inertia forces and the viscosity forces are the only ones which have to be taken into account, or which entirely determine the shape of the streamlines. The gravity force drops out on account of the hydrostatic or aerostatic lift. The gravity force, however, has to be taken into consideration in all those cases of fluid flow where the surface of the fluid plays an essential rôle, as, for instance, waves produced by a ship or the flow over a weir. If the water level, however, is not changed or disturbed by the flow as is the case in the flow around a submarine which is sufficiently far enough below the water surface, or in the flow through water turbines and pumps, the inertia and viscosity forces determine entirely the flow, or, in other words, the mechanical similarity. In this case, therefore, it can be said that for mechanically similar flows around geometrically similar bodies the ratio of inertia force to viscosity force will be the same, or, according to [2] and [4],

$$\frac{\text{inertia force}}{\text{viscosity force}} = \frac{\rho_1 \dfrac{V_1^2}{L_1}}{\mu_1 \dfrac{V_1}{L_1^2}} = \frac{\rho_2 \dfrac{V_2^2}{L_2}}{\mu_2 \dfrac{V_2}{L_2^2}}$$

or generally

$$= \frac{\rho V L}{\mu}$$

The statement, therefore, that the expression $\rho VL/\mu$ is the same for the small-scale model as for the full-sized structure indicates that at similarly located points on the model and the prototype the ratio of inertia force to viscosity force is the same, or that the streamlines are similar, and that therefore mechanical similarity is assured.

The expression $\rho VL/\mu$, which is dimensionless because it is the ratio of two forces, is called the Reynolds number. (Ref. 4.) By introducing the so-called kinematic viscosity $\nu = \mu/\rho$, we can also write:

$$\text{Reynolds' number} = \frac{VL}{\nu}\ldots\ldots\ldots\ldots\ldots[5]$$

3 The gravity force acting on a particle having the mass m is equal to mg, and therefore the gravity force per unit volume is ρg.

Considering as an example water waves produced by a ship, the viscosity force can be neglected because it is small compared with the two other forces which govern the flow lines, namely, gravity force and inertia force. It now remains to state that for the condition of mechanical similarity the ratios of these two forces at similarly located points with respect to the model and the full-sized ship must be the same. This leads to the expression

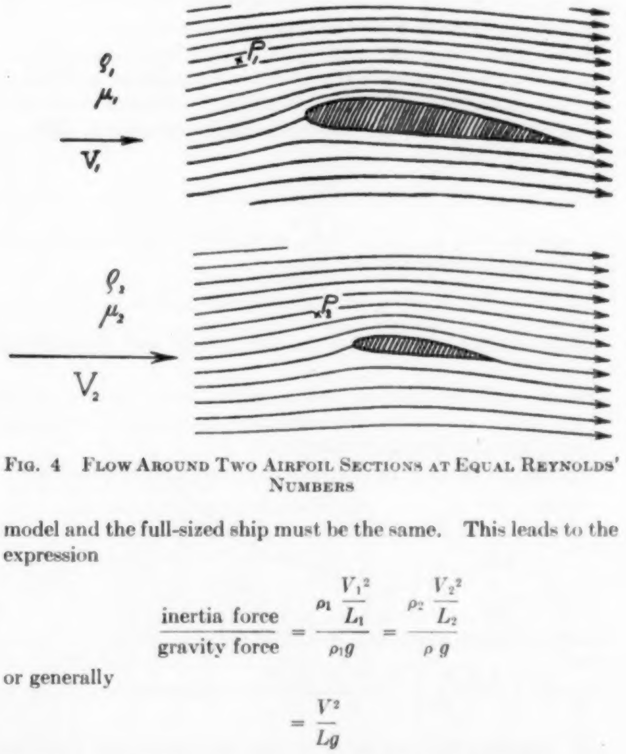

Fig. 4 Flow Around Two Airfoil Sections at Equal Reynolds' Numbers

$$\frac{\text{inertia force}}{\text{gravity force}} = \frac{\rho_1 \dfrac{V_1^2}{L_1}}{\rho_1 g} = \frac{\rho_2 \dfrac{V_2^2}{L_2}}{\rho\, g}$$

or generally

$$= \frac{V^2}{Lg}$$

where V is the velocity and L the length of the model or the ship. In other words, the shapes of the water waves produced by the model ship and the full-sized ship will be similar if the value of V^2/Lg is the same for both.

This dimensionless product, or usually its square root, is called Froude's number (Ref. 3), or

$$\text{Froude's number} = \frac{V}{\sqrt{Lg}}\ldots\ldots\ldots\ldots\ldots[6]$$

In like manner, the other laws of mechanical similarity or model rules can be obtained by establishing the ratio of those forces which are of essential importance for the particular kind of flow in question.

Another method of deriving the model rules of similarity consists of introducing dimensionless variables into the general differential equation of hydrodynamics in a manner analogous to that employed above for the expression of inertia forces and viscosity forces. Since similarity of the flow means identity of the solutions of the differential equation in dimensionless variables, the model rules can be obtained directly in a simple way. (Ref. 17, vol. II.)

---

[2] If the velocities in consideration are low compared with the acoustic velocity, say, about one-fifth of the acoustic velocity or less.

(*b*) Derivation of the Model Rules for Similarity by Considering the Dimensions of the Physical Quantities in Question

If neither the differential equation for the flow in consideration nor the expressions representing the forces are known, but if it is understood on what physical quantities, such as velocity, density, viscosity, etc., the movement of the fluid depends, another method for deriving the model rules can be applied. This is by making use of the dimensions of the physical quantities. (Ref. 11.)

It must be possible to express every physical law in a form free from the special applied system of physical units—in other words, in a form where only pure, i.e., dimensionless, figures appear. This raises the question: In what manner is it possible to combine the physical quantities essential for the flow such that this combination will be a dimensionless product?

In the case of air flow[3] or of water without free surfaces where gravity does not have to be considered, the streamline conception depends on the following four quantities: the linear dimension L, the velocity V, the mass density ρ, and the viscosity μ. Therefore in the expression

$$L^\alpha \times V^\beta \times \rho^\gamma \times \mu^\delta$$

the exponents α, β, γ, δ have to be so determined that this expression will be dimensionless; or

$$[L^\alpha \times V^\beta \times \rho^\gamma \times \mu^\delta] = l^0 \times t^0 \times f^0 = 1$$

where l is the unit of length, t the unit of time, and f the unit of force.

Since a dimensionless product remains dimensionless if raised to any power, one of the exponents, for instance, α, is arbitrary and can be assumed equal to unity.

Taking into account the dimensions of the physical quantities

$$[L] = l \qquad [\rho] = \frac{ft^2}{l^4}$$

$$[V] = \frac{l}{t} \qquad [\mu] = \frac{ft}{l^2}$$

the preceding equation may be written as

$$\frac{l \times l^\beta \times f^\gamma\ t^{2\gamma} \times f^\delta\ t^\delta}{t^\beta \times l^{4\gamma} \times l^{2\delta}} = l^0 \times t^0 \times f^0.$$

By equating the exponents of like dimensions the following equations are obtained:

$$\begin{aligned} 1 + \beta - 4\gamma - 2\delta &= 0 \\ -\beta + 2\gamma + \delta &= 0 \\ \beta + \delta &= 0 \end{aligned}$$

from which it follows that

$$\beta = 1, \gamma = 1, \delta = -1$$

or

$$\left[\frac{\rho VL}{\mu}\right] = 1$$

i.e., the Reynolds number represents the only possible dimensionless combination of the physical quantities L, V, ρ, and μ.

In a similar manner, Froude's number could be derived. In this case, however, the essential physical quantities are only the linear dimension L, the velocity V, and gravity g, and it is realized at once that V^2/Lg or $V/\sqrt{Lg}$ is the only possible combination of the physical quantities in question which is a pure number.

If a body moves through still air with a velocity close to or even higher than the acoustic velocity, or if a gas flows through a nozzle with a velocity exceeding the acoustic velocity, it is necessary to take the compressibility of the gas into account. This must be done because of the fact that such high velocities are combined with very large pressure differences, and these latter in turn alter the density, which was hitherto assumed constant throughout the gas. The rate of change in density due to a pressure difference is expressed by the modulus of elasticity.

For a flow of gas where the velocity is close to or exceeds the acoustic velocity but where the viscosity forces can be neglected, the physical quantities that have to be considered as essential[4] are the velocity V, the mass density ρ, and the modulus of elasticity E.

From the equation

$$[V \times \rho^\beta \times E^\gamma] = l^0 \times t^0 \times f^0$$

the relation

$$V\sqrt{\rho/E} \quad \text{or} \quad V/\sqrt{E/\rho}$$

can be obtained. The quantity $\sqrt{E/\rho}$, however, represents the acoustic velocity a.

Two flows of gas close to or exceeding the acoustic velocity are therefore mechanically similar if in both cases the ratio V/a is the same and provided the viscosity forces can be neglected.

III—VARIOUS LAWS OF SIMILARITY

As mentioned earlier, the application of a special law of mechanical similarity depends in a particular case entirely on the forces which determine the flow.

In Fig. 5 an endeavor has been made to present in a simple way the more important laws of mechanical similarity and their relations to the forces in question. In addition to the laws mentioned there are still further ones which involve other forces, e.g., capillary forces and forces encountered in thermodynamics.

However, it must be borne in mind that the conditions for the flow of a gas or of a liquid are not always as simple as has been shown. Quite often the flow depends not only on one of the laws of similarity mentioned, but on two, or even three.

A striking example of this is the fluid resistance of a ship. This resistance consists mainly of frictional resistance due to viscosity forces and of wave resistance due to the gravity force. Hence the ship resistance will depend on the Reynolds number and on Froude's number at the same time. While the Reynolds number involves the necessity of a higher velocity for the model, this velocity should be reduced according to Froude's number. It is therefore impossible to determine the frictional resistance and the wave resistance by testing small-scale ship models.

Theoretically, it is possible to combine both laws of similarity by using two different liquids for the model and ship. In practice, however, this is of no importance since there are no liquids available which have sufficiently different kinematic viscosities.

Similar difficulties arise when the performance of an airplane propeller is to be determined by models in cases where the tip speed of the full-sized propeller approaches or reaches the acoustic velocity. Here the flow around the blades, and therefore the performance of the propeller, depends on the Reynolds number and at the same time on Mach's number. In this case it is rather more important to have the same Mach number for the model and for the full-sized propeller than the same Reynolds number.

---

[3] Provided the velocities are low compared with the acoustic velocity.

[4] To be exact, it may be mentioned that for model tests c_p/c_v must be the same for the model as for the full-sized structure.

In regard to the last two examples of fluid flow, some doubt may arise as to the reliability of certain model tests in which but one of the two laws of mechanical similarity involved can be fulfilled, whereas the actual flow may depend on both. In such cases the law on which the flow in question most depends is to be determined, after which it is necessary to investigate by experiment whether any other law which should be taken into consideration may be neglected or not.

In this connection attention may be drawn to a point not hitherto mentioned: Regarding those flows which depend entirely on inertia and friction forces, one can be sure to have mechanical similarity if the Reynolds number is in both cases the same. If not, however, one cannot say that these flows necessary differ widely from each other, for there are quite a number of cases where even for a wide range of Reynolds numbers the flows are practically identical.

Fig. 5 The More Important Laws of Mechanical Similarity and Their Relations to the Forces Involved

This may be explained more clearly by an example. The resistance of a body moving through still air or of a body at rest in an airstream traveling at a certain velocity, is usually expressed in the following form:

$$\text{Resistance} = cA\,\frac{\rho}{2}\,V^2$$

where A is the projected area of the body, ρ the mass density of the fluid, and V the relative velocity of the fluid with respect to the body. The coefficient of resistance c, which is a dimensionless figure, depends first of all on the shape of the body, as well as on the configuration of the streamlines around the body, i.e., on the Reynolds number. Therefore it can be said that the coefficients of fluid resistance for bodies of geometrically similar shape are equal if the Reynolds number in each case is the same. However, if the Reynolds number is not the same, it cannot be said that in this case the coefficient of fluid resistance would necessarily be different; it can only be said that there is no certainty in the matter, and that it can be decided only by tests.

In order to show this, the relation between the coefficient c and the Reynolds number may be considered for a simple body, say, for a long cylinder of circular cross-section, this cross-section being parallel to the flow. In Fig. 6 the value of c is shown as a function of $R = dV/\nu$, where d is the diameter of the cylinder. It is seen that for a certain range of values of R the coefficient c varies considerably with R, while for other ranges c is almost constant. The range of Reynolds numbers of practical interest is enormously wide, in the present case up to about 8×10^5. In the ordinary manner of plotting, the region of smaller Reynolds numbers (up to about $R = 10{,}000$) is so contracted that no details of the curve can be recognized. In order to circumvent this difficulty it has been found practical to plot the logarithms of the drag coefficients as well as of the Reynolds numbers instead of the quantities themselves. Another way is to plot the drag coefficient and the Reynolds number on logarithmic paper. Fig. 7 shows the curve of Fig. 6 replotted in this manner.

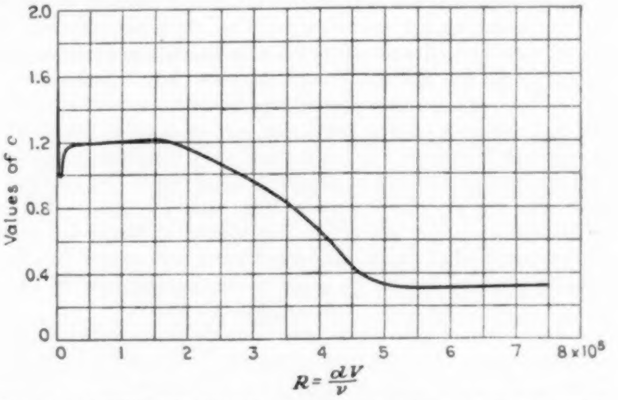

Fig. 6 Coefficient of Air Resistance for a Long Cylinder as a Function of the Reynolds Number

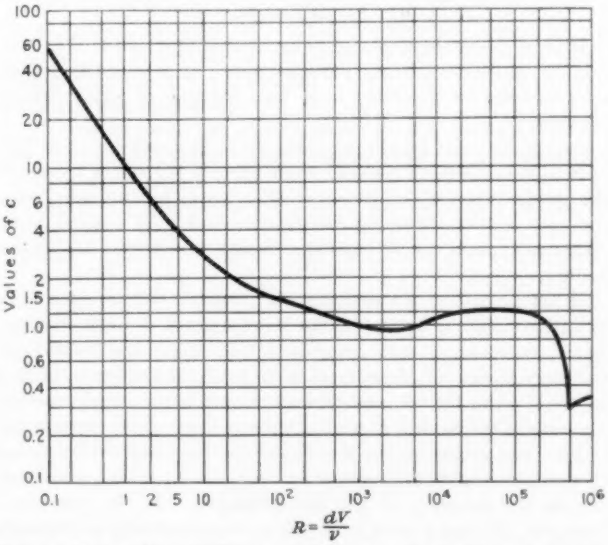

Fig. 7 The Same Curve as in Fig. 6, but Plotted on Logarithmic Paper

From both curves it is seen that, within certain ranges of Reynolds' numbers, model tests made at much smaller Reynolds' numbers can be reliably applied in full-scale practice.

The use of model tests would be considerably restricted were it necessary in every case to observe exactly the laws of similarity. This however, holds only for the Reynolds number. It is therefore often permissible to make model tests at Reynolds numbers which are quite different from those of the full-sized structure, and it is only necessary to make sure that there is no abrupt change in the kind of flow between the Reynolds number of the model test and that of the actual flow.

What is true for the Reynolds number, however, is not to the same extent true for the Froude and Mach numbers. Here it is usually much more important to fulfil exactly the conditions of mechanical similarity.

Reverting to the example of the model of a high-speed airplane propeller, the tip speed of which may be, for instance, 0.8 of the acoustic velocity a, it is necessary to have the same tip speed of 0.8 for the model notwithstanding the fact that the Reynolds number may be much smaller owing to the smaller blade size.

In the opinion of the author, the following statement deserves more attention than it generally receives. It is not sufficient in model-testing practice merely to know on which law of mechanical similarity the flow in consideration depends; but it is also necessary to have at least some general idea as to the manner in which the flow depends on the particular law or laws of similarity. If one were to endeavor to meet exactly the requirements of the various laws of mechanical similarity involved in the problems that come up, but very few model tests could be made. It may be mentioned in this connection that almost all the model tests carried out in wind tunnels and which have been proved so valuable for airplane design, are made at considerable smaller Reynolds numbers than those of the full-sized structure.

A knowledge of the various laws of mechanical similarity is an essential feature of model-testing practice, but experience of many years in the application of these laws is another feature which is certainly not of less importance.

IV—SPECIAL APPLICATIONS

(a) Fluid Resistance

It is of course beyond the scope of this short survey to present the subject with any completeness. It is only thought to refer to some of the more important features of model-testing practice.

One of the most important problems in hydrodynamics is that of fluid resistance. However, since there is no theory by which the fluid resistance, or the drag of a body, can be calculated, the only way of obtaining the data desired is by making tests. Numerous problems of airplane design are solved by model testing.

In the early days of aviation quite a number of tests were made in natural wind or by towing the test specimen through still air.[5] Later, however, it was recognized that there are several advantages in making these tests in an artificial airstream, or in a so-called wind tunnel, and nowadays this is the usual practice. By testing the models in a wind tunnel, the various components of the force acting on the test model can be measured by means of sensitive scales, and plenty of time can be taken, which improves the accuracy of the measurements. In the free wind, however, all results have to be taken from recording instruments which are inherently less accurate. This is due to the fact that the natural wind is always more or less gusty. Another advantage of the wind-tunnel method compared with testing in the natural wind is the possibility of locating all measuring instruments outside the airstream, while the test model itself is held in place therein by means of thin wires or struts. Because of this, the errors arising from the fact that the airstream is affected not only by the test specimen but also by its support, are reduced to a minimum.

If the velocities of the flow under consideration are low compared with the acoustic velocity, permitting the neglect of compressibility, gases can be treated like liquids. In this case, Reynolds' law of similarity has to be taken into account.

It has been found, however, that for certain cases where an especially high accuracy is desired, the results obtained by model tests do not always quite agree with tests made with the full-sized structure. This is due to the fact that usually the model tests are made at a considerable smaller Reynolds number, although it may be taken for granted that they are not carried out in any critical region of the Reynolds number. This departure of the results obtained from model tests from those of full-sized tests is known as the "scale effect."

In order to reduce this scale effect, the general trend in wind-tunnel practice is to obtain larger and larger Reynolds' numbers.

Different methods for obtaining sufficiently large Reynolds numbers have been used, primarily in connection with research work for aviation. One method consists in using water instead of air. Due to the fact that the kinematic viscosity of water is about one-fifteenth of that of air, the Reynolds number is 15 times larger provided the same velocity and linear dimensions are used. A disadvantage of this method, however, is the enormous power required to move a large amount of water with a sufficiently high velocity. Another and better way is to use compressed air. The kinematic viscosity of air under a pressure of, say, 15 atm. is about one-fifteenth of its normal value, so that the Reynolds number becomes 15 times as large. This method naturally involves great structural difficulties since the entire installation has to be able to withstand an internal pressure of 15 atm. In order to avoid these difficulties, wind tunnels are being developed with larger dimensions, which in turn makes possible the testing of larger models, and, therefore, at larger Reynolds' numbers. In the largest wind tunnel, which is installed in Langley Field, Va., the airstream has a cross-sectional area of about 1300 sq ft.

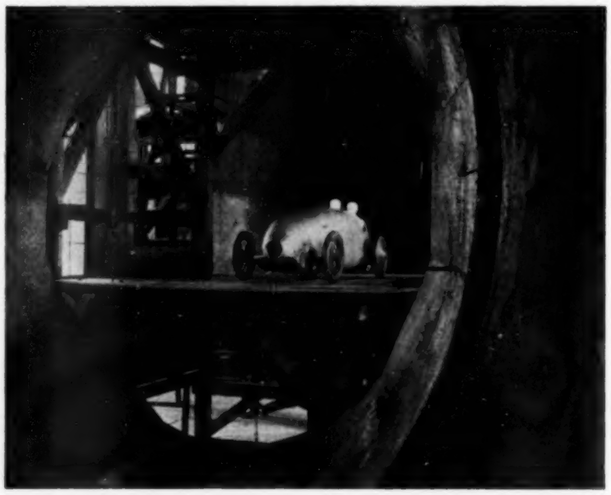

Fig. 8 Arrangement of a Racing-Car Model in a Wind Tunnel

Generally, an attempt should be made to present the data of any experimental work in dimensionless quantities whenever possible. In model-testing practice it is absolutely necessary.

Air forces acting on various bodies, as, for instance, the drag and lift of airplane wings, the drag of airships, as well as the air resistance of vehicles such as trains and automobiles, are usually expressed in the following form:

$$\text{Air forces} = c \times A \frac{\rho}{2} V^2$$

$$c = f\left(\frac{LV}{\nu}\right) = f(R)$$

---

[5] For drag measurements in water, primarily in connection with the problem of ship resistance, this method is still used successfully.

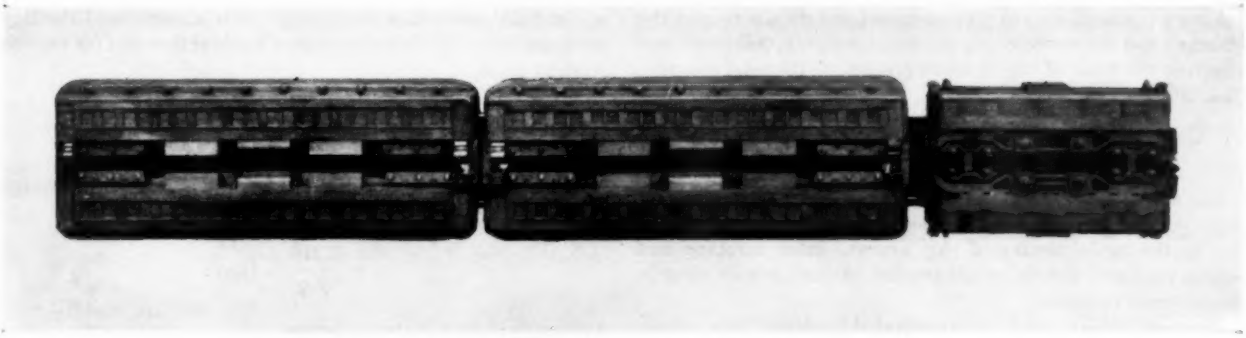

FIG. 9 MODELS OF A PRESENT-DAY TYPE OF TRAIN AS ASSEMBLED FOR TESTS

where A is a characteristic area, ρ the mass density, and V the relative velocity of the air with respect to the body.

Air pressures, or more generally, fluid pressures, are proportional to the dynamic pressure:

$$\text{Air pressure} = k \times \frac{\rho}{2} V^2$$

The dynamic pressure $\rho V^2/2$ is usually taken as the pressure unit, and the various pressures in consideration are expressed in fractions thereof.

Regarding the measurements of air resistance of *vehicles* by model tests in a wind tunnel, some difficulties arise in the satisfactory representation of the ground and track. The ideal method would be to have the ground move below and close to the models with a speed equal to that of the air in the wind tunnel. This could be done by means of an endless belt. However, in general, it is sufficient to have an arrangement which insures that the streamlines below the vehicles are horizontal and parallel to the track. This condition can be approximately obtained by two methods.

In the first method a thin, smooth, and sharp-edged flat plate is rigidly fastened below and fairly close to the wheels of the vehicle, avoiding, of course, any actual contact. Fig. 8 shows such a set-up for testing the air resistance of a racing car. (Ref. 18.)

A second method is the so-called "mirror method." In constructing the model of the vehicle, a duplicate has to be made and assembled, as shown, for example, in Fig. 9 for the model of a train. The air flow around this assembly has a plane of symmetry at the surface where the ground would be for an actual train. This plane of symmetry or of an imaginary ground preserves closely the character of the flow lines occurring with an actual train. From the resistance obtained in testing these assembled duplicates, of course, only half is to be taken for the resistance of a single model. (Ref. 19.)

In testing the *wind pressure on structures* like buildings, bridges, etc., the velocity distribution of the wind in the vertical direction must be taken into account. At the ground the wind velocity is zero, but it increases very rapidly with increasing distance from the ground. For a fairly level ground the wind velocity increases as the $^1/_7$th power of the distance from the ground. The pressure on particular parts of the structure, e.g., on the walls and roof, depends on the shape of the structure as a unit and cannot be determined separately. If other buildings are in the neighborhood of the structure under consideration, their possible influence has to be taken into account. It may be mentioned that suction forces, primarily on roofs of buildings, can exceed considerably the pressure forces.

In model tests to determine the *wind pressure on ships*, the velocity distribution of the wind in the vertical direction must also be considered.

(*b*) PROPELLERS AND FANS

The most important condition to insure mechanical similarity in testing small-scale *airplane and ship propellers* is that of having the same value of $V/D\omega$ for both model and full-scale propeller, where V is the speed of advance of the propeller, ω the angular velocity, and D the diameter of the propeller.

In addition to this the Reynolds number should be the same, and in case the tip speed of the full-scale propeller is near to the acoustic velocity a, the ratio $D\omega/a$ should be the same for both model and prototype.

Provided the tip speed is less than half the acoustic velocity, the compressibility of the air may be neglected and the model tests can be applied to full-scale practice.

In general, it is always possible to obtain the same value of $V/D\omega$ for both the model and full-scale propeller; however, it is usually not very easy to obtain also the same Reynolds number. A possibility for obtaining the same Reynolds number would consist in using a medium of lower kinematic viscosity, for instance, compressed air.

In order to avoid any possible scale effect, a special wind tunnel was built a few years ago at Langley Field, Va., in which full-size propellers can be tested.

The thrust and torque are usually expressed by the following equations:

$$\text{Thrust} = T = c_T \frac{D^2\pi}{4} \frac{\rho}{2} V^2 = k_T \frac{D^2\pi}{4} \frac{\rho}{2} (D\omega)^2$$

or

$$\text{Torque} = Q = c_Q \frac{D^2\pi}{4} \frac{D}{2} \frac{\rho}{2} V^2 = k_Q \frac{D^2\pi}{4} \frac{D}{2} \frac{\rho}{2} (D\omega)^2$$

Therefore the efficiency η of a propeller can be written:

$$\eta = \frac{T \times V}{Q \times \omega} = \frac{c_T}{c_Q} \frac{V}{D\omega} = \frac{k_T}{k_Q} \frac{V}{D\omega}$$

For a *fan*, the conditions regarding mechanical similarity consist mainly of having the same Reynolds number. However, here, as well as in the case of airplane propellers, it is not very likely that any objectionable scale effect will be encountered.

The volume delivered by a fan is given by the equation

$$\text{Volume} = \varphi \times A \times u$$

where A is a characteristic area, for instance, the discharge area of the fan, and u the peripheral speed.

The total pressure, i.e., the sum of static pressure and dynamic pressure, is usually expressed by the equation

$$\text{Total pressure} = P_s + P_d = \psi \times \frac{\rho}{2} u^2$$

A very practical way to present model test data is to plot the efficiency and the coefficients φ and ψ against φ^2/ψ, this latter representing the ratio of the dynamic pressure to the total pressure. (Ref. 20.)

(*c*) CAVITATION IN SHIP PROPELLERS, WATER TURBINES, AND PUMPS

The considerations set forth regarding the model testing of airplane propellers and fans can be employed without modification in the model testing of ship screws, water turbines, and pumps, provided there is no danger that cavitation may occur in the full-sized machine.

However, if this is just to be investigated by model tests, certain model rules have to be taken into account with respect to similarity regarding the occurrence of cavitation. Three methods can be applied:

1 Variation of the pressure heads
2 Equality of the peripheral speed
3 Increase of the water tension by increasing the temperature.

1 If H_a denotes the water head corresponding to the atmospheric pressure minus the water tension, and if H_s is the suction head and H the total head, the expression

$$\frac{H_a - H_s}{H} = \sigma$$

must be the same for both model and prototype. (Ref. 22.) The smaller σ is, the greater the danger of the occurrence of cavitation. Since H is proportional to $u^2/2g$, where u is the peripheral speed of the machine, the above expression can also be written as

$$\frac{H_a - H_s}{u^2/2g} = \sigma'$$

This model rule can be easily derived from Froude's law of similarity, which has to be taken into consideration because of the predominant importance of the formation of free surfaces. (Ref. 21.)

2 Another method for obtaining similarity as regards cavitation is to have the peripheral speed of the model equal to that of the full-sized machine. This, however, involves a very high rpm and necessitates a full-sized construction because of using the same pressure and suction head in the model as in the full-sized machine.

3 A third possibility of obtaining similarity with respect to cavitation consists in increasing the water tension by heating the water. This method, although rather inconvenient in practice, would have the advantage of providing a larger Reynolds number owing to the smaller kinematic viscosity of hot water.

(*d*) FLOW THROUGH PIPES AND CHANNELS

These flows are governed throughout by the Reynolds number, at least to the extent that the velocities are not comparable in magnitude with the acoustic velocity.

The question of interest is, generally the pressure drop along pipe lines or at elbows, or the pressure drop occurring with changes of the cross-sectional area, as for instance, in nozzles and orifices. These matters are of vital importance for the construction and calibration of flowmeter devices.

The pressure drop is generally expressed in the following form:

$$p_2 - p_1 = \lambda \times \frac{l}{d} \times \frac{\rho}{2} V^2$$

where $p_2 - p_1$ is the pressure difference at two points separated by the distance l, d is the diameter of the pipe, V the average velocity of the fluid, and ρ its mass density. λ is a function of the Reynolds number. Within the range of laminar flow and for smooth, straight pipes,

$$\lambda = \frac{64}{R}, \quad \text{where} \quad R = \frac{dV}{\nu} < 1200$$

Within the range of turbulent flow, and for smooth, straight pipes,

$$\lambda = \frac{0.316}{\sqrt[4]{R}} > 1600$$

For rough pipes, λ is always larger.

The coefficient of flow resistance ζ for elbows, throttles, etc., is usually expressed in terms of $\rho V^2/2$ and therefore

$$\text{Pressure loss} = \Delta p = \zeta \times \frac{\rho}{2} V^2$$

There are still two other extensive fields of model-testing practice which really should belong to hydrodynamics: namely, problems concerned with flows in river beds, over weirs, through sluices, etc., and those concerned with ship resistance. However, due to the importance of these problems, they are being specially dealt with in other papers of this symposium.

In closing, the author would again emphasize that it is not sufficient to find out on what various laws of similarity a given flow exactly depends, since it is generally impossible to fulfil the necessary requirements. In practically all cases a compromise has to be made. That law of mechanical similarity which is of essential importance has to be taken into account, while the others may have to be neglected; and only through extended experience can the knowledge be obtained to judge in a particular case which one should be considered and how far it is permissible to neglect the others. This is one of the most difficult sides of experimental practice in aerodynamics and hydrodynamics.

Air Resistance of High-Speed Trains and Interurban Cars

By O. G. TIETJENS[1] and K. C. RIPLEY,[2] EAST PITTSBURGH, PA.

In this paper a study is made of the economics possible by reducing air resistance of high-speed passenger trains and interurban cars. A critical survey is given of the train-resistance formulas used hitherto and of the various methods of determining the coefficients of these formulas. It is shown that the general ideas on which the train-resistance formulas are based have to be corrected according to the more modern aerodynamic conceptions on air resistance.

Data on the air resistance of train models of various shapes recently obtained in the Westinghouse wind tunnel are given in a number of curves. The methods employed and the experiment set-up are fully described. It is shown that a considerable reduction of air resistance of the present types of trains and interurban cars can be obtained by streamlining.

The fundamental laws of air resistance are stated, and it is shown on what air resistance mainly depends. The importance of the critical Reynolds number is explained, particularly in connection with the reliability of model tests. A striking example is given showing how, by means of streamlining, the air resistance of a body can be reduced to 1/20 of its original value. A more rational method of determining the total resistance of trains and interurban cars is given, and it is shown that the streamlining of present-type cars for high-speed service is more justifiable from an economical standpoint than the streamlining of the fuselage of an airplane.

O. G. Tietjens

ONE of the important advantages of the railroad train over the bus is its higher speed. Some American trains have schedule speeds of as high as 50 m.p.h. between important cities, and most of the limited trains travel at about 40 m.p.h. On the other hand, the schedule speed of buses in intercity travel reaches nowadays almost 30 m.p.h. or only 25 per cent less than that of the average limited train. This difference in train and bus speeds is illustrated in Fig. 1 by time-scale maps for travel in the United States.

However, after super-highways have been built between the larger and more important cities, there is no reason why the schedule speed of buses cannot be increased to 40 m.p.h. or even higher. This can be done, and without further increase in the power required, by streamlining the shape of the buses. The next important step in the development of bus transportation will likely be in this direction, and it will probably be taken within the next few years. Then the competition of the bus will truly become of vital importance to the railroad.

The speed of almost every means of transportation has been increased immensely during the last two decades. If we think of the automobile of 20 or even 10 years ago, what a change and improvement. The same holds for the airplane; and also the speed of ocean liners is seen to have been increased considerably when we compare the record of 4 days 19 hours for crossing the Atlantic with the time required 30 years ago.

K. C. Ripley

What can be said about the railroad and its endeavor to improve its speed? As early as 1845 a record of 45 miles in 52 minutes was made in England. At one time the train was proceeding at the rate of one mile in 48 seconds, or "at the astonishing velocity of 75 miles an hour." In the same year the *American Railroad Journal* said:

> The other day on the London and Birmingham and on the Great Northwestern Railway a rate of 65 miles an hour was accomplished. The express trains on these lines run at the rate of nearly 50 miles an hour, stoppage included.

This happened more than 80 years ago, and although these records must of course be considered as exceptions, what efforts to increase the speed of trains can be put alongside those made in the cases of ships, automobiles, and airplanes? One remarkable attempt was made a little more than 30 years ago in Zossen, Germany, with the result that with a very heavy and powerful electric locomotive speeds up to 130 m.p.h. were obtained. After having made several runs, however, the rails were spoiled, and the results of the tests offered little encouragement to increase train speed above a certain rate which had been proved to be safe.

Several years ago the matter of designing a new train or coach for high-speed service was again taken up in Germany. This time an endeavor was made to obtain the high speed by decreasing the train resistance rather than by increasing the motive power, as was done in the Zossen tests mentioned. The results of tests recently made with a new type of railway coach, designed by Fr. Kruckenberg, and having a small total resistance, proved that in their method the investigators are on the right track. The fact that this coach is driven by a modified airplane propeller is, with respect to the speed obtained, only of minor importance.

The new coach is light in weight (20.6 tons), low in center of gravity, and streamlined, all of which are departures from conventional railway practice. The speed made on an actual run

[1] Research Laboratories of the Westinghouse Elec. & Mfg. Co. Mem. A.S.M.E. Dr. Tietjens was educated in Germany at the University of Göttingen, where he studied mechanics, hydrodynamics, and aerodynamics under Dr. L. Prandtl. In 1922 he received the degree of Ph.D., after which he was for five years an assistant to Dr. Prandtl. Since January, 1929, he has been connected with the research laboratories of the Westinghouse Company, where he is now in charge of hydrodynamics and aerodynamics.

[2] Research Laboratories of Westinghouse Elec. & Mfg. Co. Jun. A.S.M.E. Mr. Ripley received his bachelor's degree in mechanical engineering from the University of Arkansas in 1927. Since then he has been with the Westinghouse Elec. & Mfg. Co., where he has completed the graduate student course in its mechanical-design school.

Contributed by the Applied Mechanics Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of 173 miles between two large cities was 106 m.p.h. with a top speed of 143 m.p.h., and the run was better by four minutes than the regular passenger-airplane time.

One of the most interesting facts regarding this new German high-speed train is its low energy consumption per mile, chiefly due to its streamlined shape. The coach, carrying 50 passengers, travels 4 miles to the gallon of gasoline. How good an economy this is will be appreciated when it is stated that the power required for coaches of the present type varies almost as the cube of speed; so that an increase of speed from 40 m.p.h to 100 m.p.h. means a more than tenfold increase in the power required for a coach of a given shape and weight.

If the train is to undertake to compete with the airplane in speed, as seems now to be the next logical development, it is important that the railroads give attention to the design considerations that make the high-speed operation of trains possible without appreciable sacrifice in safety and economy. If the railroad companies do seriously consider this matter of high-speed operation of trains, they will need to evolve some new type of streamlined, light-weight train, and probably make even other radical departures from present practice.

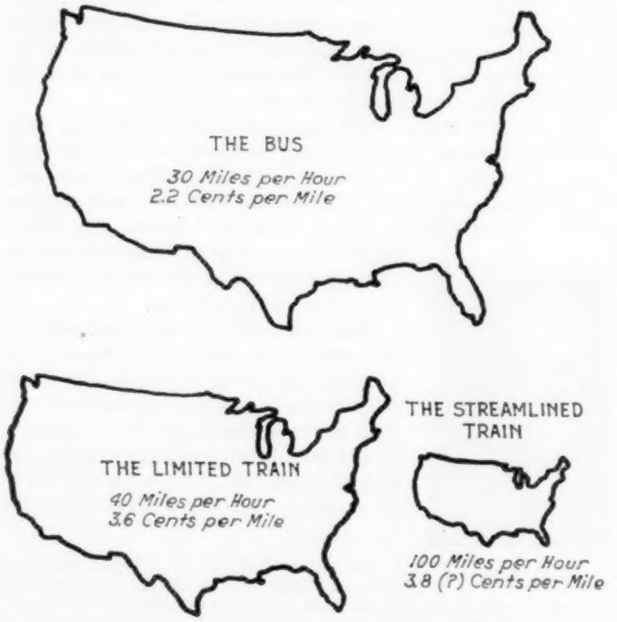

Fig. 1 Time-Scale Maps for Travel in the United States

The effect that an increase in the schedule speed of trains to 100 m.p.h. would have upon the time-scale map for travel in the United States is shown in Fig. 1, and—to anticipate—the cost of this increase in speed to the passenger per mile is also shown in this figure as the difference between the present base rate of 3.6 cents per mile and the new rates, estimated on what is believed to be a conservative basis of distribution of the burden, of 3.8 cents per mile, or less than 6 per cent.

However, even if it be considered inadvisable to increase the speed of trains at the present time, it will be shown later that with existing speeds air resistance is the predominant factor, and that from an economical standpoint streamlining of our fast trains is justified, as is also that of some of our high-speed interurban cars.

For sake of brevity, consideration of the problem of air resistance will be confined here mainly to the case of a train of fixed length—given by that of a locomotive and six coaches—and to that of a single car, as used in frequent schedule service, such as on interurban lines.

I—Train-Resistance Formulas

Those acquainted with train-resistance work are familiar with some of the common train-resistance formulas that agree in showing one part of the resistance as a function of the weight of the cars in the train, and a second part as a function of the shape and size of the train, assuming a straight, level track. The resistance mainly due to weight is commonly called the frictional resistance, and that due to shape and size, the air resistance. The frictional resistance comprises several items, as, for instance, journal, rolling, and track resistance, and wheel-flange friction, which latter, however, does not depend on weight. However, being here interested only in the air resistance and its relative importance to the total resistance, the authors will not consider the separate items of the resistance due to weight, but will include them under the general terms "frictional resistance."

Extensive experimental tests on the resistance of standard types of trains of various weights have been made during the past 30 years. Although the results of these tests differ considerably from each other, they agree that the resistance of a train depends chiefly on its weight and speed. Plotting the resistance for trains of different weight as a function of the speed, it was obvious that the relation obtained could be approximated by a formula such as

$$R = A + BV + CV^2 \dots\dots\dots\dots\dots [1]$$

where A and B are functions of the weight, C a function of the size and the shape of the train, and V the speed of the train.

In what follows, the sum of the first two terms will be called the frictional resistance; the third term, depending on the square of the speed, represents the air resistance.

Without exaggeration, one may say that there are almost as many formulas similar to Equation [1] as there are series of tests. J. A. F. Aspinall, in his famous paper on train resistance,[3] gives a list of 55 train-resistance formulas, including five of his own, and C. O. Mailloux,[4] in his discussion on "Problems of Heavy Electric Traction," estimates the number of train-resistance formulas to be 200 or more. It is not intended to discuss even the more important of these formulas. Mr. Mailloux, in the discussion mentioned, points out the following:

> It may be said of many of the train-resistance formulas that they give results close to actual practice in some specific case; at some particular speed, with a certain kind or length of train, or under other peculiar conditions; but not one of them fits all cases, even approximately, as becomes painfully evident when one sees the way in which the curves wander over the curve sheet when plotted together in the same sheet and according to the same scale.[5]

It has been proposed[6] to develop an average curve by using all experimental data available, or in other words to establish an equation with unknown coefficient and to determine this coefficient by means of all test data available. This, of course, is possible; however, it should be realized that such an "average curve" has only slight value due to the fact that the special features of the train corresponding to this curve—the "average train," so to speak—are not known.

It is therefore obvious that it is necessary to do more than merely introduce a new set of coefficients in Equation [1] in order to accomplish something representing a material advance in our methods of dealing with train resistance in railroad engineering.

[6] E. H. Croft, "Railway Track Resistance," *Electrical Review* (1929), p. 349.

If it is impossible, as will be seen later, to devise a single general formula giving the train resistance with sufficient accuracy, one may rightly be of the opinion that there is not much need for a formula which is so simple that one can calculate in a moment the resistance, but with only ± 50 per cent accuracy. It would be much better to investigate the fundamentals of train resistance. The data obtained by such studies would make it possible to predict with reasonable accuracy the power required. Instead of calculating the total resistance by using one of the many train-resistance formulas, it would be much safer to determine each portion of the total resistance separately, as, for instance, the journal resistance or the air resistance, taking into consideration the particular features of the train.

Considering for a moment the frictional resistance, the first two terms of Equation [1], we may mention the values of A and B as determined by A. H. Armstrong and H. J. Davis. According to Armstrong,

$$A = C_1 \sqrt{W} \quad \text{and} \quad B = C_2W$$

where C_1 and C_2 are constants and W is the weight of the train.

W. J. Davis,[7] in his valuable paper on "The Tractive Resistance of Electric Locomotives and Cars," gives a somewhat more complicated value for A, namely,

$$A = C_1\,(1 + C_2W) \quad \text{and} \quad (B = C_3W)$$

for axle weights in excess of 5 tons, and

$$A = C'\,(1 + C''\sqrt{W}) \quad \text{and} \quad (B = C_3W)$$

for axle weights of less than 5 tons.

These coefficients for the frictional resistance, though of different form, do not give very divergent results. This is mainly due to the fact that for different trains the construction of the bearings, wheels, and tracks is rather similar. The largest uncertainty in train resistance lies in the air resistance.

The coefficient C in the third term of Equation [1], which term represents the air resistance, is usually assumed to be proportional to the cross-sectional area A_1 of the train: or

$$\text{Air resistance} = C' \times A_1V^2$$

Considering the dimensions in this equation, it will be seen that the coefficient C' is proportional to the ratio of the specific weight γ of the air to the specific gravity g, or $C' = c(\gamma/g)$. In other words, the air resistance will vary directly with the density of air. This fact has been very often neglected. In cold weather and with a high barometric pressure, however, the specific weight of the air may be 15 per cent larger than in hot weather and with a low barometric pressure. The coefficient C' determined by air-resistance tests made with trains operating under different weather conditions may therefore vary as much as 15 per cent if the difference of the specific weight of the air has not been taken into account.

Therefore, as is common in aerodynamics, we may write:

$$\text{Air resistance} = c\,\frac{\gamma}{2g}\,A_1V^2 \ldots\ldots\ldots\ldots\ldots [2]$$

This coefficient c by which the air resistance is determined for a train of a given cross-sectional area A_1, moving with a certain speed through quiet air of specific weight, depends largely on the shape of the train. There is no theory by which this coefficient can be calculated, the only way of determining it for trains of different shapes being by tests.

In some train-resistance formulas the resistance of additional coaches is expressed as a percentage of the air resistance of the locomotive and for long trains this can be done without error. The coefficient c in Equation [2] is then split up in a number of coefficients:

$$c = c_0 + c_1 + c_2 + \ldots\ldots + c_n$$

where c_0 represents the coefficient of the locomotive and c_1, c_2, ...c_n the coefficients of the n coaches. It must be understood, however, that the coefficients $c_1 \ldots . c_n$ do not refer to a single isolated coach, but to the coaches considered as parts of a train. For long trains there is little difference between the coefficients of the different coaches, so that we may write

$$c = c_0 + n\,c_1$$

However, it must be emphasized that the manner in which c is split into the two parts c_0 and c_1 holds only for a particular kind of train and therefore cannot be used in a general formula for different trains, even though the trains should accidentally have the same c.

It is very often proposed to divide the total air resistance into one portion due to the front pressure, another due to the rear suction, and a third due to skin friction. This distribution is hardly practicable, especially since the third portion, due to what is called skin friction, actually consists also of a kind of pressure resistance because of the space between adjoining coaches.

In the authors' opinion it is much more advisable, instead of seeking vainly for a few coefficients applicable to all kinds of trains, to investigate the fundamentals of air resistance. Systematic tests with trains of different shapes would show us on what it depends. Such experiments would teach us how we might change the shape of locomotives and coaches without changing the air resistance, and, on the other hand, what changes of the shape would influence the air resistance. The information gained in this way would put us in a much better position to predict the air resistance of a train than that of using train-resistance formulas based on front pressure, etc.

In this respect, much can be learned from aviation engineers. They have no airplane-resistance formulas, but have had an extended experience with air resistance in general. Numerous tests have been made by using wind tunnels, and if the need arises for an air-resistance coefficient of, say, a new fuselage, they will very likely find tests that have been made with a fuselage similar in shape and which will give a coefficient of sufficient accuracy.

If it is agreed that investigations should be made to clear up the still obscure point of air resistance of trains, there is the question of which method is the most suitable. Here again we may ask the aviation engineers for their advice. Generally speaking, there are two methods of testing: one using actual trains moving through quiet air, and the other employing models of trains in wind tunnels. Both methods have their advantages and both were used in earlier days by aviation engineers. However, it was found that the latter method, of using wind tunnels, was not only more convenient but also more exact, and nowadays practically all the tests on airplanes and airships are made with models in wind tunnels.

The main objection to the method of using actual trains is that the total resistance is first determined and the air resistance then figured as the difference between this total resistance and the frictional resistance determined in a different way. Further, it is very seldom possible to have sufficiently quiet air on the day the tests are being made or a wind of constant uniformity. Even a scarcely perceptible wind of 3 m.p.h. will increase the power required to overcome air resistance about 20 per cent, assuming a speed of 50 m.p.h., and will increase the power required about 50 per cent assuming a speed of 20 m.p.h. This can be easily seen if we take into account that the power required to overcome air resistance varies with the third power of the speed:

---

[7] *General Electric Review*, vol. 29 (1926), p. 685.

$$\frac{53^3 - 50^3}{50^3} \times 100 = 20\% \text{ and } \frac{23^3 - 20^3}{20^3} \times 100 = 52\%$$

The speed of the air in wind tunnels, on the other hand, can easily be kept constant to within 1 per cent.

II—WIND-TUNNEL TESTS ON TRAINS AND INTERURBAN CARS

When the senior author came to the United States about three years ago in order to organize research work on hydrodynamics and aerodynamics at the Westinghouse Electric & Manufacturing Co., East Pittsburgh, he soon realized the great importance of faster transportation in this country. Finding that concern closely connected with the railway business, the

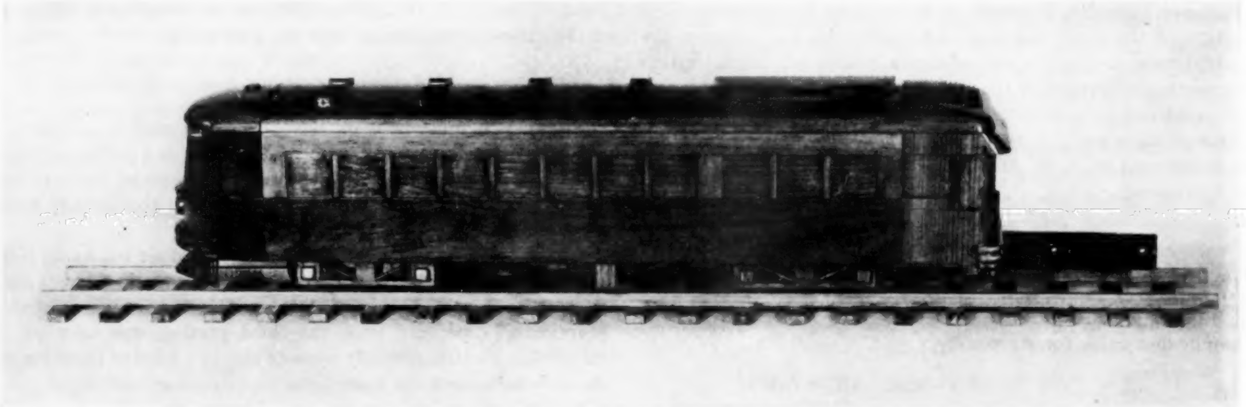

FIG. 2 MODEL OF A PRESENT-TYPE INTERURBAN CAR

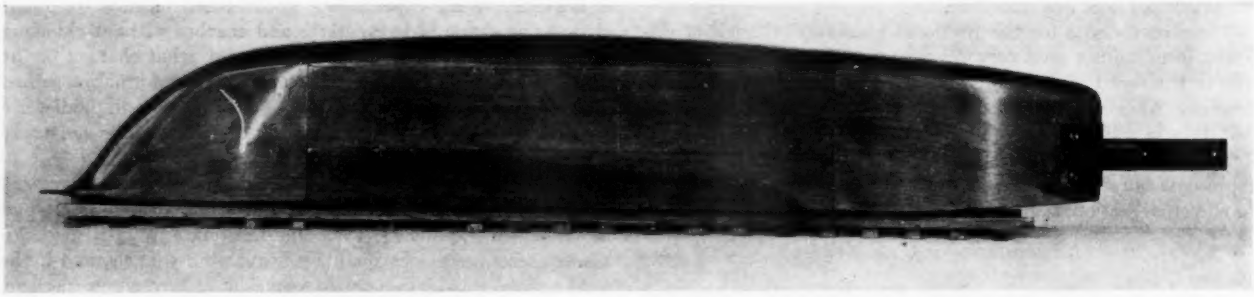

FIG. 3 MODEL OF A STREAMLINED INTERURBAN CAR

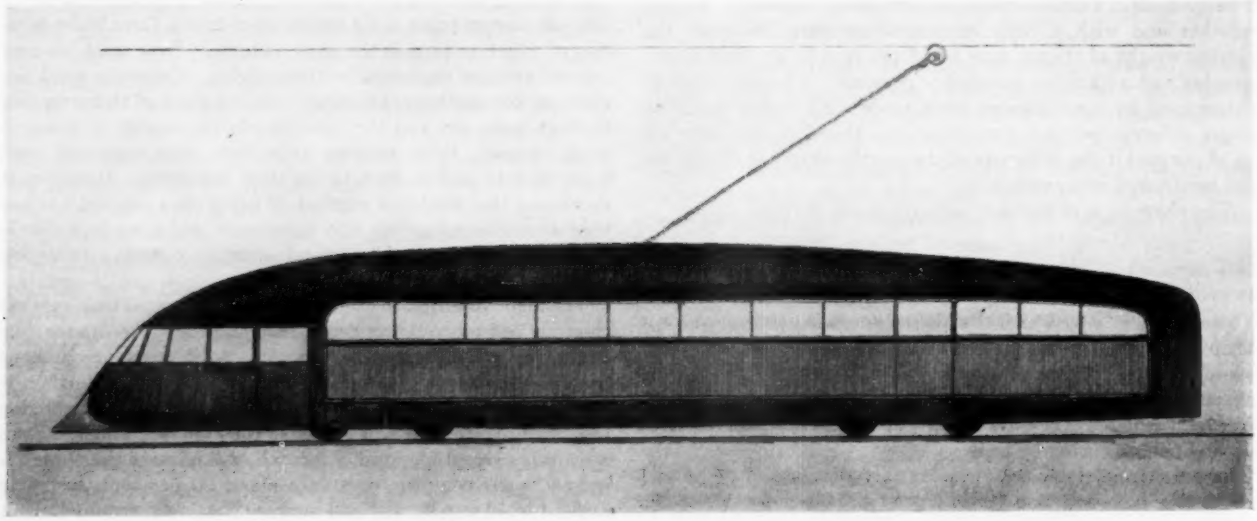

FIG. 4 SKETCH OF A STREAMLINED INTERURBAN CAR

development of new features of design of electric locomotives, coaches, and interurban cars was taken under consideration.

The work was started about two years ago by the building of a special wind tunnel for testing models of present-type trains and interurban cars as well as those of a streamlined shape. Fig. 2 shows as an example the model of a present-type interurban car, which is about 1/25 the size of the actual car. Fig. 3 shows a model of a streamlined interurban car of the same cross-sectional area, but 20 per cent larger in capacity. It will be noted that current-collecting devices were omitted from both types of models, as it is the intention to study the air resistance of these devices separately. Fig. 4 is intended to give an idea of how a streamlined interurban car will look.

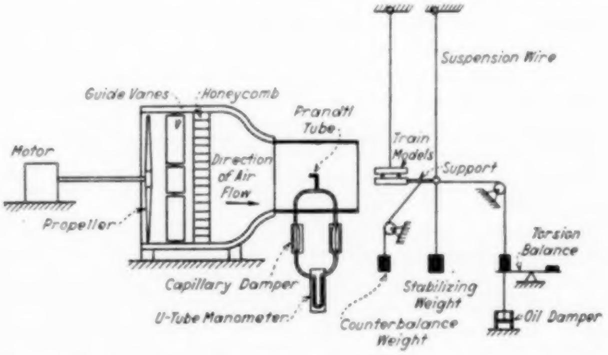

FIG. 5 SCHEMATIC DIAGRAM OF WIND TUNNEL USED IN TESTS

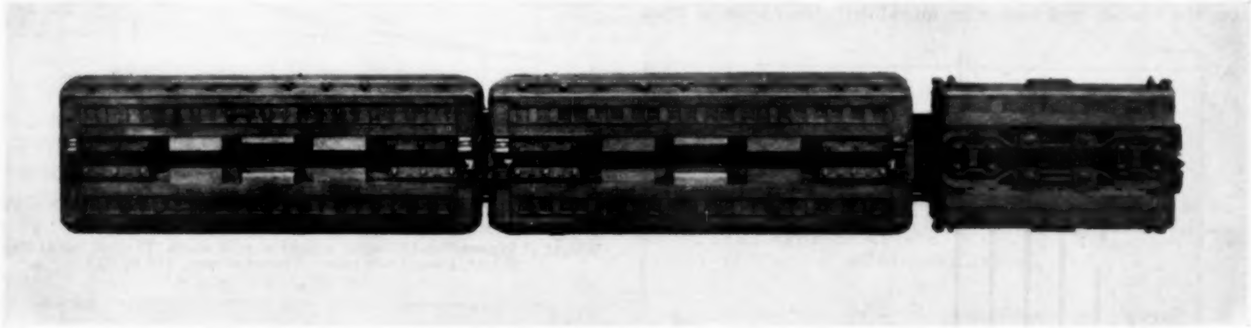

FIG. 6 MODELS OF A PRESENT-TYPE TRAIN AS ASSEMBLED FOR TESTS

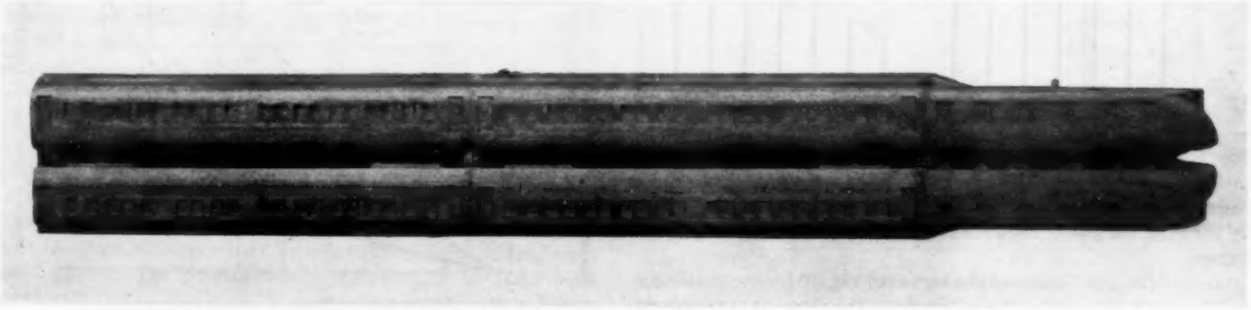

FIG. 7 MODELS OF A STREAMLINED TRAIN AS ASSEMBLED FOR TESTS

The wind tunnel built for these tests is shown in a schematic way in Fig. 5. In tests on small-scale models in a wind tunnel it is better, as will be shown in the succeeding part of the paper, to have a turbulent rather than a uniform air flow and therefore, in order to check the characteristics of this particular wind tunnel against those of certain well-known wind tunnels, a preliminary test was made on a 10-in.-diameter sphere with various air speeds. This and other tests showed the wind tunnel to be satisfactory.

Generally, in constructing the models, a duplicate was made of each train and the two trains assembled as shown in Figs. 6 and 7. This assembly, known as the "mirror method," was used to make the air flow symmetrical about the plane of the imaginary ground, and thus to preserve closely the character of the flow lines occurring with actual trains. From the resistance obtained in testing these assembled duplicates, of course, only half is to be taken for the resistance of a single model. For single cars, such as interurban cars, it was found by experiment that a flat plate parallel to the air flow will give the effect of ground upon a moving train, but with models of long trains the stagnation of air due to a plate stationary with respect to the models would have been for the rear cars objectionably large.

The suspension of the train models in the wind tunnel, and the testing of the air resistance of the models and suspension, and then of the suspension separately to get the air resistance of the models alone, followed conventional practice in these matters. The sensitivity of the test arrangement was sufficient to make the systematic error in the reading of the instruments only about 1 to 2 per cent. Damping devices on the torsion balance and on the manometer permitted mean values being read. The tests were made with a range of air speeds of from about 40 to 70 m.p.h.

III—AIR RESISTANCE OF TRAINS

The results of the tests with trains are summarized in Fig. 8. The tests were made on models of a locomotive alone and with one and two coaches for both types of trains. In Fig. 8 the test results have been extrapolated to trains of six coaches. A straight-line extrapolation was assumed to be permissible owing to the fact that practically no difference could be detected between the air resistance of the first and the second coaches in either of the train models.

The values of coefficient of air resistance shown in Fig. 8 are, if anything, probably somewhat high if used for full-sized trains, and especially so for the streamlined trains. The reason is that in the streamlined models most of the resistance is surface resistance, and owing to the complexity of the present-type models, the models, all of the same smoothness of surface, were not smooth as, with more expense, they might have been made. However, the streamlined locomotive, after having been fitted with a streamlined rear part, was tested before and after being highly waxed and polished, and a reduction of over 40 per cent in the air resistance was obtained simply by this change in smoothness of surface.

Since this paper deals only with tests on air resistance, certain assumptions had to be made regarding the frictional resistance in order to determine the total train resistance. After considering various methods of calculating the frictional resistance, the method of A. H. Armstrong was finally adopted: namely,

$$R_f = 50\sqrt{W} + 0.03\,W \times V$$

where R_f is the frictional resistance in pounds, W the weight of a car in tons, and V the speed of the train in miles per hour.

From this expression for the frictional resistance and from Equation [2], in which the coefficients of air resistance obtained from the wind-tunnel tests were introduced, the curves of train resistance of Fig. 9 were drawn, and from these the curves of Fig. 10 showing the power requirements of the trains were readily obtained.

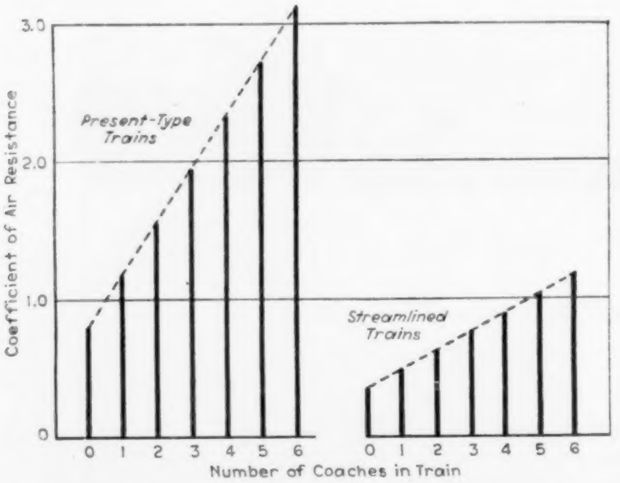

FIG. 8 THE COMPARATIVE AIR RESISTANCE OF VARIOUS TRAINS

To find the significance of the curves of Fig. 10 for the passenger on the one hand and for the railroads on the other, it is necessary to convert them into expressions of dollars and cents' economy.

The passenger is interested in the effect of streamlining and high speed upon the cost of travel per passenger-mile, and the railroad is interested in the comparative earning power of the alternative investments required by streamlined and non-streamlined equipment, everything considered.

It is not possible in an elementary study such as the present one to consider in detail or with great accuracy all of the items that enter into the economy of streamlined trains and high speeds over present-type trains and present speeds, but it is possible to show, by giving approximate values to the more important items, that high-speed, light-weight, streamlined trains have sufficiently great economic advantages over present trains amply to justify, apparently, any railroad in adopting them wherever the existing track, right of way, schedules, etc., permit high speeds of, say, 80 m.p.h.

It will be necessary first to justify the use of high speed for trains by considering the cost of high speed to the passenger per mile, after which it will be significant to inquire into the difference in capitalization required for present-type and streamlined trains operating at the same high speeds.

Such difficultly determined items as the saving in labor overhead due to the higher schedule speed, and the increased cost of track maintenance due to the same cause, will not be considered here in figuring the net cost of high speed to the passenger. The items considered will be those due to changes in power rating of the locomotives with increases in schedule speed. For electric operation these items are the expenses due to increased energy consumption of the train, to increased cost of the locomotive, and to increased cost of the electric transmission system.

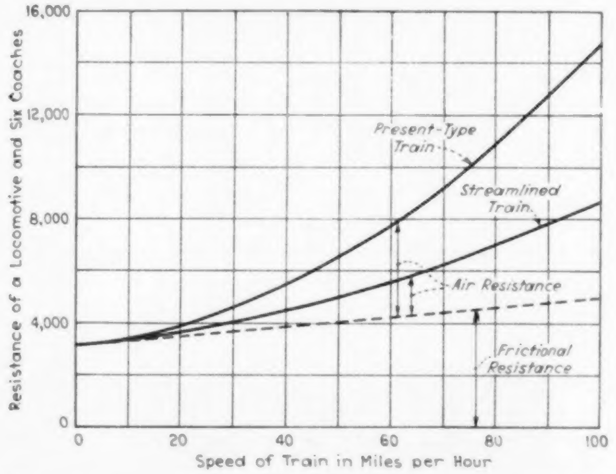

FIG. 9 RESISTANCE IN POUNDS OF FULL-SIZED TRAINS AS CALCULATED FROM THE MODEL TESTS

(Weight of locomotive, 145 tons; weight of each coach, 75 tons; total train weight, around 600 tons. Projected area, 126 sq. ft.)

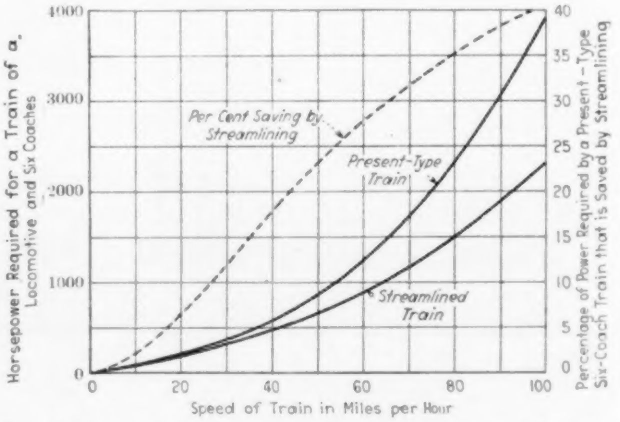

FIG. 10 POWER REQUIREMENTS OF FULL-SIZED TRAINS AS DERIVED FROM FIG. 9

In estimating the expense of increased energy consumption with increased speeds a number of assumptions must be made, for which the following values are offered as reasonable for approximate purposes: Let the cost of electric energy at the car wheels be 1.5 cents per kw-hr. Let the average annual mileage of the train be 100,000 × $\frac{V_s}{40}$, where 100,000 is in round numbers the mileage of present passenger locomotives, and V_s is the schedule speed of the train in miles per hour. Since the average resistance of a train for a distribution of speeds about a schedule speed is for any ordinary distribution equal within a few per cent to the resistance at the schedule speed, let the resistance at the schedule speed be taken as the average resistance of the train. If C_A is the annual cost of electric energy per train and P_s is the horsepower required at the schedule speed by either a streamline or present-type train, as given by Fig. 10, it can be shown that

$$C_A = \$28{,}000 \times \frac{P_s}{1000}$$

To find the annual fixed charge C_B per train due to the cost of the locomotive, assumptions such as the following may be made: Let the weight of a locomotive vary directly as its power rating for a fixed voltage, with a 150-ton locomotive developing 2500 hp. continuous rating, and let the cost of the locomotive vary directly as its weight according to the approximate formula of 50 cents per lb., with or without streamlining. Let the annual straight rate on the locomotive investment to cover interest, taxes, depreciation, insurance, and incidentals be 15 per cent. Let the locomotive have a sufficient power rating to maintain continuously on a straight, level track a train speed of 1.4 times the schedule speed of the train. Then

$$C_B = \$12{,}600 \times \frac{P_s}{1000}$$

If it is assumed that the ratio between the cost of the transmission system for an electrified railroad, including substations and overhead lines, to the cost of the electric locomotives will, for present purposes, be 2 : 3, with an annual rate for figuring fixed charges of 15 per cent, the total annual cost C_{ABC} of the three items that have been considered will, in round numbers, be

$$C_{ABC} = \$50{,}000 \times \frac{P_s}{1000} \quad \ldots\ldots\ldots\ldots\ldots [3]$$

While it is probable that the next developments in increasing the speed of trains will come gradually as in the past, it is of interest to calculate the cost in cents per passenger-mile of an increase in schedule speed to as high as 100 m.p.h. from a schedule speed of 40 m.p.h., for at such a high speed the train would be comparable to the airplane in speed. Assuming, therefore, an increase of schedule speed from 40 to 100 m.p.h., it is found from Fig. 10 that for a streamlined train the additional horsepower required ($P_{s2} - P_{s1}$) is 1800. Assuming that for day-coach travel the average number of passengers per coach is 30, the cost of this additional speed to the passenger per mile can readily be figured from Equation [3] to be 0.2 cent. For sleeping-car passengers, the additional expense would be somewhat greater. This additional expense per passenger-mile is obviously so small compared with the advantages of high-speed travel that the railroads ought to be able to recover it many times over by the increased patronage of the public if the latter are offered this new mode of travel at little or perhaps no increase in fare. The rate for cross-country travel by airplane is at present (1931) about 6.5 cents per passenger-mile on a railway-mileage basis, with a schedule speed on the same railway mileage basis of usually between 100 and 120 m.p.h.

It is interesting, now, to find the capitalized value of the saving effected by streamlined trains over present-type trains for different schedule speeds up to 100 m.p.h. The life of an electric locomotive is variously estimated for depreciation purposes to be from 20 to 30 years. Taking an interest rate of 5 per cent for finding the present worth of an annuity, capitalization factors of 12.5 and 15.4 are, respectively, obtained for annuities running 20 and 30 years. Using these factors to capitalize the annual savings to be found from Equation [3] and Fig. 10, the curves of Fig. 11 are obtained. It should be noted that these are for the savings obtained by streamlining of the kind shown in Fig. 7, and hence do not take into account the savings possible by reducing the projected area of the trains by lowering the height of the trains. Neither do they take into account the savings possible by reducing the weight of the trains.

IV—AIR RESISTANCE OF INTERURBAN CARS

In making the interurban-car models it was desired to provide two, one of a present-type car and one of a perfectly streamlined car, and to have a number of parts on one model that were interchangeable with the corresponding parts on the other. In this way it would be possible to change by gradual steps from a present-type car to a perfectly streamlined car, and by making tests after each of these changes to find the relative importance of the various changes in shape. The two types of models are shown in Figs. 2 and 3, and it will be seen that the streamlined car would have a larger passenger capacity than the present-type car. Eight different tests were made on these models, but for sake of brevity the results of only four will be given here, as shown in Fig. 12.

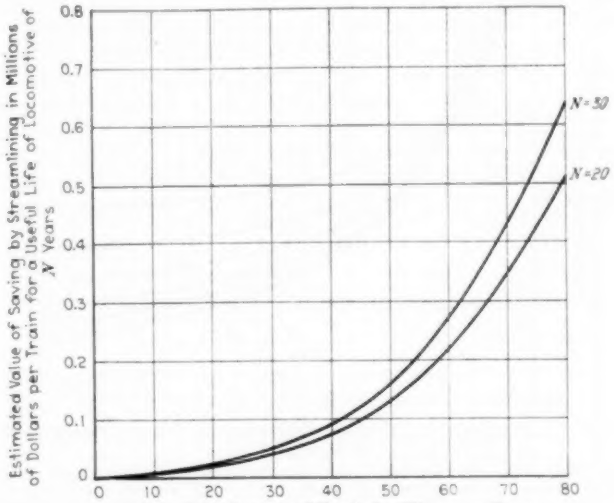

FIG. 11 THE ESTIMATED VALUE OF ADOPTING STREAMLINING FOR HIGH-SPEED TRAINS

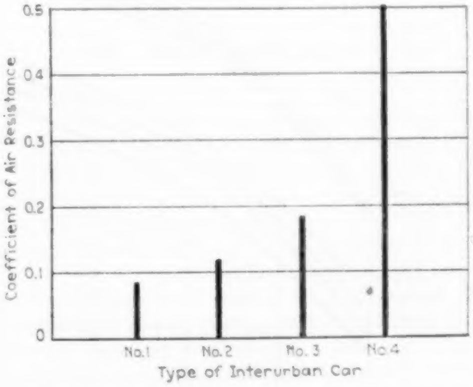

FIG. 12 COEFFICIENTS OF AIR RESISTANCE OF INTERURBAN CARS

Car No. 1 referred to in Fig. 12 is the perfectly streamlined car.

Car No. 2 is car No. 1 made the same in the rear as in the front for two-way operation. Car No. 3 is car No. 1 with the windows and under parts of the present-type car, but with streamlined front, rear, and roof. Car No. 4 is the present-type car. The scale of the models is 1:25. Trolleys were omitted from the models.

The weight of each of the full-sized cars was taken as 25 tons, and the projected area as 83 sq. ft.; so that by using Equation [1], one could, if desired, construct curves of total resistance and of horsepower required by the different full-sized cars as functions of the speed of the cars, assuming no scale effect to exist with the models. If this were done it would be found that for the partially streamlined car, No. 3, the saving by streamlining, in horsepower required to overcome total resistance, would at a speed of 50 m.p.h. amount to about 40 per cent, and at 35 m.p.h., to about 30 per cent. The reason for this large saving effected by streamlining interurban cars as compared with that brought about by streamlining trains is due to the fact that as compared with a train, the air resistance of a car forms a larger part of the total resistance, and this because of the lighter weight of the interurban car in proportion to its projected area.

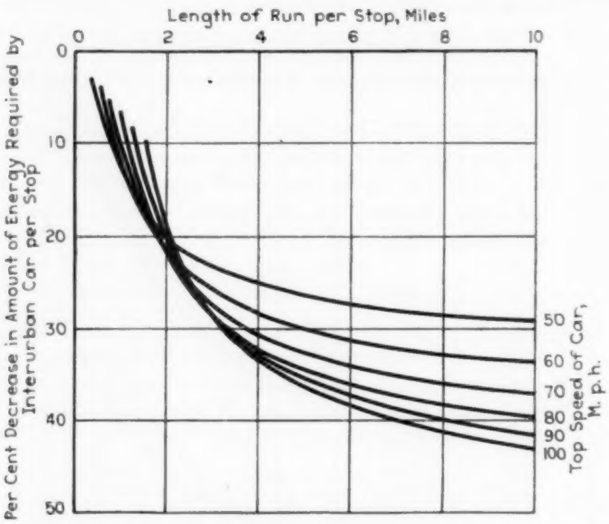

FIG. 13 DECREASE IN ENERGY CONSUMPTION FOR A STREAMLINED INTERURBAN CAR

(Weight of car, 25 tons; projected area, 83 sq. ft.; grade, 0.25 per cent; acceleration, 1.7 m.p.h. per sec.; braking, 2.0 m.p.h. per sec.; reduction of air resistance, 65 per cent; ratio of schedule speeds before and after streamlining, 1.0.)

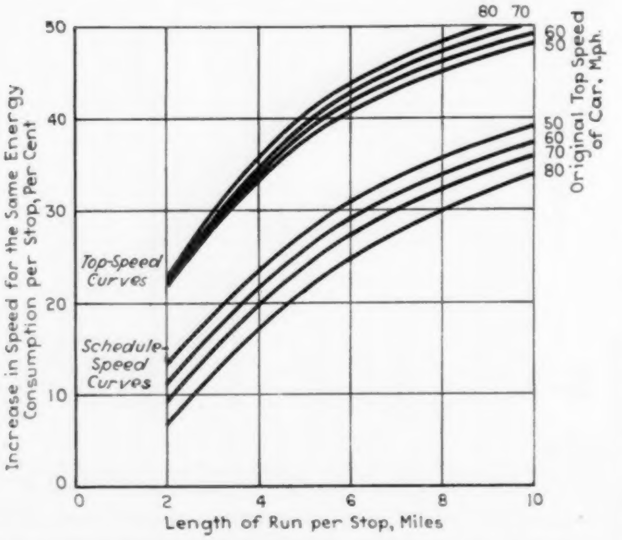

FIG. 14 INCREASE IN SCHEDULE AND TOP SPEEDS FOR A STREAMLINED INTERURBAN CAR

(Length of stop = 5 sec. per mile.)

Such curves of total resistance and of power consumption have a much more limited use for interurban cars than for trains due to the short distance between stops for the former. Much more useful curves for frequent stop service are those showing the effect of streamlining upon the performance of a car as a function of the length of runs in miles per stop. In this way account is taken of the fact that with a frequent-stop service a portion of the operating time is required for accelerating and retarding the car, which means that the average resistance of the car may differ considerably from that existing when the car has reached its normal running speed.

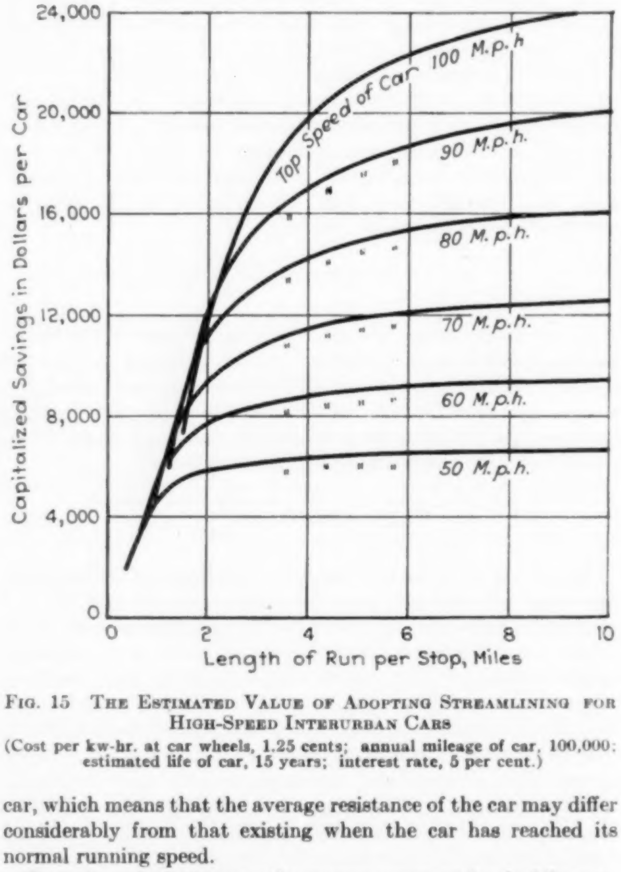

FIG. 15 THE ESTIMATED VALUE OF ADOPTING STREAMLINING FOR HIGH-SPEED INTERURBAN CARS

(Cost per kw-hr. at car wheels, 1.25 cents; annual mileage of car, 100,000; estimated life of car, 15 years; interest rate, 5 per cent.)

To make calculations on the energy consumption in kilowatt-hours per stop for various interurban cars for various lengths of runs per stop and for various normal or "top" speeds, it is necessary to make certain simplifying assumptions. One of the most important of these is as to how the car shall be accelerated—whether at a constant rate by use of oversize motors and special control equipment, or by the common method of a variable acceleration for a large portion of the acceleration period while the "balancing speed" is being reached. For comparatively long lengths of run per stop a constant acceleration up to the normal running speed of the car is not important, but in short lengths of run where it is desired to make a high schedule speed, the matter resolves itself into a question of the comparative economy, everything considered, of a constant acceleration and a given normal speed as compared with the alternative of a decreased acceleration during "balancing," with a necessarily higher balancing speed for the same schedule speed. For short lengths of run and high schedule speeds it is economical to use a constant acceleration up to substantially the top speed of the car, and hence a constant acceleration of 1.7 m.p.h. per sec. up to the top or normal running speed of the car was assumed in calculating the curves of Figs. 13 and 14. The other assumptions upon which the curves were based are given in the captions of the figures. It was assumed for simplicity that, after reaching their normal running speed, the cars would run at a constant speed until braking for making a stop became necessary.

Interurban cars may be streamlined for either of two purposes: to reduce the energy consumption for the same schedule speed, or to increase the speed of the car without increasing its energy consumption. Fig. 13 shows the percentage that the energy consumption of the present-type car can be decreased for the same schedule speed by only partial streamlining, such as in car No. 3. Fig. 14 shows the percentage by which the normal running and the schedule speeds of car No. 4 can be increased without change in energy consumption by partial streamlining, such as in car No. 3.

As in the case of trains it is of interest to gain some idea of the economic importance of streamlining as applied to interurban cars, this time as a function of length of run per stop as well as of speed. With this idea in mind the curves of Fig. 15 have been plotted. These curves include only the savings due to decreased energy consumption for the same schedule speeds and acceleration.

It may be well at this point to call attention to the fact that one large interurban company is now using cars that have a balancing speed of 79 m.p.h.

V—SOME GENERAL ASPECTS OF AIR RESISTANCE

With respect to the reliability of the results of small model tests as applied to actual trains and interurban cars, it may be justified at this point to discuss briefly the question of air resistance in general. The statement previously made, that the coefficient of air resistance is only a function of the shape of a body, has to be corrected to a certain extent. The resistance of a body moving through still air or of a body at rest in an air stream traveling at a certain velocity depends largely on the shape of the streamlines around the body and on the wake in its rear. The form of these streamlines, however, is closely connected with the aerodynamic forces acting on each air particle flowing around the body. There are two sets of forces which have to be taken into account: the inertia forces and the friction forces.

Considering the flow around bodies geometrically similar in shape but differing in size, it can be said that the streamlines are also geometrically similar, and therefore the coefficients of resistance are the same for the bodies in question, if the ratios of inertia forces over friction forces are the same at points similarly situated. This ratio of inertia force to friction force is commonly called the Reynolds number. Therefore it may be stated that the coefficients of air resistance for bodies of geometrically similar shape are the same if the Reynolds number in each case is the same. If, however, the Reynolds number is not the same, it cannot be said that in this case the coefficients of air resistance would necessarily be different; it can only be said that there is no certainty in the matter, and that it can be decided only by tests.

The expression for the Reynolds number is

$$R = \frac{dV}{\nu}$$

where d is a characteristic length of the body—for instance, the diameter of a sphere or the height of an interurban car, V the velocity of the air flowing against the body, and ν the kinematic viscosity.

Applying the Reynolds number to the tests with train models, it is seen at once that the Reynolds numbers of the models are only a small fraction of the Reynolds number of an actual train. The question that arises now is: can the coefficient of air resistance obtained from small-model tests be employed in the calculation of the air resistance of an actual train, notwithstanding this difference in the Reynolds numbers?

In order to answer this question let us consider the relation between the air-resistance coefficient and the Reynolds number for a simple body, say, for a long cylinder of circular cross-section, this cross-section being parallel to the air flow. Fig. 16 shows c as a function of R, and it is seen that for R between 20,000 and 160,000 the coefficient is almost constant and equal to 1.2. When the Reynolds number exceeds 160,000, however, the coefficient gradually decreases to about 0.3 for $R = 500{,}000$, beyond which critical region its value remains constant according to tests so far made.

This change of the coefficient c from 1.2 to about 0.3 is connected with an essential change of the streamlines around the cylinder, which in turn is caused by the fact that the flow in the so-called "boundary layer" changes from a laminar to a turbulent one. This is not the place to go into further details of this interesting and important branch of aerodynamics.[8] Suffice it to state that all those bodies which have a rounded shape, such as a sphere, a streamlined interurban car, etc., have a more or less pronounced critical region of Reynolds' numbers, in which region a considerable decrease of c with increasing Reynolds' number occurs. The better streamlined the body, the smaller is the critical Reynolds number. Bodies with a more or less sharp-edged outline such as a cube or a present-type interurban car do not have this transition of air-resistance coefficients from higher to lower values. For them, c is constant over a wide range and independent of R.

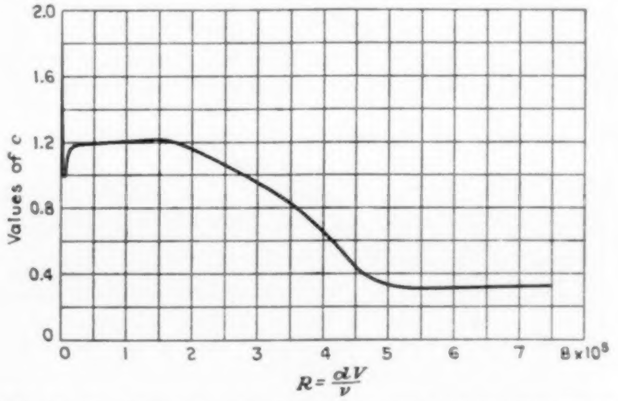

FIG. 16 COEFFICIENT OF AIR RESISTANCE FOR A LONG CYLINDER AS A FUNCTION OF THE REYNOLDS NUMBER

Returning to the question of whether the tests with small models are reliable or not, it may be said that there is no objection to small-model tests if these models have a more or less sharp-edged shape like that of present-type trains. With respect to models of streamlined trains or interurban cars, however, one has to be sure that the tests are made at Reynolds' numbers beyond a certain critical value, which latter in turn depends upon the shape of the model. For bodies like a streamline train the critical Reynolds number is about 100,000. The tests with models of trains and interurban cars described in this paper, however, were made at Reynolds' numbers of about 300,000, or three times the critical value.

---

[8] O. G. Tietjens, "Hydro- und Aerodynamik nach Vorlesungen von L. Prandtl," Julius Springer, Berlin, vol. 2 (1931), p. 111.

It may be emphasized, however, that it would be desirable to check the assumption made that the coefficients for streamline bodies will change but very little beyond the critical Reynolds number. This check could be made by testing larger models in a very large wind tunnel, such as the new wind tunnel of the Advisory Committee for Aeronautics at Langley Field, Virginia.

Another very important matter is the question of the streamlining itself. To begin with, it is not sufficient to take a present-type train and round off a few corners or change somewhat the front part of a locomotive. The whole train has to be considered as a unit and the very first layout of the design of locomotive and coaches must be based on experimental data already obtained and on theoretical considerations regarding air resistance. A feeling how a train or an interurban car should look in order to have low air resistance will be of considerable assistance in designing streamline trains. Such a feeling, however, can only come as the result of work for many years on air resistance.

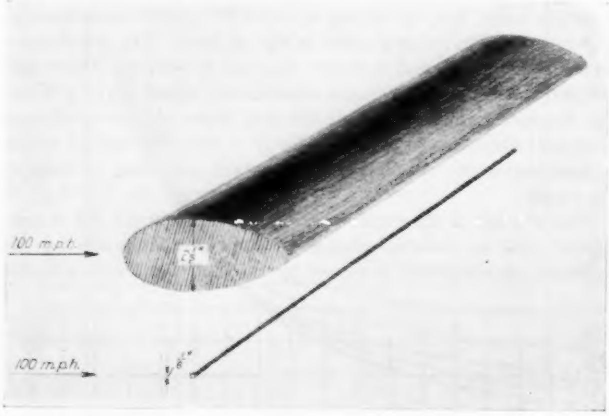

Fig. 17 Strut and Rod Having the Same Air Resistance for a Velocity of 100 M.p.h.

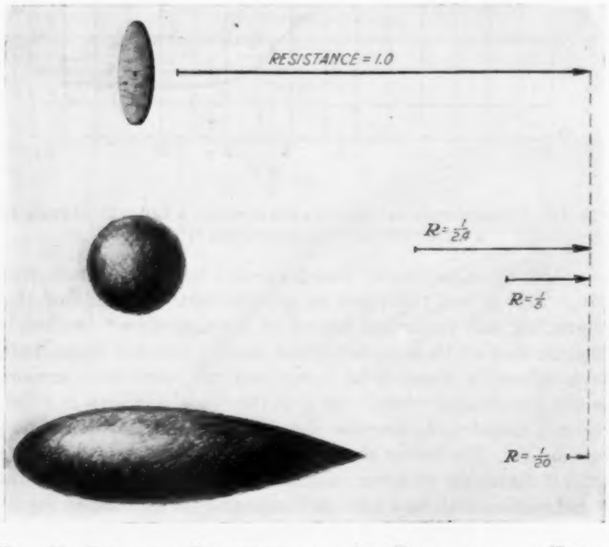

Fig. 18 Relative Difference of Air Resistance of Three Bodies Having the Same Projected Area

Some striking examples may be cited showing that good common sense is not in itself sufficient in rating the excellence of a particular shape of a body as regards its air resistance; but it would lead too far into the theory of air resistance to furnish explanations of the following illustrations.

Fig. 17 shows two bodies of equal air resistance, assuming a speed of 100 m.p.h. The rod has a diameter of $^1/_8$ in. and the strut has a cross-section whose maximum width perpendicular to the direction of air flow is of $2^1/_2$ in.

Fig. 18 shows three bodies having the same projected area. If the air resistance of the disk is denoted by 1, the air resistance of the airship hull is equal to 1/20, and that of the sphere to 1/5 for Reynolds' numbers above the critical and to 1/2.4 for Reynolds' numbers below.

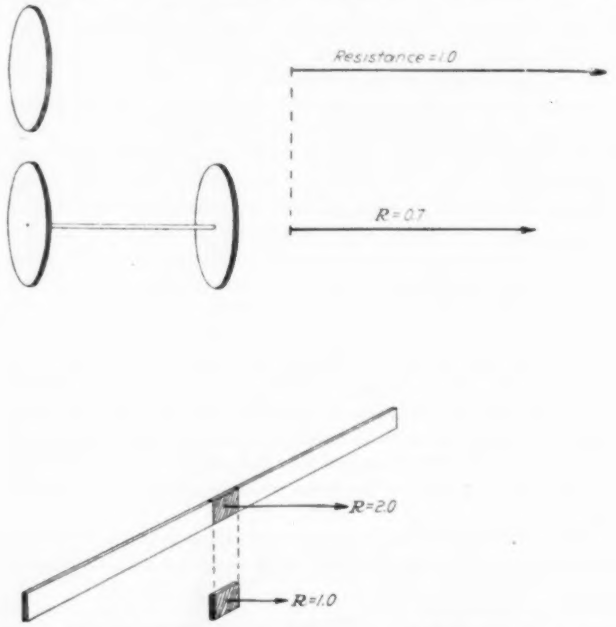

Fig. 19 Air Resistance of Disks and Rectangular Plates

(The air resistance of one disk is less than that of two disks if the two are placed at a certain distance apart. The air resistance of a rectangular plate when isolated is but half what it is when considered as a part of a long plate.)

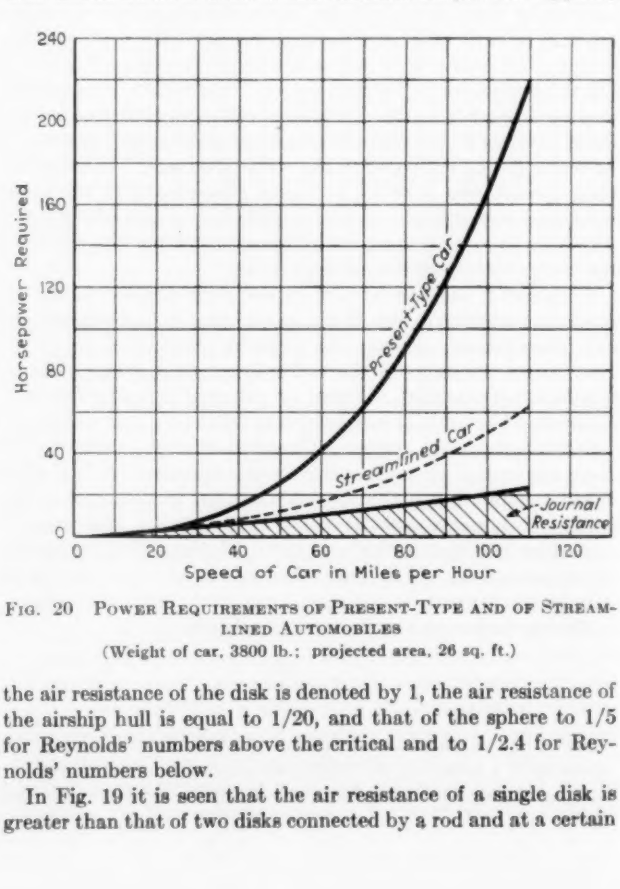

Fig. 20 Power Requirements of Present-Type and of Streamlined Automobiles

(Weight of car, 3800 lb.; projected area, 26 sq. ft.)

In Fig. 19 it is seen that the air resistance of a single disk is greater than that of two disks connected by a rod and at a certain distance from each other. It is also there shown that the air resistance of a square plate is twice as great if considered as a part of a long rectangular plate as it is when isolated.

These few examples will make it obvious that a thorough aerodynamic training is necessary for those who propose to "streamline" modern trains and interurban cars.

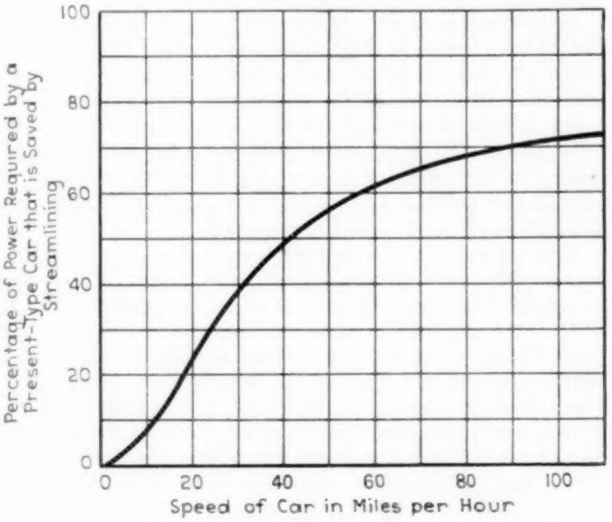

FIG. 21 PERCENTAGE OF THE POWER REQUIRED BY A PRESENT-TYPE CAR SAVED BY STREAMLINING

VI—EFFECT OF STREAMLINING ON AUTOMOBILES

Although the air resistance of automobiles does not strictly come within the scope of the present paper, it nevertheless seems advisable to devote some attention to the important means of transportation it involves. Inasmuch as the automoblie is even nowadays a severe competitor of the railroads, it is highly important for them and particularly for the interurban lines to realize the immense possibilities of the streamline automobile as a means of high-speed transportation especially after super highways have been built.

The air resistance of automobiles was an important factor even years ago when the speed on the open road did not exceed 30 or 40 m.p.h., and is a vital one nowadays when the traveling speed often reaches 60 or 70 m.p.h.

In Fig. 20 the two solid lines show how the power required to overcome air resistance and the power required to overcome journal and rolling resistance depend on the speed. A car weight of 3800 lb. and a projected area of 26 sq. ft. are assumed. These curves are based on numerous tests[9] made in this country and abroad.

According to Fig. 20, a speed of 80 m.p.h. calls for an engine of about 90 hp. of which 14 hp. is required to overcome journal and rolling friction, and the remainder, namely, 76 hp., or 84 per cent of the total power required, is needed to overcome air resistance. Even for the comparatively low speed of 40 m.p.h. the power required to overcome air resistance runs up to 60 per cent of the total power. This comparatively enormous amount of power required to overcome air resistance, however, can be reduced considerably by proper streamlining.

It has been proved by numerous tests made by the senior author in Germany[10] that partial streamlining such as rounding a few corners or sloping the windshield a little more has but little effect on the air resistance. If, however, the body, wheels, and fenders considered as a unit are shaped according to the precepts of modern aerodynamics, a considerable reduction in air resistance can be effected. As a result of the various tests made by the above-mentioned author, a shape was finally developed that had but one-fifth of the air resistance of the present type of car, and yet afforded the same ample space for four or five passengers as did a sedan (Fig. 22).

Assuming, for example, a speed of 80 m.p.h., the streamlined design shown in Fig. 22 requires but 14 + 76/5 = 30 hp. instead of 14 + 76 = 90 hp. The broken line in Fig. 20 refers to a streamlined car such as that shown in Fig. 22, and it is a striking fact that less than 50 hp. is sufficient to maintain a speed of 100 m.p.h., whereas more than 150 hp., i.e., more than three times as much power, is necessary to obtain the same speed of 100 m.p.h. with the present type of car. The Dusenberg car is said to deliver 265 hp. and to attain a speed of 116 m.p.h. or slightly more. The same speed could be maintained with an engine of 70 to 80 hp. if the body of the car were streamlined as shown in Fig. 22.

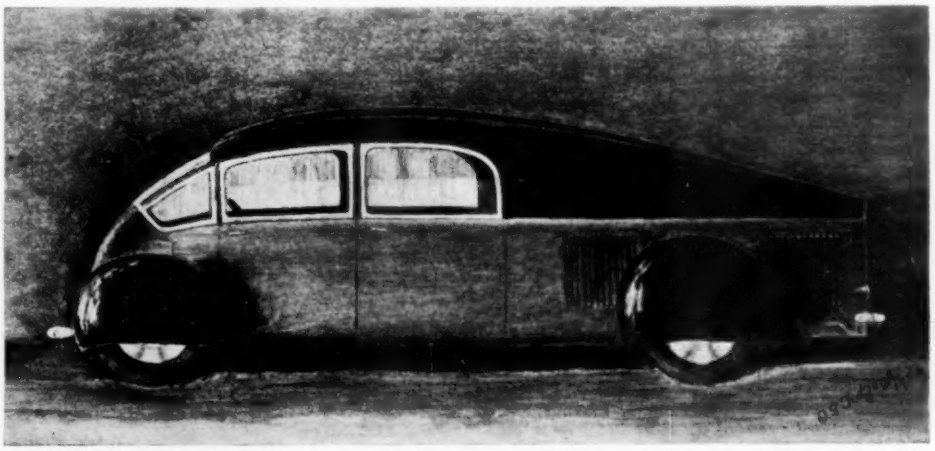

FIG. 22 STREAMLINED AUTOMOBILE WHICH GIVES THE SAVING IN POWER SHOWN IN FIG. 21

In Fig. 21 the saving in total power required is shown for a streamlined car (Fig. 22) in percentage of the total power required for a present-type car. It is seen that even for a speed of 40 m.p.h. a saving of 50 per cent can be effected. This saving increases with the speed, so that at 70 m.p.h. 65 per cent of the power will be saved, and at 90 m.p.h., 70 per cent.

Whereas a present-type car of, say, 80 m.p.h. top speed will travel about 10 miles per gallon of gasoline consumed, 30 miles per gallon could be obtained with a car streamlined according to Fig. 22 and having the same top speed.

These data should be sufficient to convince the reader that within the next few years the bulky-bodied vehicle of today will without doubt be supplanted by the streamlined car.

VII—Conclusion

The aim of this paper has been to emphasize, first of all, the importance of considering air resistance in its relation to high-speed transportation. It has then been shown in what manner the air resistance can be determined more precisely than by using one of the existing train-resistance formulas. Furthermore it has been pointed out that a considerable saving in the power required can be obtained by the streamlining of high-speed trains and interurban cars, and it has been shown how this saving will affect the economics of the problem of high-speed transportation.

The savings in power consumption made possible by streamlining could be utilized to bring about some of the improvements proposed by Egmont Arens in a recent article entitled "The Train of Tomorrow."[11] Air conditioning, it is believed, will be one of the most desirable of these.

Of course it is beyond any dispute that existing rolling stock cannot be scrapped merely to replace it with streamlined equipment. However, it should be clearly understood that railroad companies anticipating the future development of high-speed trains should start now to build experimental trains of streamlined shape, in order to acquire the experience necessary for the final design of the trains of tomorrow.

As the authors see it, the question is not whether the streamlined shape will be adopted, but when this will happen and who will be the first in this new field of modern transportation.

Discussion

F. W. Pawlowski.[12] Since the authors mention the attempt to greatly increase the speed of electric traction made by the Allgemeine Elektricitaets-Gesellschaft and the Siemens & Halske Company on a German military railroad in 1901, it will be of interest to recall that a similar, although much more thorough, investigation was made in this country on the occasion of the Louisiana Purchase Exposition in 1903, and therefore almost as far back as the other. An "Electric Railway Test Commission" was appointed by the president of the exposition, at the suggestion of Prof. W. E. Goldsborough of Purdue University, to conduct tests with the electric-railway equipment assembled for the exhibit in order "to secure data relating to the train resistance of an interurban car, operated both with and without a trailer, at speeds of from 30 to 70 miles an hour," and also "to obtain similar data on a dynamometer car, specially constructed for the purpose of separately measuring the air resistance . . . with different forms of front and rear vestibules." This dynamometer car, named "Louisiana," was developed and built jointly by several companies, among which the J. G. Brill Car Company, the Pressed Steel Car Company, and the Westinghouse Electric and Manufacturing Company contributed the major parts. One-fourth of the 620-page report of the commission deals with the tests of the car "Louisiana." While the car did not bear any relation to the German car, aerodynamically (as we can see now) it was of a superior and more rational design.

An old engineering principle is that stating, "every engineering problem is a compromise problem," and from that point of view the Kruckenberg car, or the so-called "railway Zeppelin," comes under the category of freaks and its performance into that of stunting. Everybody knows that a car shaped like a cigar or a fish will have much smaller air resistance than a box-type car, and also that a car built like an airplane fuselage (a skeleton of alloy-steel tubing, partially covered with fabric) will be much lighter than the usual type of car; but such a car will deteriorate before it will earn any profit.

The writer's admiration is diverted from the generally lauded automobile engineer to the railway-car engineer. Of the $25,000 which the interurban-car manufacturer receives, he pays out two-thirds to others for the chairs, windows, window sashes, doors, electric power equipment, and various auxiliaries, and then for the remaining one-third he produces a car that will run up to 300,000 miles per year for more than 30 years. In view of this astounding performance, many an engineering feat will certainly fade into the background.

Even an empirical formula should be dimensionally correct and should stand a physical interpretation. While it is possible to ascribe the necessary dimensions to the constants C_1, C_2, or C_3 in the expressions for the functions A and B of the weight of the car, in Equation [1], it is rather hard to find any physical meaning for the first term, as well as any good reason for the presence of the factor V in the second term of this equation.

The well-known chaos in the equations for train resistance should not be surprising at all, considering the date of origin of all these equations. A very similar chaos characterized our notions about the apparently simplest case of experimental aerodynamics, resistance of a flat normal plate.

Splitting the train resistance in two items, one representing the road resistance (or mechanical resistance, as some of the railroad engineers call it) and the other the air resistance, the total train resistance can be expressed accurately enough as:

$$R = K_r W + K_a A V^2$$

where K_r is a pure number and K_a has the dimensions of mass per unit volume and is a product of another pure number and mass density of air at some standard conditions.

By using this formula, together with reasonable values of K_r, as found in literature on railway engineering, and K_a, as determined from modern wind-tunnel tests, an excellent agreement of results can be found with those of the Aspinwall formula.

The motor power in horsepower delivered to the wheels of the car on level road in still air can be therefore written as

$$P = 0.00267\,(K_r W + K_a A V^2)V$$

The coefficient K_r takes care, not only of the work necessary to overcome the car wheels and the bearing friction, but also the deformation work of the whole car (never running on a perfectly even track) and that of the rails and the track, which goes into heat. This last item constitutes an appreciable amount in the whole.

The coefficient K_a can be considered as the specific air resistance of the car, in pounds per square foot per miles per hour, based on cross-sectional area of the car A in square feet and the translational speed V in miles per hour. The relation between this coefficient and the coefficient used by the authors in Equation [2] is:

$$K_a = \left(\frac{5280}{3600}\right)^2 c\,\frac{\gamma}{2g} = \left(\frac{5280}{3600}\right)^2 \cdot \frac{0.0765}{64.4}\,c = 0.00255\,c$$

for standard atmosphere (15 deg. cent. and 76 cm. Hg).

It is of course very important to consider in problems of train resistance the climatic, seasonal, and even hourly variations of air density, but the 15 per cent variation mentioned by the authors is a rather optimistic value. The writer can recall cases, right here in Michigan, when the air density on a crisp winter morning was 30 per cent greater than on a hot summer afternoon.

---

[11] *Advertising Arts* (Supplement of *Advertising and Selling*), July, 1931.

[12] Guggenheim Professor of Aeronautics, University of Michigan, Ann Arbor, Mich.

In splitting the coefficient c of Equation [2] into components corresponding to the locomotive and the n cars of a whole train ($c = c_0 + c_1 + c_2 + \quad . \quad . \quad . \quad . \quad + c_n$), it is quite true that "there is little difference between the coefficients of the different coaches, so that . . . " the expression may be written in a simpler form. However, this observation does not apply at all to the last car, so that the simplified expression shall read as follows:

$$c = c_0 + (n - 1)\, c_1 + c_n$$

All of this has been known ever since Prof. W. F. M. Goss, of Purdue University, published in *The Electric Review* of October, 1898, the remarkable results of his wind-tunnel experiments with scale models of railway trains. Wind velocities up to 100 m.p.h. were used in this experiment. While these results might have been rather startling at that time, they are perfectly obvious in view of our present notions concerning aerodynamics.

Undoubtedly an experienced aeronautical engineer is in a position to make offhand suggestions as to the shaping of vehicles with the view of reducing their air resistance; however, in order to determine the quantitative effect of any suggested modification, in each case, an aerodynamic test will be necessary, until the so-called perfectly streamlined shapes will be generally adopted. In the meantime we do not know as yet what the shape of the perfectly streamlined vehicle should be.

Of the two possible methods of aerodynamic tests, the scale-model wind-tunnel method and the full-size road-test method, the former is unquestionably more convenient and less expensive, but it is doubtful whether it is "more exact," and this particularly on account of the very crude reproduction of the ground effect by means of the "reflection method." While the reflection method is the easiest to use, it certainly is not entirely satisfactory.

The laboratory equipment used by the authors, shown in Fig. 5, is interesting, since it is not of the usual type. The wind tunnel seems to be simplicity itself. Unfortunately, however, the dynamometric balance provides for drag measurement only.

It is impossible to guess from the content of the paper why this balance is referred to as "torsion balance;" however, if the authors really make measurements with a systematic error of between 1 to 2 per cent, they should be congratulated for the success in developing such a sensitive and accurate equipment.

In view of the writer's statements regarding the split coefficient for trains composed of several cars, the results for trains as summarized in Fig. 8 of the paper do not appear convincing; besides, extrapolation of results obtained for one and two cars back of the locomotive, up to as many as six cars, is entirely unwarranted.

Professor Goss, who experimented systematically with trains up to 25 cars, found that the resistance of the last car in a train composed of two cars and a locomotive is 3.7 times that of the preceding car. This multiple gradually decreases to a value of 2.5 at 10 cars in the train, and then remains constant up to 25 cars. While the resistance of the intermediate cars in a train varied within $\pm 2^1/_2$ per cent, the resistance of the first car back of the locomotive was always 20 per cent less than that of the intermediate cars. Since Professor Goss used models of nearly the same size as the authors of the paper used ($3^3/_8$ in. wide and $4^1/_2$ in. high) and experimented at higher wind velocities (up to 100 m.p.h.) and therefore was dealing with forces of a magnitude which do not offer difficulties in obtaining accurate measurement, it is impossible to reject his results as erroneous.

If the statement as to a 40 per cent reduction of air resistance of a locomotive model obtained by highly waxing and polishing the model surface is correct, then this will be the most valuable information found in the paper. The original finish of the model was very likely nothing other than the usual finish produced with a fine sandpaper. That waxing and polishing could reduce the air resistance so greatly on a model of the size in question is difficult to understand.

The advantages of streamlining electric trains, from the business point of view, is interesting, for it does not follow the familiar method based usually on performance curves worked out according to the S. B. Cooper method. It seems that "the additional horsepower required" for "an increase of schedule speed from 40 to 100 m.p.h." for a streamlined train, as found from the diagram (Fig. 10), should be 3700 instead of 1800, with the resultant cost per passenger mile, figured from Equation [3], to be 0.41 cent instead of 0.2 cent.

Also it seems that the conclusions as to the advantageous capitalization of the streamlined cars will be considerably reduced if one takes into consideration the longevity and the low cost of the well-built American electric cars of the present (conventional) type and the possibility of a great increase in the cost of cars of some novel design.

A great Eastern electric-railway company for which the writer investigated during the past year 30 car designs, among others one much like the authors' car 1, some of them offering a possibility of cutting the total power at 90 m.p.h. one-half or two-thirds, as compared with the conventional type, has adopted for one line a compromise design with a power reduction of not quite 30 per cent. These people, with years of experience in operating and in buying electric trolley cars, do not deliberately handicap their own interests in adopting an aerodynamically less efficient type of car. In these 30 designs the middle body of the car was left unchanged; the streamlining was limited to the vestibules.

The values of air-resistance coefficients given by the authors (Fig. 12) seem to be remarkably low for all four models.

Among the 30 cars tested, there were at least two corresponding closely to the authors' cars 1 and 4; however, the writer obtained for them much higher coefficients. The models were of practically the same size (scale 1 to 24) and employed wind velocities up to 90 m.p.h. The writer soon will be able to conclude, from the comparison of actual performance of the old-type and the new cars now in operation, how bad or how good are the coefficients obtained.

The writer is unable to agree with the statement that "partial streamlining such as rounding corners or sloping the windshield . . . has but little effect on the air resistance" of vehicles. Experiments made a few years ago with parallelopipeds, approaching roughly the proportions of a sedan body and having 1 sq. ft. cross-sectional area, developed that even a little rounding of edges (with a radius $^1/_{12}$ of the side of the square section) reduces the coefficient of the air resistance 47 per cent at 60 m.p.h. and 77 per cent at 90 m.p.h., as compared with the sharp-edged shape, and that there is a certain radius of rounding the edges at which the coefficient is a minimum for a given wind velocity. Beveling of the flanks of the parallelopiped an amount as observed in some of the modern automobile bodies reduces the coefficient more than 60 per cent at wind speeds between 60 and 90 m.p.h. Even a slight sloping of the windshield reduces appreciably the air resistance.

The proposed design of an automobile, although esthetically pleasing, does not seem to be practical: (1) The protruding tailpiece (on the same wheelbase) will render the already acute parking situation still more difficult; (2) the rear location of the motor will undoubtedly result in a much less reliable car. All possible ways of distributing the vital parts of the car mechanism have been tried, but the real development of automobiles begins with the discovery by Panhard and Levaseur, some 30 years ago, of the present arrangement (engine, clutch, transmission, propeller shaft, rear axle), evidently the most practical one. Any radical change in this arrangement will result in a loss of years of experience responsible for the remarkable reliability of present automobiles.

The authors give an excellent discussion of the so-called scale effect and a presentation of some of the principles of aerodynamics. This section of the paper certainly renders it much clearer to engineers not familiar with this branch of mechanics.

O. C. Cromwell.[13] It will be interesting to bring to attention the early attempt of the Baltimore & Ohio in research on train resistance. In 1890, 40 years ago, Mr. Frederick U. Adams, of Chicago, had assigned to him a train consisting of one baggage car and five coaches at the Mt. Clare shops of the Baltimore & Ohio Railroad, in Baltimore, to be fitted up with what is now called streamline design, to demonstrate the improvement in train air resistance.

The cars were fitted up with uniform contour lines on top of the train, giving an appearance of a torpedo, and the sides were extended below the sills to just above the track, with sufficient clearance to avoid right-of-way obstructions; this extension was to cut out the air resistance of the running gear of the train. Fig. 23 will give an idea of the smooth contour of the exterior of the cars, the photograph having been taken on the viaduct, Relay Station, Baltimore, Md., about 9 miles out of the City of Baltimore.

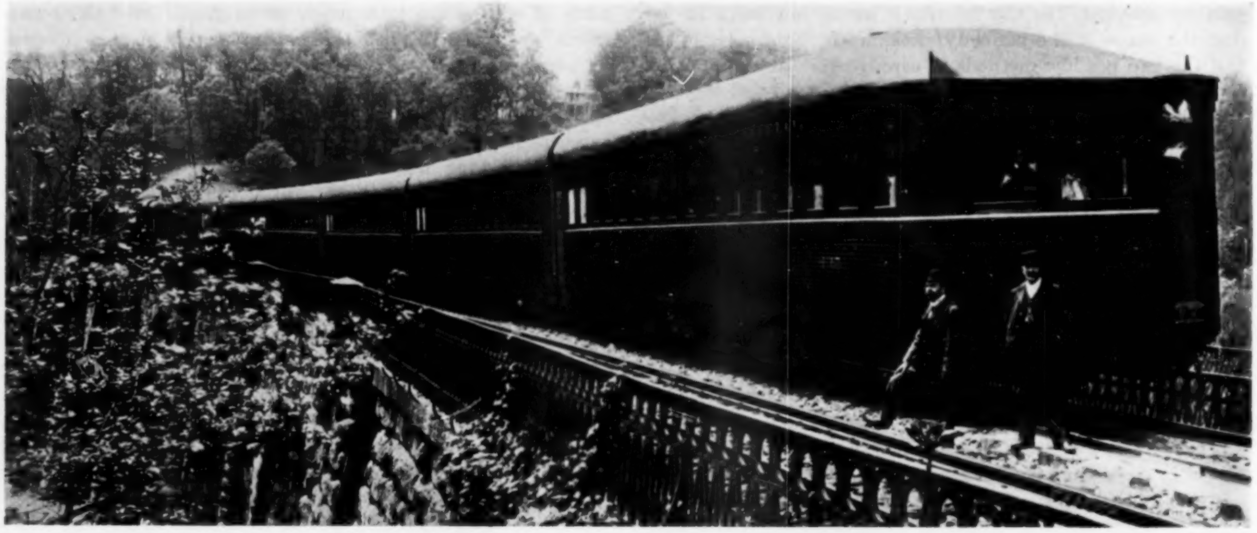

Fig. 23 Baltimore & Ohio "Streamlined" Train Successfully Operated in 1890

After being equipped, this train was popularly termed the "Wind Splitter," and it operated, while being developed, between Baltimore and Washington, a distance of 40 miles, attaining at times a speed of 68 m.p.h., the train being handled by American-type locomotive 822, which was rather light for the service. The drivers were 69 in. in diameter, the weight 94,300 lb., and the tractive power 15,476 lb.

After the development between Baltimore and Washington, the train was operated between Baltimore and Philadelphia, a distance of 96 miles, by American-type locomotive 854, of heavier weight. The drivers were 78 in. in diameter, the weight 114,500 lb., and the tractive power 16,700 lb.

On the return trip, Philadelphia to Baltimore, the train at times attained a speed of 82 m.p.h.

The test demonstrated the values of streamlining, but the experiment was ahead of the times, and after a few minor mishaps with the extension below the sills, the train was removed from service.

William Elmer.[14] It is a little unfortunate that the data in regard to trains is limited to a locomotive and six cars. Most of the heavy through trains are composed of twelve to fourteen cars, and on our railroad we are looking forward to speeds of 90 to 100 m.p.h. in the electrified territory. There is also a lack of information concerning the effects of a quartering wind or a side wind. Our experience with long freight trains on the road indicates that a head wind of, say, 30 m.p.h. against such a train of, say, 100 cars moving at 30 m.p.h. is not so serious as a side wind, and this does not increase the resistance as much as a quartering wind. Experience on a locomotive indicates that under favoring conditions the train resistance may be more than doubled by a quartering wind. This is of course due to the fact that there are one hundred openings between the cars, each of which presents a resistance point.

In the early days of passenger transportation the coaches were of the open-platform type, and while the speeds were of course low, there was a serious amount of air resistance even at speeds of 40 m.p.h. Later the narrow vestibules were introduced, and the air resistance was cut down, and now we have wide vestibules with the corners of the cars and roofs rounded off, but there are still openings between cars amounting to a foot or so from the corners into the diaphragms forming the passageway between platforms.

It would seem to be quite difficult to design steam-railroad cars with smooth surfaces at the ends where the cars couple together, but there is certainly much food for thought in the paper, and undoubtedly the results obtained will justify considerable research on the part of railroads and manufacturers.

Boris A. Bakhmeteff.[15] The paper should be welcomed as a most valuable and timely contribution to the art. Any one who has had to deal with locomotive and train resistance is aware of how scant and insufficient is the actual knowledge in the case. Until lately railroad engineers have been working with notions and figures which date back to a rather antiquated period, and so far no real advantage has been taken of the more recent development of aerodynamics and of the progress in the methods of testing models in wind tunnels.

[13] Motive Power Department, Baltimore & Ohio Railroad Company, Baltimore, Md. Mem. A.S.M.E.

[14] Special Engineer, Pennsylvania Railroad, Philadelphia, Pa. Mem. A.S.M.E.

[15] Professor, Columbia University, New York, N. Y. Mem. A.S.M.E.

The present state of the art is revealed, for example, by the diversity of basic data regarding the so-called "wind" or head resistance of a locomotive. In American practice[16] the usual formula $W = a \cdot S \cdot V^2$ (W being the resistance in pounds, S the cross-section in square feet, taken to be 120 sq. ft., and V the speed of the wind in miles per hour) is used with a coefficient $a = 0.002$. Translated into the terms of the dimensionless drag coefficient in Equation [2], the coefficient $a = 0.002$ corresponds to $c = 0.784$, or to a so-called disk ratio of about 0.70.

The German practice of evaluating train resistance is based principally on the work of Frank[17] and of Strahl.[18] The latter in discussing the value of the coefficient K to be used in the formula $W = K \cdot S \cdot \left(\frac{V}{10}\right)^2$ (W being the resistance in kilograms, S the cross-section in square meters, and V the speed in kilometers per hour) arrives finally at the figure of $K = 0.6$, his conclusions being drawn from experimental evidence collected by the Prussian railways and based on the premise that the head resistance of a locomotive exceeds by about 10 per cent the resistance of a disk of equivalent section. In other words, Strahl suggests a disk ratio of 1.1, which would make the coefficient C in Equation [2] close to 1.25, or over 50 per cent above the American value.

Whether this discrepancy is to be attributed to the necessarily unexact methods used in experimenting on trains in service or whether the form lines of an American engine are more advantageous than the outline of a Continental locomotive could be answered only by reliable aerodynamic tests.

The authors lay particular stress on the resistance of the train, advocating the streamlining of the train as a whole, and appear to attach less importance to the head resistance of the locomotive as such.

There is no question that in the resistance of the aggregate the part played by the cars usually predominates. Nevertheless, the resistance of the locomotive front should by no means be ignored, particularly with passenger trains operated at high speed.

Garbe, the great German authority, when evaluating the wind resistance caused by a normal passenger train, weighing 600 tons and traveling at 90 km. per hour, figures the locomotive resistance to be nearly 30 per cent of the total.[19]

The American formula when applied with $a = 0.002$ to an engine running at 100 m.p.h., gives a resistance measured at the base of the wheel of near 2400 lb. and a loss in power of over 600 hp. A reduction of head resistance by proper shaping might measurably add to the tractive force, which of course is particularly important at high speeds.

C. E. Barba.[20] The authors' analysis of the helpfulness in considering modification in design of passenger equipment for high-speed and interurban service is most opportune, and indicates the adaptation of the principles long used in ship-hull construction by the use of models to determine the proper waterlines for a minimum of friction at maximum speeds.

The paper presents many interesting results based upon a definite design, but these cannot always be applied. The query therefore arises as to how this data could be utilized without making additional experiments on a complete practical application to a whole train.

The energy generated by a railroad prime mover is utilized in storing up kinetic energy in the train load and overcoming frictional and wind resistances. The authors have shown how the large item of wind resistance can be minimized. Frictional resistance in its relation to the other two factors is a small item and one that already, at speed, is at a more or less irreducible minimum.

Kinetic energy from its nature is directly proportional to mass or weight of train. The use of improved materials of construction will permit of decreasing unit car weight, consequently train load for equal carrying capacity, and with a fixed energy-producing prime mover, increased speed with equal carrying capacity or increased hauling capacity with fixed speed can be attained through reduced light car weight or, as pointed out by the authors, through lessened wind resistance, or by a combination of both.

Energy cannot be destroyed, but must be overcome or dissipated through work done. In normal stops this dissipation is through the work of the brakes. Under abnormal stopping conditions, as through wreck or accident, equal safety with lighter materials of construction and lighter design is obtained in that the energy required to be dissipated in a short period of time takes place in the crumpling up of the vestibules and car platforms and not in damage to the car bodies.

A lighter car structure can be employed, since the kinetic energy at any given speed will be reduced proportionately to the weight of the structure, and therefore the destruction forces to be absorbed in accident will be proportionately reduced for equal carrying capacity.

Since the damage done is therefore proportional to the resistance offered, and as this resistance is based on weight, a lighter structure could therefore be employed, so that the damage it would sustain would be equivalent.

Streamlining would start with the prime mover, and although the front of our present locomotives, either steam or electric, could be modified to produce the necessary effects, the following conditions would bear some investigation as governing determinates in such modified constructions:

(1) The necessity of smokebox inspection at frequent intervals
(2) Relocation of air pumps at front end and the necessary ability to inspect same or to get at them for repacking purposes
(3) The headlight and front marker lamps would have to be relocated
(4) Dummy coupler and uncoupling mechanism could not be covered up
(5) Removal of front cylinder heads for packing-ring renewals would mean removable shields
(6) Steps at front end from running board and handrails would no doubt be eliminated
(7) Passing from one side to the other at bumper beam would not be practicable
(8) Cab vision may be obscured.

The foregoing is based upon the idea of a superimposed body, made of light material, based upon the design of a streamline front end.

Streamlining, theoretically, should also inclose the sides of locomotive, in which the shape of boiler, running board, and space below should blend into the cab. This would present the following difficulties:

1. (1) If half the diameter of the driving wheels is covered over by a shield below the modified running board, the inspection of the spring rigging is not possible, and although such an enclosure is prevalent in European practice, the spring rigging is usually found below the driving box, which is not American practice, although such a design is practicable
2. (2) The cab front would undoubtedly have to be modified, which in some designs would permit the steam turret to be within the cab, as the center portion of the cab front would project along the center line of the boiler
3. (3) The cab and its connection to the tender would undoubtedly have to incorporate a vestibule type of tender; this has been done
4. (4) The height of the tender would require the same contour as in passenger cars, and could be roofed over by having hatches, hinged and overlapping, for coaling purposes. Going up over the tender for taking water should not be considered as good practice where large tenders are involved.

The connection between tender and train or between the units of the train cannot be accomplished as indicated in Fig. 7, as so far no practicable means has yet been discovered wherein two cars do not require the clear space which now exists between vestibule corner posts or end sills to take care of curving, unless the connection made between corner posts is made of a flexible material similar to the diaphragms now in use. This is possible, but hardly practicable, due to the make-up of trains and frequent separations.

Sloping car roofs at ends of cars such as usually prevail are not necessary and neither are clearstories, since any interior ceiling effect can be obtained with a circular or so-called turtle-back roof by the application of falsework attached to the carlins.

In conclusion, it should be remembered that, irrespective of the ideals the present railway fraternity may foster, the final results in design are largely hampered by legislative acts, both state and Federal, that will not permit modernization to the same extent as agencies in other fields of transportation.

The authors are to be congratulated on the presentation of a subject foreign to present engineering practices in railway equipment construction that should assist in stimulating others in performing experiments useful in the development of super-transportation units for high-speed service.

B. S. Cain.[21] This paper indicates very clearly the direction toward which the design of high-speed trains must shortly be directed and gives some idea of the benefits which may result.

It is hardly practicable to divide total air resistance into front pressure, rear suction, and skin friction. However, it seems that for some typical trains of the present day, it should be possible to state approximately what improvements could be made by providing a streamlined locomotive or a streamlined rear-end observation car since such changes may well precede the general replacement of all high-speed Pullman cars; that is, if the authors could show that substantial benefits might be obtained by a partial change while awaiting the day when completely redesigned trains may be available.

It would be interesting to hear the results of any tests with oblique winds on trains, since the effect of a transverse wind may be greater at speed than at rest. Rare as such occurrences may be, there are records of the overturning of trains due to transverse wind.

It also would be interesting to know the effect of streamlining on the head-end stability of a train; that is, the stability of the streamlined locomotive, which would have very little head resistance and might have an appreciable tendency at very high speed to deviate from straight progression.

Referring to the figures of estimated savings, the authors indicate clearly that they have made numerous simplifying assumptions. For example, a 150-ton locomotive developing 2500 hp. is considered, and it is assumed that the locomotive weight will vary with the horsepower. Actually, 150 tons, 2500 hp. corresponds to a recently built locomotive of the Pennsylvania Railroad, which at the same time designed a larger locomotive with 50 per cent more horsepower and only 25 per cent more weight. Actual figures of savings will therefore require to be calculated in greater detail to cover specific cases.

Authors' Closure

By O. G. Tietjens. The discussion by Prof. F. W. Pawlowski is very much appreciated, at least so far as it is of a constructive nature. The principal difference between the tests of the Electric Railway Test Commission mentioned by Professor Pawlowski and the tests of the German companies in 1901 is the different speed applied. The tests with the "Louisiana" car were made at speeds between 30 and 70 m.p.h., which speeds cannot be considered as very high, whereas the Berlin-Zossen tests were made at 130 m.p.h., which is about twice the maximum speed of the "Louisiana" car.

The author agrees absolutely with Professor Pawlowski that even an empirical formula should be dimensionally correct and should stand a physical interpretation. It may therefore be mentioned that in Equation [1] of the paper the quantity A represents that part of the total resistance that does not depend on the velocity; its dimension is of course that of a force, and has the same physical meaning as the first term of Professor Pawlowski's equation. The "good reason" for the presence of the factor V in the second term of Equation [1] is the fact that a certain part of the resistance is approximately proportional to the first power of the speed.

Since the air-resistance coefficient K_a of the second term of the equation suggested in the discussion is not a dimensionless number, but depends on the atmospheric pressure, temperature, and humidity, it is generally conceded to be preferable to use the pure number C instead of K_a or any similar coefficient.

The author cannot quite understand what Professor Pawlowski has in mind when he says that the statement in the paper that 15 per cent variation in air resistance may occur, due to changes in temperature, barometric pressure, and humidity, is rather optimistic. If in some extreme cases, as he observed, the change in air density amounts to 30 per cent, then of course the air resistance also changes 30 per cent, the other conditions remaining unchanged. Just this relation between the air resistance and the atmospheric conditions makes it advisable to use the pure number C in the air-resistance formula instead of K_a, as suggested by Professor Pawlowski.

The author does not agree with Professor Pawlowski that the air-resistance coefficient of the last car will be considerably different from the last-but-one car. The reference to experiments made by Prof. W. F. M. Goss does not mean anything in this connection. The fact that Professor Goss attacked the problem of air resistance of trains in a rational way as early as 1898 must be highly appreciated. However, the results of these tests have no practical value. The objections against the method applied could not be realized at the time Professor Goss carried out his tests. But now, after about 20 years of wind-tunnel practice, it is well known to every one that is at all acquainted with wind-tunnel work that a tube of 60 ft. length and a cross-section of 20 in. by 20 in. will not give results that are free from objections.

---

[21] Locomotive Division, Transportation Engineering Department, General Electric Company, Erie, Pa.

Even those wind tunnels of the closed type that have a length of only about twice or three times the diameter, take into consideration the fact that there would be a variation of static pressure in the direction of flow if the diameter of the closed wind tunnel remained constant. The general rule is therefore to increase the diameter of closed wind tunnels slightly in direction of flow. Tests of trains up to 25 cars long in a tube which had a length of more than 20 times its diameter do not represent conditions which can be considered similar to those of the actual train. Furthermore, the method of representing the ground is objectionable and is bound to give wrong results. Although these tests undoubtedly have a certain historical value, and although Professor Pawlowski feels it impossible to reject the results as erroneous, there is no question that they are absolutely out of date on account of the foregoing reasons.

The author agrees that the extrapolation in Fig. 8 of the paper from tests with a locomotive and two coaches to a train of a locomotive and six coaches may be open to discussion. However, it was only intended to give in this paper qualitative figures regarding air resistance of conventional and streamlined trains and to emphasize thereby the importance of streamlining trains and interurban cars as well as automobiles.

With respect to the capitalization of the streamlined cars, it cannot be seen why the cost of cars of some novel design should be necessarily much greater than the cost of the present design, as is the opinion of Professor Pawlowski. The streamlined car may be less expensive due to greater simplicity.

That the smoothness of a very well-streamlined body is of enormous importance regarding its fluid resistance should not be surprising. The statement as to a 40 per cent reduction of air resistance due to polishing the model is made in the paper only for a very well-streamlined body where the total air resistance is almost entirely resistance due to surface friction. The author wishes to refer Professor Pawlowski to tests[22] made at Göttingen, Germany, on air resistance of bodies of various surfaces. The well-known fact may be mentioned, in this connection, that it is very important to have the wetted surface of racing boats as highly polished as possible in order to reduce the frictional resistance to a minimum. The reason for the large influence of the surface condition on the resistance is found in the relation of the breakdown of the laminar boundary layer to the smoothness of the boundary itself.

The extent to which a laminar or a turbulent boundary layer influences the fluid resistance was recently shown in a paper by Dr. C. B. Millikan.[23] The thorough study of this paper may justify Professor Pawlowski's opinion that the statement as to a 40 per cent reduction of air resistance due to a changed surface condition will be for him the most valuable information found in the paper.

It is very interesting for the author to learn from Mr. O. C. Cromwell that the Baltimore & Ohio had built a streamlined train as far back as 40 years ago.

The question of side wind brought up by Mr. W. Elmer and Mr. B. C. Cain is very important. In the near future tests will be carried out at the Research Laboratories of the Westinghouse Electric & Manufacturing Company to determine the influence of side winds on the air resistance of trains of various shapes.

Vibration During Acceleration Through a Critical Speed

By FRANK M. LEWIS,[1] NEW YORK, N. Y.

This paper gives an exact solution of the problem of running a system having a single degree of freedom and linear damping through its critical speed from rest at a uniform acceleration. An exact expression is found for the envelope in which are located the maximum amplitudes. The results are plotted for various rates of acceleration and for various dampings.

MANY reciprocating engines, turbines, and other types of machinery capable of vibration are normally operated above their critical speed, and must pass through this critical speed in being started, and again in coming to rest. A problem of interest in this connection is the relation between the maximum amplitude of vibration attained, the number of dangerous vibrations, and the rate at which the machine is accelerated through its critical.

Again, in testing such machinery for vibration, continuous records are often taken over a wide range of speeds as the speed of the machine is either increased or decreased. It is known that in such cases the recorded amplitude will be smaller than if the machine were held at constant speed directly on a critical; and further, that an apparent shift in the position of the critical will occur, and that it will appear higher than the true critical when the speed is increasing and lower when it is decreasing.

This paper is a quantitative study of these effects. In particular, the exact solution is obtained for the motion of a single-mass elastic system, with linear damping, under the action of an exciting periodic force, the frequency of which is (*a*) increasing and (*b*) decreasing at a uniform rate. This corresponds to the case of a machine with uniform acceleration.

Passing over for the present the mathematical analysis of the problem, the results, which are shown in dimensionless form in Figs. 1 to 5, inclusive, will be discussed.

Let N = natural frequency of the vibrating system in cycles per second

N' = instantaneous frequency of the exciting periodic force

h = acceleration of the system in cycles per second per second

r = number of undamped free vibrations the system would make from time zero to time t

q = the value of r at which the instantaneous frequency of the exciting force is equal to the natural frequency of the system. q is a measure of the rate at which the system is accelerated.

In the analysis there are obtained the relations

$$q = \frac{N^2}{h} \quad \text{and} \quad N' = N\frac{r}{q}$$

We note that $q = 10$ implies an extremely rapid acceleration rate, probably faster than could be obtained in practice. $q = 500$ implies a rather slow rate; $q = \infty$ implies that the critical is passed through with infinite slowness, and the $q = \infty$ curves are, in consequence, the classical resonance curves for constant frequency.

R, the resonance factor, is the ratio of the force actually in the spring of the system at any instant to the maximum value of the periodic force.

γ, a dimensionless damping constant, is, in the case of constant frequency, the reciprocal of the value of R at resonance.

It is shown in the analysis that a periodic force in which the frequency is increasing at a uniform rate may be specified by

$$P \cos\left(\frac{\pi r^2}{q} + \sigma\right)$$

where σ, a phase-angle constant, may have any value.

The results for the case of zero damping are shown in Fig. 1. Curve A is the periodic-force curve $\cos\left(\frac{\pi r^2}{q} + \sigma\right)$ for $q = 10$ and $\sigma = 0$.

Curve B gives the somewhat irregular motion of the body when initially at rest and then acted upon by the force specified by curve A.

If the body were initially held so that the spring force was equal to the initial value of the periodic force, the resultant motion curve would be of the simpler form given by C.

After the maximum amplitude has been reached the exciting periodic force is able to extract but little of the energy which it has put into the system, and, as there is no damping, the body will continue to vibrate with an amplitude but little short of its maximum. It may be shown that ultimately the body will be vibrating with its natural frequency and with an amplitude $R = \pi\sqrt{q}$.

With a value of σ different from zero, a periodic-force curve such as A and a motion curve such as C are obtained. The variation of σ produces a family of such curves, and the envelope of this family of curves is of particular interest since the maximum amplitudes obtainable are located on it. Further, the envelope is much easier to compute than the curves of actual motion of the body.

R_e denotes this resonance envelope, and the full lines of Fig. 1 give the envelope solution for $q = 10$, 20, 40, and 80, respectively.

The case of a machine with decreasing speed is simulated in the following manner. Assume that at time infinity in the past the body was at rest and was acted on by a periodic force of infinite frequency. At time zero this frequency has decreased to zero. Then if we fix our attention on negative values of time, the body will pass through a critical at some negative value of r. The solution thus obtained for decreasing frequency is very similar to that for increasing frequencies. The shift of the critical is practically the same, the maximum amplitudes now occurring at speeds lower than the constant-frequency critical. The maximum amplitudes are slightly larger for decreasing speed than for increasing.

Since machines entirely without damping cannot be con-

[1] Professor of Engineering, Webb Institute of Naval Architecture. Mem. A.S.M.E. Professor Lewis has specialized in research relative to the vibration of ships and machinery.

Presented at the Second National Meeting of the A.S.M.E. Applied Mechanics Division, New Haven, Conn., June 23–25, 1932.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

structed, the results for the case of zero damping are purely of academic interest.

Figs. 2 to 5 show the R_e-curves for various values of the damping constant γ and the acceleration constant q, the upper set of curves being for decreasing frequency and the lower for increasing.

In a qualitative way, at least, many of the features of these curves could be anticipated.

The greater the acceleration rate, the greater the shift of the maximum and the smaller its amplitude.

The greater the damping, the more nearly do the curves approach the resonance curves for constant frequency.

After the maximum is passed, the envelope curves, where the damping is small, are oscillating in character, but are eventually asymptotic to the resonance curves for constant frequency.

It may be noted that unless the acceleration is extremely rapid, or there is little damping, the amplitudes are not a great deal smaller than the constant-frequency amplitude. With normal acceleration rates the shifts of the critical are sufficient to be of importance when making vibration tests.

Attempts to find empirical formulas which will approximate to the amplitude and shift of the critical over the entire range of q and γ have not as yet been wholly successful.

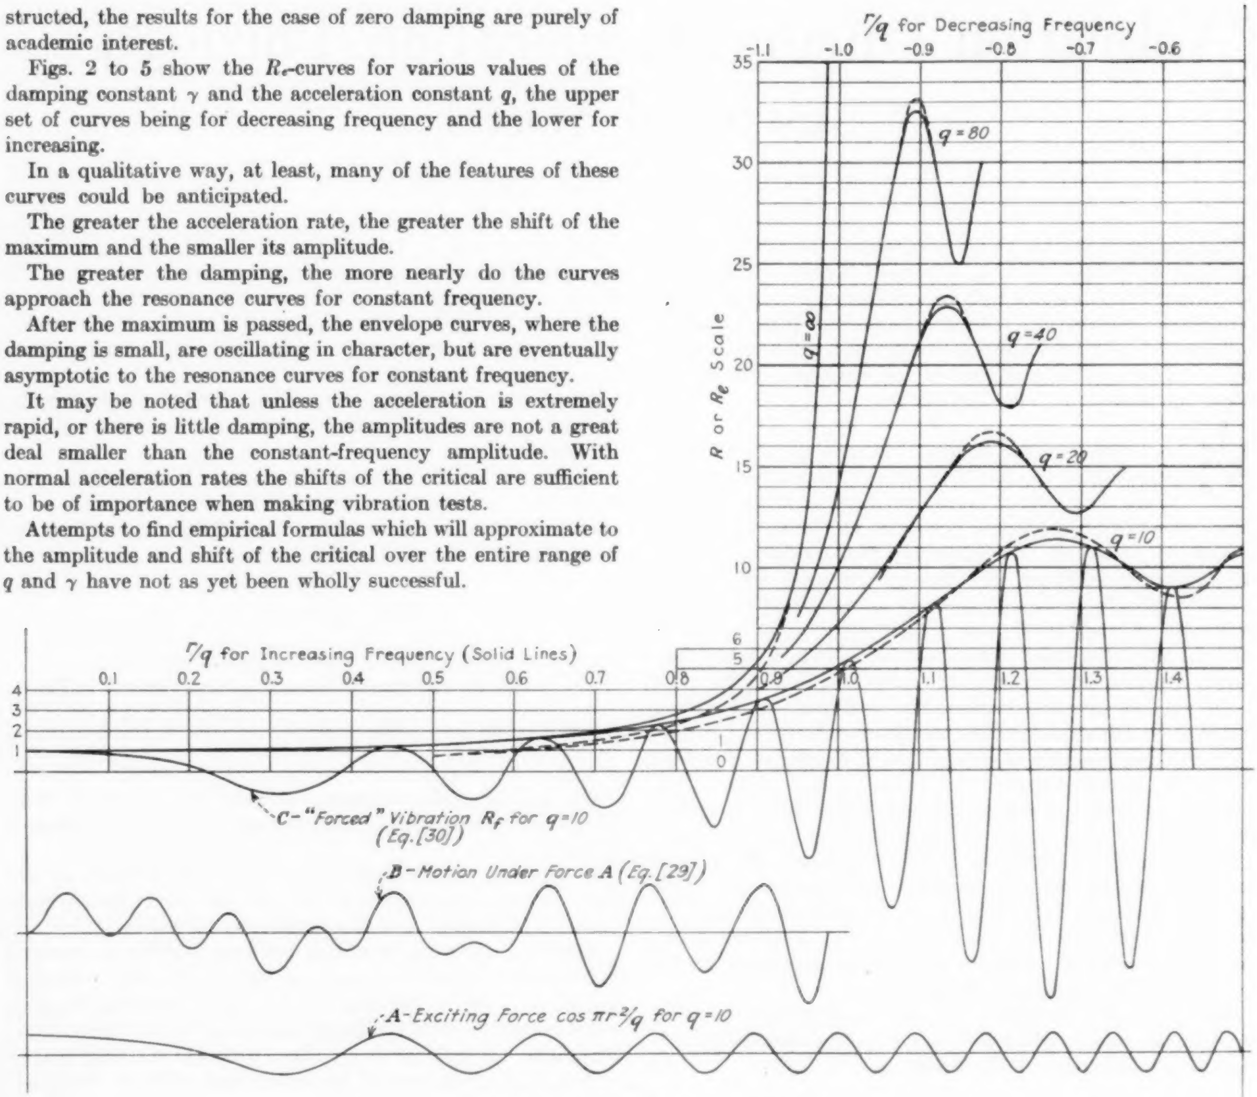

FIG. 1 CASE OF ZERO DAMPING ($\gamma = 0$)

[Solid lines for increasing frequency; broken lines for decreasing frequency. For large values of q, R_e (max.) = $3.67\sqrt{q} \pm 1/4\sqrt{2}$ (— for increasing frequency, + for decreasing). Shift of the maximum from $r/q = 1$ is equal to $0.853/\sqrt{q}$.]

The application of the results is limited for the present to single-mass elastic systems, or systems which can be considered sufficiently close approximations to this type. Further remarks on systems of several degrees of freedom are made in the analysis.

ANALYSIS

Consider the motion of a single-mass elastic system with linear damping under the action of a variable force $f(t)$. Let the weight be W, the damping constant d, and the spring constant k. Then the well-known differential equation of motion of such a system is

$$\frac{W}{g}\ddot{x} + d\,\dot{x} + kx = f(t) \quad \ldots\ldots\ldots\ldots\ldots [1]$$

or

$$\ddot{x} + 2n\dot{x} + p^2x = \frac{g}{W}f(t) \quad \ldots\ldots\ldots\ldots\ldots [2]$$

where

$$\left.\begin{array}{ll} p^2 = \dfrac{kg}{W} & 2n = \dfrac{dg}{W} \\ \text{also let} & \\ \gamma = \dfrac{2n}{p} & p = 2\pi N \end{array}\right\} \quad \ldots\ldots\ldots\ldots [3]$$

It may easily be verified that a solution of [2] subject to the condition $dx/dt = 0$ and $x = 0$ when $t = 0$, is:[2]

$$x = \frac{g}{W(\alpha - \beta)}\left\{e^{\alpha t}\int_0^t f(t)e^{-\alpha t}dt - e^{\beta t}\int_0^t f(t)e^{-\beta t}dt\right. . \quad [4]$$

where

$$\left.\begin{array}{l} \alpha = -n + i(p^2 - n^2)^{1/2} \\ \beta = -n - i(p^2 - n^2)^{1/2} \end{array}\right\} \quad \ldots\ldots\ldots\ldots\ldots [5]$$

---

[2] See Jeffrey's "Operational Methods in Mathematical Physics," 1.7 (8).

MUST ASSUME

Equation [4] is the solution for the motion of a body initially at rest and then subjected to any variable force which is a function of the time. If $f(t) = P \cos mt$, this solution reduces to the classical solution for constant frequency, plus a term representing a damped harmonic motion which is due to the initial conditions imposed.

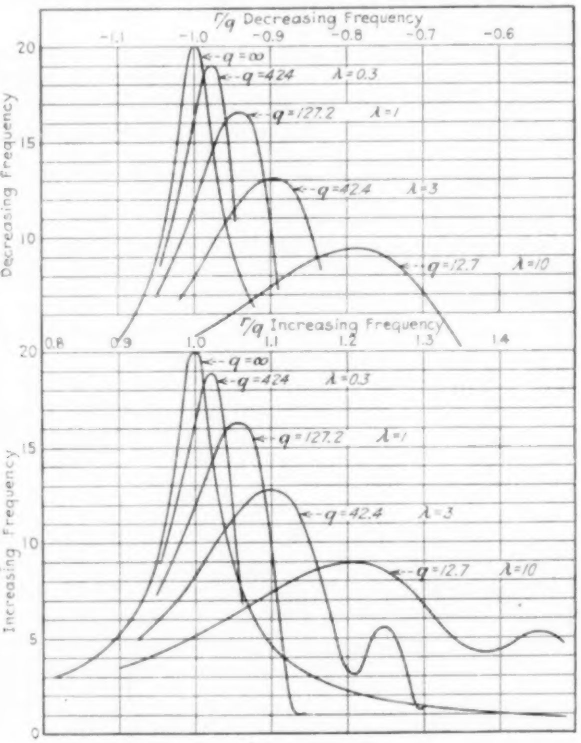

FIG. 2 RESONANCE ENVELOPES ($\gamma = 0.05$)

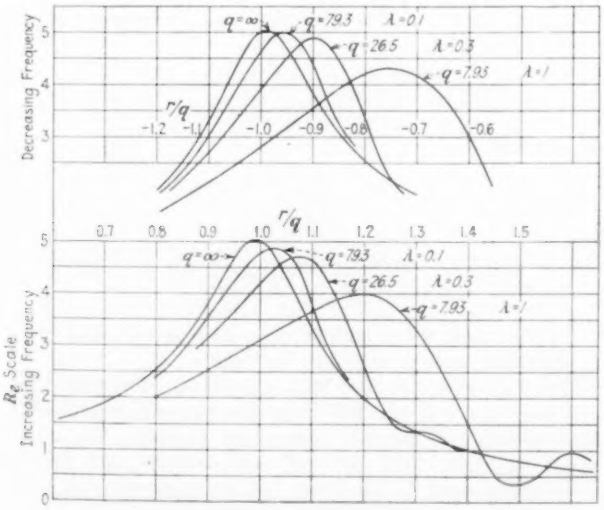

FIG. 4 RESONANCE ENVELOPES ($\gamma = 0.2$)

A periodic force in which the frequency is increasing at a linear rate may be specified by the equation

$$f(t) = P \cos (\pi h t^2 + \sigma) \dots\dots\dots\dots\dots\dots [6]$$

where h and σ are constants, σ being the initial phase angle of the exciting force.

It is perhaps not permissible to speak of "frequency" in connection with a force as specified by [6]. We may, however, define the "instantaneous frequency" of a periodic force $\cos \pi h t^2$ as being the same as the frequency of $\cos mt$, which is equal to $m/2\pi$ when

$$\frac{d}{dt}(\pi h t^2) = \frac{d}{dt}(mt)$$

since this will make the slopes of the two curves equal at the

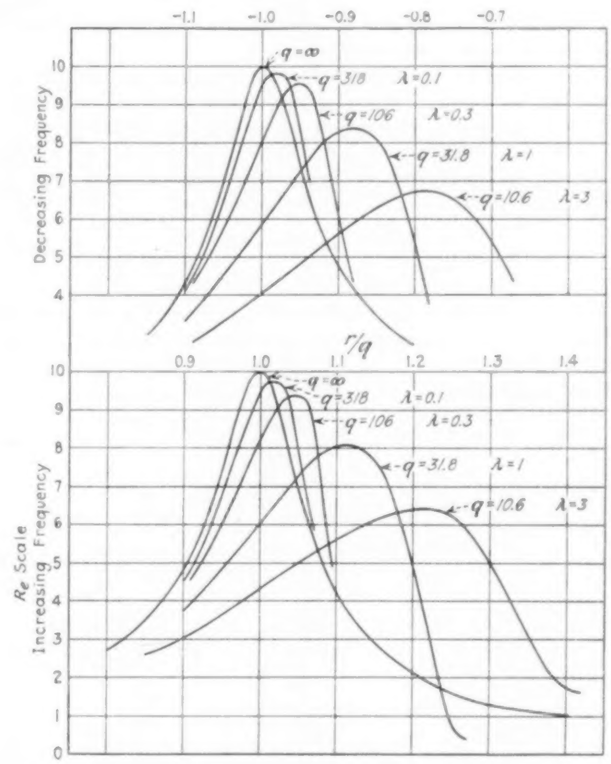

FIG. 3 RESONANCE ENVELOPES ($\gamma = 0.1$)

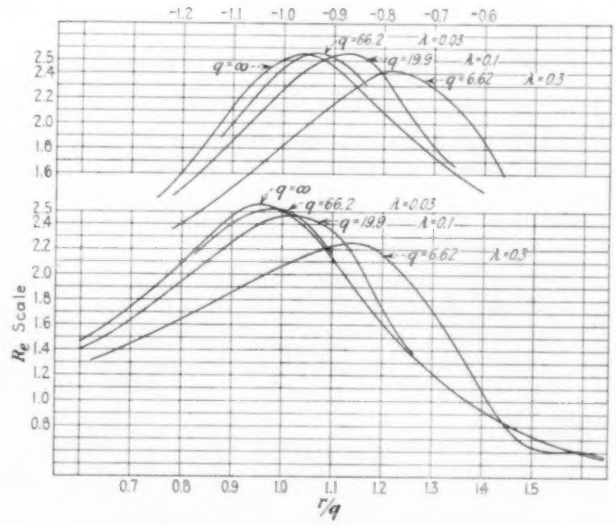

FIG. 5 RESONANCE ENVELOPES ($\gamma = 0.4$)

same angular phase of the motion. From this, if we call N' the instantaneous frequency,

$$N' = ht \quad \text{.........................} [7]$$

from which it follows that h is the acceleration of the system in cycles per second per second.

Substitute [6] in [4] and there is obtained the solution for the case of a body initially at rest and acted on by a periodic force in which the frequency is increasing at a uniform rate.

Before proceeding further it will be convenient to express this solution in dimensionless form. The time variable will be changed from t to r, according to the relation

$$pt = 2\pi r \quad \text{or} \quad Nt = r \quad \text{....................} [8]$$

N being the natural frequency of the system. Let q be the value of r at which the instantaneous frequency of the periodic force is equal to the undamped frequency N of the elastic system. In [7] make $N' = N$, and in [8], $r = q$; then, eliminating t, there is obtained

$$q = \frac{N^2}{h} \quad \text{......................} [9]$$

From [7], [8], and [9] there is obtained

$$N' = N\frac{r}{q} \quad \text{....................} [10]$$

and

$$\pi h t^2 = \frac{\pi r^2}{q} \quad \text{....................} [11]$$

Let

$$R = \frac{kx}{P} \quad \text{........................} [12]$$

and

$$\delta = \left(1 - \frac{\gamma^2}{4}\right)^{1/2} \quad \text{.................} [13]$$

In place of [6], $f(t)$ will be written in the exponential form

$$f(t) = Pe^{i(\pi h t^2 + \sigma)} = Pe^{i(\pi r^2/q + \sigma)} \quad \text{.........} [14]$$

in virtue of the relation $e^{i\theta} = \cos\theta + i\sin\theta$ and with the understanding that the imaginary part of the result will be ultimately discarded.

With these changes of variable, Equations [4] and [5] reduce to the dimensionless form:

$$R = -\frac{i\pi e^{i\sigma}}{\delta}\left\{e^{2\pi i u_1 r}\int_0^r e^{i\pi(r^2/q - 2ru_1)}dr - e^{2\pi i u_2 r}\int_0^r e^{i\pi(r^2/q - 2ru_2)}\,dr\right\} \quad \text{......} [15]$$

where

$$\left.\begin{aligned} u_1 &= \delta + i\gamma/2 \\ u_2 &= -\delta + i\gamma/2 \end{aligned}\right\} \quad \text{................} [16]$$

If reduced to real form, [15] contains four integrals of the type

$$\int_0^r e^{ar}\cos br\cos cr^2\,dr$$

These integrals cannot be reduced to any functions which have been evaluated. We are interested in their value in the vicinity of the critical speed; that is, for large values of r. In cases of engineering interest, involving relatively slow acceleration rates, there may be several hundred nearly equal positive and negative loops in the integrand between time zero and the critical speed. For this reason we consider their evaluation, with the slightest attempt at accuracy, quite impossible by any direct method of numerical integration, or by mechanical or electrical integraphs.

In the case of zero damping, when $a = 0$ the integrals may be reduced to Fresnel's integrals.

The so-called process of contour integration gives a successful method of attack, and even in the case of zero damping furnishes a simpler solution than the one involving Fresnel's integrals. In Equation [15] assume that r may have not only real but complex values. Then $\int_0^r$ is to be interpreted as an integration along the real axis in a complex r-plane.

Consider the first or u_1-term of the integrals in Equation [15] and transform from a complex variable r to a complex variable z_1 according to the relation

$$\begin{aligned} z_1 = x_1 + iy_1 &= -i\pi q\left(\frac{r}{q} - u_1\right)^2 \\ &= -i\pi q\left(\frac{r}{q} - \delta - \frac{i\gamma}{2}\right)^2 \quad \text{......} [17] \end{aligned}$$

then

$$r = \sqrt{\frac{iz_1q}{\pi}} + qu_1 \quad \text{................} [18]$$

In [17] assume that r has real values only, and separate the real and imaginary parts. Then

$$\left.\begin{aligned} x_1 &= \gamma\pi q\left[\frac{r}{q} - \delta\right] \\ y_1 &= -\pi q\left[\left(\frac{r}{q} - \delta\right)^2 - \frac{\gamma^2}{4}\right] \end{aligned}\right\} \quad \text{..........} [19]$$

Eliminating $\left(\frac{r}{q} - \delta\right)$ between these equations there is obtained

$$y_1 = -\frac{x_1^2}{\pi q\gamma^2} + \frac{\pi q\gamma^2}{4}$$

or, writing

$$\pi q\gamma^2 = \frac{1}{\lambda} \quad \text{.....................} [20]$$

$$y_1 = -\lambda x_1^2 + \frac{1}{4\lambda} \quad \text{................} [21]$$

This parabola is the path of integration in the z-plane which is equivalent to the real axis in the r-plane.

Fig. 6 shows a sketch of such a parabola. The point z_1' corresponds to $r = 0$, and the integration proceeds from here in a counter-clockwise direction around the parabola. In order to make Equations [17] and [18] self-consistent, the following conventions must be observed. Of the two values of $\sqrt{i}$ the value $\left(-\frac{1+i}{\sqrt{2}}\right)$ must be used. z_1' must be taken to lie in the (—1) quadrant, that is, arg z_1' lies between $-\pi/2$ and 0. As we proceed around the parabola, z_1 passes through the first, second, and third quadrants, so that ultimately arg z_1 lies between π and $3\pi/2$.

With these conditions and substituting r from [18], the first term of [15] within the braces can be written:

$$e^{2\pi i u_1 r}\int_0^r e^{i\pi(r^2/q\,-\,u_1 r)}\,dr = \frac{1}{2}\sqrt{\frac{iq}{\pi}}\,e^{z_1'}e^{2\pi i u_1 r}\int_0^r \frac{e^{-z_1}dz_1}{\sqrt{z_1}}\ldots\ldots[22]$$

where

$$z_1' = -\,i\pi q u_1^2\ldots\ldots\ldots\ldots\ldots\ldots[22a]$$

Returning to Equation [15], the u_2-term is transformed according to the relation

$$z_2 = x_2 + iy_2 = -\,i\pi q\left(\frac{r}{q} - u_2\right)^2 = -\,i\pi q\left(\frac{r}{q} + \delta - \frac{i\gamma}{2}\right)^2\ldots\ldots[23]$$

Separation into real and imaginary parts will lead to a parabola identical with that given by [21]. The point z_2', corresponding to $r = 0$, lies in the third quadrant, and the part of the parabola along which integration is carried out is located wholly in this quadrant. The u_2-term of [15] reduces to an equation of the same form as [22], subscripts 2 instead of 1 being used.

Consider, in Fig. 6, integration around the path ∞_r, A, B, ∞_r. Around this path by Cauchy's theorem

$$\int_c \frac{e^{-z}\,dz}{\sqrt{z}} = 0$$

since no singularities of the integrand are enclosed within it.

If, however, arg $z > \pi$, integration is around a path such as $\infty_r, A, B, C, D, \infty_r$, and the singularity at the origin is enclosed within the contour.

In the latter case the contour may be deformed into Hankel's integral for the gamma function,[3] and

$$\int_c \frac{e^{-z}\,dz}{\sqrt{z}} = -\,2\sqrt{\pi}$$

In either case there may be written

$$\int_{z_1}^{z_1}\frac{e^{-z}\,dz}{\sqrt{z}} = -\,2\sqrt{\pi}\,K + \int_{z_1'}^{\infty_r}\frac{e^{-z}\,dz}{\sqrt{z}} - \int_{z_1}^{\infty_r}\frac{e^{-z}\,dz}{\sqrt{z}}\ldots\ldots[24]$$

where

$$\left.\begin{array}{l} K = 0 \text{ if } \arg z < \pi \\ K = 1 \text{ if } \arg z > \pi \end{array}\right\}\ldots\ldots\ldots\ldots\ldots[25]$$

The integration in [24] proceeds along lines parallel to the x-axis.

In the first integral write

$$\left.\begin{array}{l} z = z_1' + v \\ z = z_1 + v \end{array}\right\}\ldots\ldots\ldots\ldots\ldots\ldots\ldots[26]$$

and in the second,

where v is purely real. Then

$$e^{2\pi i u_1 r}\int_0^r e^{i\pi(r^2/q\,-\,2ru_1)}\,dr = \frac{1+i}{\sqrt{2}}\sqrt{(q)}e^{2\pi i u_1 r\,+\,z_1'}K - \frac{1+i}{2\sqrt{2}}\sqrt{\frac{q}{\pi}}\,e^{2\pi i u_1 r}\int_0^\infty \frac{e^{-v}dv}{\sqrt{z_1'+v}}\ldots\ldots\ldots[27]$$
$$+ \frac{1+i}{2\sqrt{2}}\sqrt{\frac{q}{\pi}}\,e^{i\pi r^2/q}\int_0^\infty \frac{e^{-v}dv}{\sqrt{z_1+v}}$$

The z_2-integral starts for $r = 0$ in the third quadrant and terminates for $r = \infty$ in the same quadrant. No singularities can be enclosed within the contour, and an expression for this integral similar to [27] with subscripts 2 and with the K-term omitted can be written as follows: Let

$$\phi_1 = \int_0^\infty \frac{e^{-v}dv}{\sqrt{z_1+v}}\ldots\ldots\ldots\ldots\ldots[28]$$

and let ϕ_1', ϕ_2, ϕ_2' designate the corresponding expression when z_1 becomes z_1', z_2, z_2', respectively. Then with this notation, and substituting [27] and its companion equation with subscripts 2 in [15], there is obtained

$$R = \frac{(1-i)e^{i\sigma}\sqrt{q\pi}}{2\sqrt{2}\,\delta}\left\{\left(2\sqrt{\pi}e^{z_1'}K - \phi_1'\right)e^{2\pi i u_1 r} + \phi_2'e^{2\pi i u_2 r} + e^{i\pi r^2/q}\,(\phi_1 - \phi_2)\right\}\ldots\ldots\ldots[29]$$

The terms containing ϕ_1' and ϕ_2' represent a damped harmonic vibration. They arise from the initial conditions $x = 0$ and $dx/dt = 0$ at $t = 0$ which were imposed.

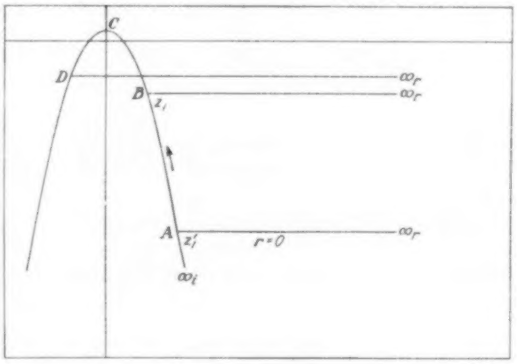

FIG. 6

Where any damping is present in the system, the contribution to R by these terms in the vicinity of the critical will be practically nil. The vibration represented by the remaining terms, in analogy to the case of constant frequency, will be designated as the "forced vibration." For this forced vibration we have

$$R_f = \frac{(1-i)e^{i\sigma}\sqrt{q\pi}}{2\sqrt{2}\,\delta}\,e^{i\pi r^2/q}\left\{2\sqrt{\pi}e^{z_1}K + \phi_1 - \phi_2\right\}\ldots[30]$$

Only the real part of this solution is to be utilized. Assume that the expression within the braces has been evaluated and is of the form $a + bi$, where a and b are real. Then, writing the exponentials in sine and cosine form, and multiplying out, the real part is found to be

$$R_f = \frac{\sqrt{q\pi}}{2\sqrt{2}\,\delta}\left\{\left[(a+b)\cos\pi r^2/q + (a-b)\sin\pi r^2/q\right]\cos\sigma + \left[(a-b)\cos\pi r^2/q - (a+b)\sin\pi r^2/q\right]\sin\sigma\right\}\ldots\ldots[31]$$

This equation represents an oscillating curve. As the phase angle σ is varied we obtain a family of such curves. By the elimination of σ between R_f and $\partial R_f/\partial\sigma = 0$ there is obtained the equation for the envelope of the family of curves, namely,

$$R_e = \frac{\sqrt{q\pi}}{2\delta}\sqrt{a^2+b^2}$$

---

[3] See Whittaker and Watson, "Modern Analysis," art. 12.22.

or, in the customary notation of the complex variable,

$$R_e = \frac{\sqrt{q\pi}}{2\delta} \text{ modulus} \left\{ 2\sqrt{\pi}\, e^{z_1}K + \phi_1 - \phi_2 \right\} \ldots . [32]$$

Consider next methods for evaluating the ϕ-integrals of Equation [28]. Writing $v = \tan s$, there is obtained

$$\phi_1 = \int_0^{\frac{\pi}{2}} \frac{e^{-\tan s}\, ds}{\cos^2 s \sqrt{z_1 + \tan s}} \ldots\ldots\ldots\ldots [33]$$

which is more convenient for purposes of direct computation than [28].

The evaluation was carried out as follows:

Referring to Fig. 8, the complex number $z_1 = x_1 + iy_1$ was plotted with reference to the real and imaginary axes, any convenient scale being used and a line $z_1 \infty$ drawn parallel to the real axis, and on this $\tan s$ laid off from z_1 at 5-deg intervals of s.

Writing $z = z_1 + \tan s = \rho e^{i\theta}$

$$z^{-1/2} = \rho^{-1/2} e^{-i\theta/2} = \rho^{-1/2}(\cos \theta/2 - i \sin \theta/2)$$

But $\rho = y_1 \csc \theta$, and by trigonometric reduction,

$$z^{-1/2} = y_1^{-1/2} \left\{ \left(\frac{\sin \theta}{2} + \frac{\sin 2\theta}{4} \right)^{1/2} - i \left(\frac{\sin \theta}{2} - \frac{\sin 2\theta}{4} \right)^{1/2} \right\} \ldots\ldots\ldots [34]$$

the radical terms were computed and plotted as polar curves from a base circle and are the curves marked "real" and "imaginary" in Fig. 8.

The function $e^{-\tan s} \sec^2 s$ was computed for the 5-deg intervals of s.

A straight edge, with scale, is passed through the origin and the successive points on the $z_1 \infty$ line, corresponding to the 5-deg intervals of s. The intercepts of this scale between the base circles and the real and imaginary curves are tabulated. These intercepts are then multiplied by the function $e^{-\tan s} \sec^2 s$ and the products summed by Simpson's rule. Dividing by $y_1^{1/2}$ there are obtained the real and imaginary parts of the ϕ_1-integral.

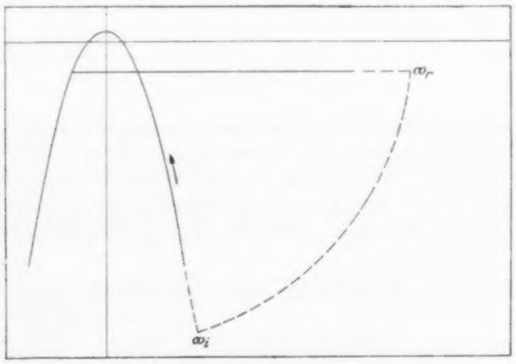

FIG. 7

The same real and imaginary base curves serve for all values of z_1, and it is merely necessary to shift the position of the z-scale to compute for a new value of z_1.

This procedure fails for small values of z_1 and for points on or near the real axis, but for computing such points complex series can be obtained.

The ϕ-function is related to the confluent hypergeometric W-function.[4]

Referring to Whittaker and Watson,[4] write in their notation $k = -{}^1/_4$, $m = {}^1/_4$, and equate the definite integral of Art. 16.12 to the asymptotic series of Art. 16.3. There is thus obtained the following asymptotic expansion, useful for large values of z:

$$\int_0^\infty \frac{e^{-v} dv}{\sqrt{z + v}} = z^{-1/2} \left\{ 1 - \frac{1}{(2z)} + \frac{1 \cdot 3}{(2z)^2} - \frac{1 \cdot 3 \cdot 5}{(2z)^3} \ldots \right\} [35]$$

and it may be shown to hold over the range necessary for our purpose from

$$\frac{3\pi}{2} > \arg z > -\frac{\pi}{2}$$

In like manner, equating the series of Art. 16.41 to the definite integral of Art. 16.12, there is obtained the convergent series

$$\int_0^\infty \frac{e^{-v}\, dv}{\sqrt{z + v}} = (1 - 2K)\sqrt{\pi}\, e^z - 2z^{1/2} \left\{ 1 + \frac{2z}{1 \cdot 3} + \frac{(2z)^2}{1 \cdot 3 \cdot 5} + \ldots \right\} \ldots\ldots [36]$$

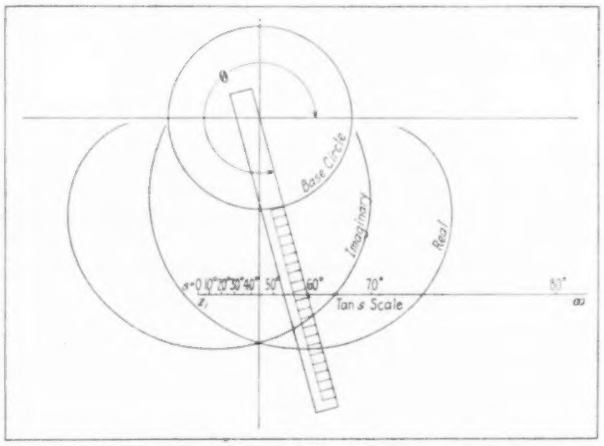

FIG. 8 CONSTRUCTION FOR EVALUATING ϕ-INTEGRALS

Whittaker and Watson do not consider the value of the function for $\arg z > \pi$, but the necessity for the K-term may be independently established.

It will be found that in [30], in the vicinity of the critical speed, the ϕ_2-term contributes only from 1 to 5 per cent of the value of the term within the braces. Further, z_2 will be large. An approximate expression of sufficient accuracy may be developed for ϕ_2. In the asymptotic expansion [35], drop all but the first term. Then

$$\phi_2 = z_2^{-1/2}$$

But

$$z_2 = -i\pi q \left(\frac{r}{q} + \delta - \frac{i\gamma}{2} \right)^2$$

from which it may be shown that z_2^{-12} is approximated by

$$z_2^{-1/2} = \phi_2 = -\sqrt{\frac{\lambda}{2}} \frac{\gamma}{(r/q + \delta)} \left\{ \left[1 - \frac{\gamma}{2(r/q + \delta)} \right] + i \left[1 + \frac{\gamma}{2(r/q + \delta)} \right] \right\} \ldots\ldots [37]$$

While ϕ_2 may be calculated by using the exact expression, the effect of so doing upon the curves plotted in Figs. 1–5 could hardly be detected.

---

[4] Cf. Whittaker and Watson, "Modern Analysis," chap. 16.

THE CASE OF DECREASING FREQUENCY

As previously stated, the case of decreasing frequency is simulated by fixing our attention on negative values of r. If we write $\int_{\infty}^{r}$ in place of $\int_{0}^{r}$ Equation [15] will apply to this case.

Referring to Fig. 7, we have the parabola into which the real axis is transformed. The z_1-integral will now start at α_i on the parabola, and the part in which we are interested for $r < 0$ will lie wholly in the (—1) quadrant.

The z_2-integral will likewise start at ∞_i in the (—1) quadrant, but $r = 0$ will lie in the third quadrant.

In either case, the contour is closed by a quadrant at infinity, and it may be proved that the integral around this is zero.

A solution corresponding to [30] may then be written:

$$R_f = \frac{(1 - i)e^{i\sigma}\sqrt{q\pi}}{2\sqrt{2}\,\delta}\, e^{i\pi r^2/q} \left\{ \phi_1 - \phi_2 - 2\sqrt{\pi}\, e^{z_1^2}K \right\} \ldots . \quad [38]$$

where in this case

$$\begin{aligned} K &= 0 \text{ if } \arg z < \pi \\ &= 1 \text{ if } \arg z > \pi \end{aligned}$$

The real and imaginary parts of the expression within the braces are calculated, and [32] applies for the equation of the envelope.

SUMMARY OF THE CALCULATION PROCEDURE

It is desired to calculate the equation of the envelope R_e for specified values of the damping constant γ and the acceleration constant q. If we know the natural frequency of the system in cycles per second and the rate of acceleration in cycles per second per second, q is first determined from [9].

The λ-constant is then determined from [20] and a series of values of z_1 on the parabola of [21] determined. For each such value of z_1, ϕ_1 is calculated by either [33], [34], or [35] as proves convenient. In general, for large values of z, $|z| > 5$, the asymptotic series [35] is used. For small values, $|z| < 0.5$, and for points on the real axis the convergent series [35] is employed, and for all other values, the definite integral [33].

To the resulting real and imaginary parts are added $2\sqrt{\pi} \times e^{z_1^2}K$ and the sums plotted against x_1 as the abscissa.

It may be noted that although K is a discontinuous function, no discontinuity is implied in the motion of the body for there is a discontinuity in the function ϕ_1 which exactly compensates, so that where $\arg z$ passes through π the function $\phi_1 + 2\sqrt{\pi}e^{z_1^2}K$ and all its derivatives are continuous.

In the case of zero damping the parabola in the z-plane degenerates into the negative imaginary axis, considered as looped about the origin, and the sole difference in treatment is that $\sqrt{y_1}$ is used for the abscissa in the plot instead of x_1.

The r/q-values corresponding to the x_1-values are determined from [19].

The real and imaginary parts of ϕ_2 are determined from [37] and added in, and finally a series of points on the envelope are calculated by [32].

It may be noted that the calculation for ϕ_1, which is the difficult part to determine, will furnish data for all the curves over which $\gamma^2 q$ is constant.

It may be noted also that the ϕ_1-calculation for positive values of r is identical with the calculation of ϕ_2 for negative values of r. The calculations for increasing frequency will therefore also detail the curves for decreasing frequency.

SYSTEM OF SEVERAL DEGREES OF FREEDOM

The foregoing methods may, in theory at least, be extended to systems of several degrees of freedom.

Assume a system comprising several masses with elastic connections between, with or without damping, and with a periodic force S acting on one of the bodies.

For each mass of the system a differential equation is written, and in this family of differential equations p is written for d/dt and p^2 for d^2/dt^2.

Solve this family of equations simultaneously for the motion of the particular body desired, treating p as an algebraic constant, and the resulting equation in p can then be expressed in the form

$$x_s = \frac{f(p)}{pF(p)}\, S$$

Determine the roots of the equation $F(p) = 0$. These roots, in the case of zero damping, will be imaginary, but to each pair of roots corresponds one of the natural frequencies of the system, and there are several methods available for determining such frequencies. With damping in the system, the roots are complex and the procedure is limited by the possibility of their determination.

By the rules of operational calculus[5] the foregoing may then be broken up into a number of terms of the form $S/(p - \alpha)$, and each term "interpreted" by the formula

$$\frac{S}{p - \alpha} = e^{\alpha t} \int_{p}^{t} Se^{\alpha t}\, dt$$

There is thus obtained an equation similar to [4], and each term of this equation may be evaluated by the method of contour integration outlined in the paper.

The author is somewhat doubtful whether the importance of the problem would in many cases justify the considerable labor involved in evaluating the solution. It is quite possible, however, that an approximate solution can be obtained, and the exact solution might then serve as a guide for its construction and accuracy.

Discussion

R. G. STURM.[6] In connection with vibration during acceleration through a critical speed, an example of a practical application of this phenomenon might prove of interest. The Stockbridge vibration damper, which is used quite extensively on overhead transmission lines, has two natural frequencies resulting from two degrees of freedom—that is, direct oscillation and rotational motion of the damper weight. The use of this damper has been described by R. A. Monroe and R. L. Templin.[7] The fact that the damper is subjected to varying speeds of vibration which extend over one or both of its critical speeds and at the same time is affected by a considerable damping action which is analogous to a velocity damping, makes an analysis of the action of the damper extremely complicated.

Experimental determination of these natural frequencies reveals the fact that if the damper is vibrated at a speed greater than the critical speeds and then permitted to coast through all speeds to rest, the observed maximum throws occur at speeds less than when the damper is operated at a uniform speed. These observations are qualitatively in agreement with the findings of the author and show quantitative agreement with the theory applied to two degrees of freedom.

It may be stated that theoretical values of maximum throw and critical speeds, as well as the shape of the deformed damper cable, have been checked by experiments.

[7] "Vibration of Overhead Transmission Lines," by R. A. Monroe and R. L. Templin, presented at the Summer Convention of the A.I.E.E., Cleveland, Ohio, June 20–24, 1932.

E. A. Tulus.[8] In high-speed Diesel applications it is almost always true that the fundamental mode of vibration is below the operating speed of the installation. In one of the recent cases of Diesel drives brought to the writer's attention, the operating speed was so high and the elastic system was so flexible that in a final design both major orders of vibration of the first and second mode were below the operating speed. Naturally, the question arises in the designer's mind as to how dangerous it is to operate an installation of this sort and as to what the stresses would be in such a drive as the unit passes through the major orders in speeding up to its rated speed.

It is understood that the danger is not serious, since the unit passes through the critical and it takes time to build up the appreciable amplitudes of vibration. But in some cases where the rate of acceleration is very low and the damping in the system is negligible, the amplitudes may reach such values that the operation of the unit is out of question.

The author has solved the problem completely. The writer has been interested in the same problem for some time and has obtained both experimental and theoretical solutions. In obtaining the theoretical solution, certain approximations were made, with the following line of reasoning.

Taking the case of a vibrating body with 1 deg of freedom, the differential equation may be written:

$$m\ddot{x} + c\dot{x} + kx = 0 \quad \ldots\ldots\ldots\ldots [39]$$

Introducing the initial condition of $t = 0$, $\dot{x} = \dot{x}_0$, $x = 0$, the solution of [39] may be written:

$$x = \frac{\dot{x}_0}{w_n} e^{-ct/2m} \sin w_n t \quad \ldots\ldots\ldots\ldots [40]$$

Let us assume now that a force is acting on a vibrating body and that the force varies from m to n as a function of t, as shown on the curve in Fig. 9.

---

[8] Development Engineer, Power Engineering Department, Westinghouse Elec. & Mfg. Co., East Pittsburgh, Pa.

In order to obtain the displacement of the system at any time τ, we have to divide $f(t)$ into elementary intervals $d\tau$. Due to the action of the force $f(t)$ during this interval, the velocity of the mass m is increased, which can be found from the following equation:

$$f(t)\,d\tau = m\,d\dot{x}_0$$

or

$$d\dot{x}_0 = \frac{f(t)}{m}\,d\tau \qquad [41]$$

From Equation [40] it can be concluded that any addition to the velocity at the time τ will produce at the moment t a displacement:

$$dx = \frac{f(t)\,d\tau}{mw_n} e^{-c/2m\,(t-\tau)} \sin w_n\,(t-\tau)$$

Assuming that $f(t) = P \sin w\tau$ between $\tau = 0$ and $\tau = NT$, where T is the period of any given forced frequency, and taking the summation, we have:

$$X(t) = \frac{P}{mw_n}\int_0^{NT} e^{-c/2m\,(t-\tau)} \sin W_n\,(t-\tau) \sin w\tau d\tau \qquad [42]$$

Integrating [42] from 0 to NT for any desirable number of cycles of forced frequency, it is possible to obtain $X(t)$ for a given damping coefficient and the rate of acceleration. The writer carried calculations for the particular case of $N = 100$ and $c/cz = 0.05$, which is equivalent to the author's notation $\gamma = 0.1$.

The amplitude of vibration as a function of τ is shown in Fig. 10, which checks almost exactly the curve on Fig. 3 in the paper.

It is appreciated that the method is long and requires many calculations, so together with Mr. J. G. Baker,[9] a model was built, as shown in Fig. 11, to obtain similar results experimentally. A magnetic damper was used to introduce damping into the system. Constant rate of acceleration was maintained with a vacuum-tube current regulator. The results of the investigation are shown in Fig. 4 and differ 10 to 15 per cent from the results as obtained by the author. This is within the accuracy of the measuring instruments. As a conclusion, it may be pointed out that the model study presents wonderful possibilities for study of systems of many degrees of freedom where theoretical solution hardly could be approached.

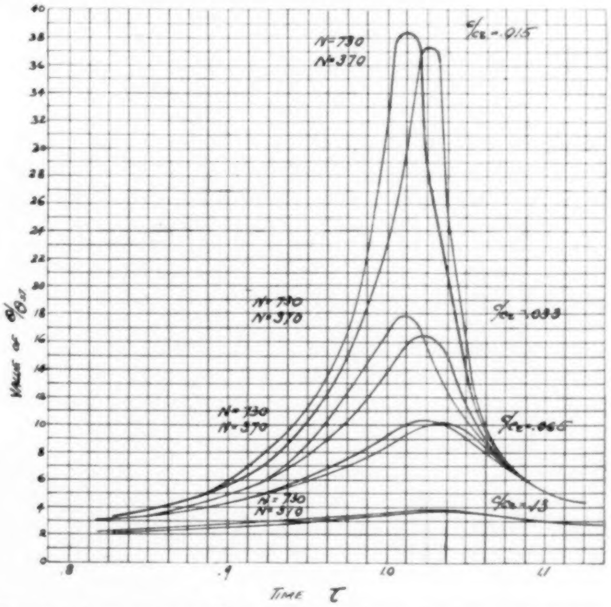

FIG. 12 AMPLITUDE OF VIBRATION DURING ACCELERATION THROUGH CRITICAL SPEED

Erratum

On page 116 of the Applied Mechanics section (paper APM-54-10), Equation [9], has been incorrectly derived and should read:

$$\tan \alpha = -\frac{\partial \tau/\partial y - \partial \sigma_y/\partial x}{\partial \tau/\partial x - \partial \sigma_x/\partial y}$$

In view of this fact, the procedure as outlined in the discussion is useless as a practical method of stress determination based on photoelastic readings.

APM-54-25

The Use of Models in Determining the Strength of Thin-Walled Structures

By HAROLD E. SAUNDERS[1] AND DWIGHT F. WINDENBURG,[2] WASHINGTON, D. C.

This paper discusses the status of fundamental theories and explains the circumstances surrounding the use of models to determine the strength of three types of thin-walled structures. The particular types selected represent problems in naval architecture, but their counterparts are frequently encountered in other engineering structures.

Special emphasis is devoted to the necessity for obtaining geometrical similarity between the model and its original and for using identical materials if consistent and reliable data are to be obtained.

The actual methods used in the fabrication of representative models are described in considerable detail, as an aid in their application to other model research. The limits to which riveting and welding can be duplicated are defined, and the use of soldering and spot welding as alternatives is discussed.

In conclusion, the authors point out that the application of intensive thought and study to model research, commensurate with the care devoted to the design of the full-scale structure, is imperative if reliable results are to be expected from the work.

H. E. SAUNDERS

D. F. WINDENBURG

THE keynote of present engineering design is economy. In land structures, weight as a rule is of secondary importance for a given performance, and the primary consideration is cost. However, in ship design, economy of weight is generally predominant, although in merchant work the question of operating cost and profits is again the controlling factor. In the design of airplanes and submarines, weight saving becomes of preeminent importance.

By correct design, much weight can be saved in airplane spars and struts, ship's hulls, ship's bulkheads, machinery and turret foundations, and other ship structures. Correct design, however, involves much thought and requires extended study of many possible combinations of material to find those which are most satisfactory. The selected combinations, in turn, require confirmation to the greatest possible degree before they can be used in building engineering structures. Such confirmation is one of the functions of model tests in engineering.

For example, the design of a submarine hull involves the attainment of the required collapsing pressure with a minimum weight of structure. In detail, this design hinges upon the correct distribution of material in the stiffening frames and shell. Although the problem has been generously treated from the theoretical standpoint, it is imperative that direct experimental tests be made, especially since the demands for military performance and weight saving require the factor of safety to be extraordinarily low. The naval architect is at once confronted with the practicability and reliability of model tests in determining the strength of his submarine-hull design, as it is impossible for him to test the full-scale submarine to destruction.

The use of these models offers the designer a comparatively economical indication of the correctness of his theories, and, in many cases, the only advance proof he can obtain. However, he must recognize the necessity of approaching the model program with the same systematic study as was used in developing the tentative designs of the full-scale structure, and of applying great care and discretion to the conduct of the model tests and to the interpretation of their results.

For example, during the World War, the German Navy (1)[3] prepared an elaborate model-testing program to prove the theories which their scientists had developed in an endeavor to obtain the greatest strength for the least weight in the pressure hulls of their submarines. Their tests were intended to show the influence of the scale of a submarine-hull model upon the collapsing pressure, and also the influence of framing upon the strength of the shell against collapse. They found, however, that in each series of supposedly similar models, the maximum collapsing pressure was more than twice as great as the minimum, the larger models usually possessing the greater strength. Such erratic results could of course give no reliable information upon the influence of framing. Nevertheless the tests indicated that inaccuracies in workmanship were relatively greater in the smaller cylinders and that model-test results could not be applied safely to the design of submarine hulls unless the thickness of plating was at least 0.16 in. In other words, they realized that their models had to be exactly similar before they could expect consistent results. Further experiments were planned, but the work

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[3] Numbers in parentheses refer to bibliography at the end of the paper.

could not be carried out because of the general breakdown at the close of the war.

In 1929 the U. S. Experimental Model Basin at Washington undertook an extensive series of model tests to investigate completely the strength of submarine hulls. All the tests to date have been made on small-scale models with a wall thickness about one-third of the minimum indicated by the German experiments of twelve years previous. Additional tests have been made on models of elementary ship structures, using material as thin as 0.03 in. It is the purpose of this paper to show that small-scale model tests on these thin-walled structures are not only possible, but practical, economical, and reliable.

GENERAL SCOPE OF TESTS

Three types of thin-walled structures have been constructed and tested as models. These comprise (*a*) cylindrical shells representing pipes, tanks, submarine hulls, diving bells, and other vessels subjected to external pressure, (*b*) flat, unstiffened bulkheads for submarines, and (*c*) hollow girders representing primary hull structures of surface ships.

These tests have been systematic and extensive, embracing some hundreds of models. The influence of certain features has been investigated experimentally by changing one variable at a time in a series of models. This procedure required the making of many models in each series, but after the technic for the fabrication of one satisfactory model had been developed, the building of the remaining models of that series was generally found to be a simple and economical operation. In later paragraphs of this paper, the fabrication methods for these multiple models are described.

INDIVIDUAL VS. MULTIPLE MODELS

If, for special reasons, a single model is to be built, it should be constructed to a relatively large scale so that the general construction and the details may be faithfully reproduced. An individual model must be made with even greater care than multiple models, as no verification of the test is intended. Hence it is doubtful if there is much saving in time or cost in the construction of a single model. It is certain that definite conclusions can be drawn with greater assurance when they are based upon the closely duplicated results of several identical models rather than upon data from one isolated example.

THE ATTAINMENT OF GEOMETRICAL SIMILARITY

The theory of similitude, upon which the whole art of model testing is based, requires (*a*) geometrical similarity and (*b*) similar or identical materials. Both of these requirements present real, but not insurmountable, problems in thin-walled model construction.

If models are to give results comparable to those expected from the full-size structure, they must be geometrically similar to that structure. For a simple structure, such as a tube of circular cross-section, the attainment of geometrical similarity in a model at first sight presents no great obstacles. However, difficulties soon arise as the scale is reduced.

Suppose it is desired to build and test a model of a long tubular column belonging to a hydraulic ram or elevator. If the original were, say, 10 in. in diameter, we should expect a manufacturing tolerance in diameter and roundness of 0.001 in., or one ten-thousandth part of the diameter. If the model were to be 1 in. in diameter, we should have to specify a tolerance of 0.0001 in., again one ten-thousandth part of the diameter. If the model tube were to be 0.1 in. in diameter, the corresponding tolerance would be 0.00001 in. This is an extremely exacting requirement.

The earliest experimenters with vessels subjected to external pressure soon discovered that their models must be geometrically similar to the original if the test data obtained from them were to be used to predict the performance of the full-sized structure. One of the first of these was Fairbairn (2), whose experiments on the strength of lap-jointed as compared to butt-jointed tubes led him to declare: "These facts are conclusive in showing the necessity of adhering in these constructions to the true cylindrical form."

Later experimenters, in various lines, following further developments of the law of similitude, have had the matter of geometrical similarity brought forcibly to their minds. In spite of repeated warnings, however, tests continue to be made on decidedly inferior models. As Buckingham (3) points out, "it is a familiar fact that in many instances small-scale models do not act at all like their full-sized originals under conditions which seem at first sight to be similar, and that hasty conclusions from model experiments are very unsafe indeed."

A flat plate is one of the simplest geometrical forms, yet it is one of the most difficult to produce accurately to small scale. Rolled sheets are rarely of uniform thickness and they invariably lack homogeneity, even when elaborately fabricated, with the result that they are difficult to form. Black sheet steel, for example, is totally unsuited to the manufacture of external-pressure-vessel models, for it refuses to roll into a smooth, circular cylinder. The high-grade stretcher-leveled steel used in the manufacture of metal furniture and automobile bodies possesses the greatest all-around uniformity in available ferrous material, and is the only material which can at the present time be recommended for the building of models of relatively thin-walled steel structures.

THE USE OF IDENTICAL MATERIALS

If the model and full-sized structure are to give similar results, they must also be made of materials having identical physical properties. Although the variations in the physical properties may be known and approximately allowed for, corrections of this kind usually introduce uncertain factors and hence should be avoided. Fortunately, Young's modulus and Poisson's ratio, which enter as the principal physical constants in most elastic equations, are practically the same for all steels used in engineering construction, and their values can be assumed with reasonable accuracy when reliable tests are not available. On the other hand, both the yield point and the proportional limit are in general poorly defined and they may be found to vary with the direction of rolling.

The following table gives the results of physical tests on many samples of black sheet steel and metal-furniture steel used in constructing models at the Experimental Model Basin:

	Thickness of sheet in inches		Young's Modulus $\times 10^{-6}$		Yield point $\times 10^{-3}$		
Material	Nominal	Tolerance	Low	High	Low	High	Probable value
Black sheet steel.......	0.05	0.001	..	..	22.6	32.6	26.0
Metal - furniture steel..	0.05	0.0005	..	..	30.7	39.3	36.0
Medium-steel plate......	0.25	0.01	29.2	29.7	39.7	40.9	40.0

THE SIMPLE CYLINDRICAL SHELL

Perhaps the simplest model of a thin-walled structure is the circular, cylindrical shell, or common tube. Nevertheless the fabrication of such a model shell or tube which is to withstand external pressure without premature buckling is by no means an easy matter. Seamless tubes, suitable for very thin-walled models, are not made commercially, and it is slow and expensive work to turn down a thick seamless steel tube on a lathe. It would also be unduly expensive to build the necessary apparatus

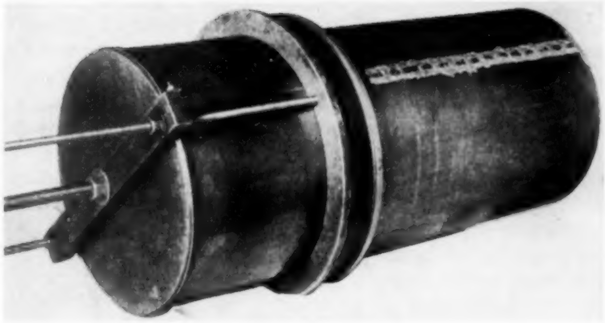

FIG. 1 THIN CYLINDRICAL SHELL DURING FABRICATION, SHOWING CENTER DRAWBOLT FOR PLUNGER AND TWO SIDE DRAWBOLTS FOR RING. SEAM STRAP SECTIONS PARTLY SOLDERED IN PLACE

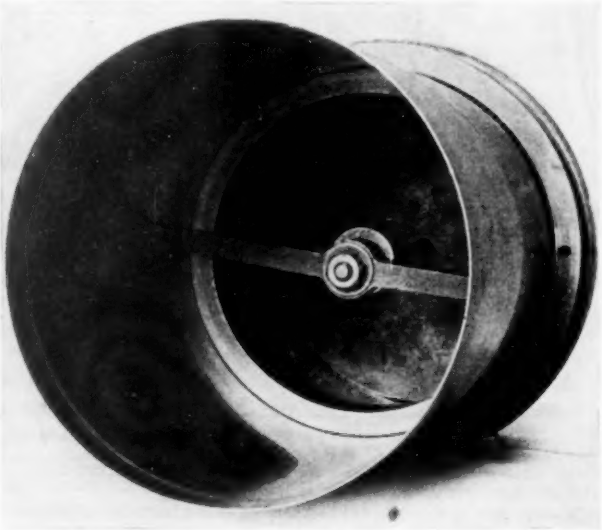

FIG. 2 CYLINDRICAL SHELL WITH INSIDE PLUNGER AND OUTSIDE RING

for forming thin seamless tubes, assuming the walls could be reduced to the dimensions required. Moreover, seamless tubes, machined or drawn, are not representative of large pressure vessels which must be fabricated from steel plates.

For models of such pressure vessels, including submarine hulls, an internal diameter of 16 in. has been found economical and satisfactory. This diameter, for a number of applications, permits the use of sheet steel about 0.05 in. thick for the shell. The edges are butted, and the seam is covered by a narrow longitudinal strap soldered in place.

FABRICATION OF THE SHELL

A thin sheet of steel cannot be rolled uniformly in a cylinder, unless the rolls are heavy and the sheet has first been formed to the proper curvature at the ends adjacent to the butt. To eliminate the latter difficulty, the rolls are first set to the required radius by using a sheet of the same dimensions as will be used for the finished model. The sheet to be fabricated is then cut about a foot too long in the direction of rolling, and is formed in the rolls, with the excess length lapped over. With the two overlapping ends held temporarily in proper position by soft solder, the two butt edges are formed by cutting through the double-thickness laps with a metal saw. The butt edges are then dressed carefully with a file to a previously scribed line.

To maintain the cylindrical form while the butt joint is made, a steel plunger 4 in. long and exactly 16 in. in outside diameter is placed inside the tube and a steel collar or ring about the same length is fitted snugly over the outside of the shell. The plunger and ring are drawn along the tube abreast each other by means of threaded rods as shown in Figs. 1 and 2. They are so rigid and they fit the shell so tightly that they iron out all local irregularities and hold the shell in exact and uniform circular shape while the seam straps are soldered in position. In practice, the plunger and ring are drawn along alternately, about two inches at a time, the ring always remaining over and abreast the plunger. After each movement of the ring, a narrow strip about two inches long and tapered at the edges, as shown in Fig. 3, is soft-soldered over the seam thus exposed. Since the strap is soldered on that portion of the shell which is held rigidly in circular form by the inside plunger, the heat from soldering will cause no warping.

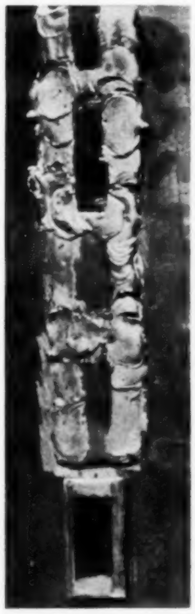

FIG. 3 CLOSE-UP OF SHELL SEAM WITH SHORT SECTION OF STRAP READY FOR SOLDERING IN PLACE NEXT TO OUTSIDE RING

The result is a smooth cylindrical model, without frames or stiffening rings, which is very nearly uniform in diameter and circular in cross-section. However, it is not enough to know that it is a *good* model. The question which must be answered is: *How good?* That is, how closely does the model resemble the full-scale original? The answer to this question requires the building of apparatus and the perfecting of a technic for measuring the contour of the shell of both the model and its prototype.

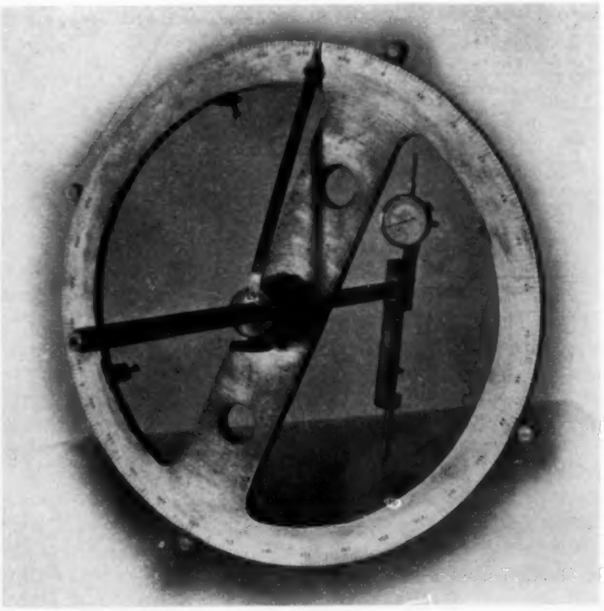

FIG. 4 APPARATUS FOR MEASURING VARIATIONS IN RADIUS OF CYLINDRICAL SHELLS

(The large ring is placed over the open end of the model and secured to it. The cross-arm on the central spindle, carrying the dial micrometer and sliding plunger, may be placed at any desired height in the model. The dial micrometer measures variations in radius at all points around the selected circumference.)

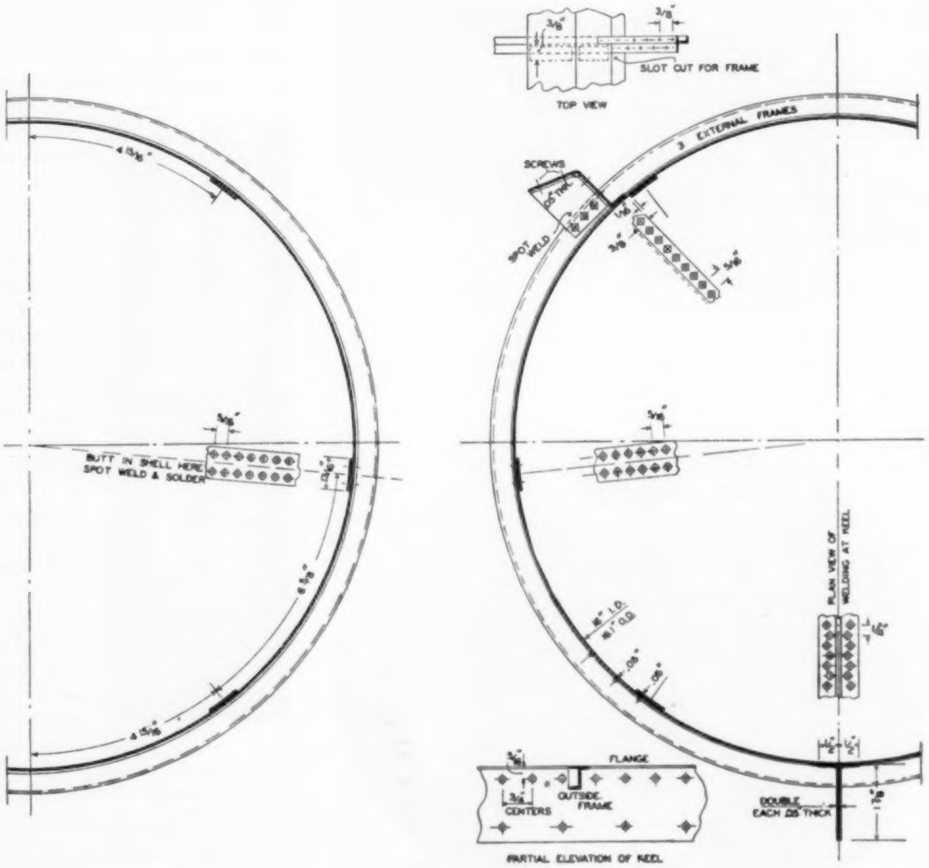

FIG. 6 WORKING DRAWING OF CYLINDRICAL SHELLS STIFFENED BY CIRCUMFERENTIAL EXTERNAL FRAMES AND LONGITUDINAL MEMBERS
(The model on the left has longitudinal straps only; that on the right has keel and upper longitudinals in addition.)

MEASUREMENT OF SHELL CONTOUR

Hitherto, either no measurements of out-of-roundness of vessels subjected to external pressure were made, or else experimenters were satisfied with measuring variations in diameter only (4), (5), (6). Although such measurements give a misleading picture of the true contour of the shell, systematic variations in diameter are very significant in determining the strength of long tubes. However, the problem becomes more complicated for tubes of shorter length, which collapse in a number of lobes greater than two. In this case, as the authors have previously pointed out (7), the variation in circular form within the region of one lobe is the significant feature.

To determine the actual contour of the shell, the measuring apparatus shown in Fig. 4 is used. This consists of a radial arm carrying a sliding plunger and dial micrometer which are swung around inside the shell at any station desired. One end of the shell under test is blanked while the other remains open to view. Dial-micrometer readings for various angles around the circumference are plotted on polar-coordinate paper, giving a graphical picture of the variations from circular form to a greatly magnified scale like that shown in Fig. 5. Similar readings are taken at successive pressure increments during the test and plotted on the same sheet, showing how the deflections increase with increasing load, and illustrating the characteristic lobe formation which always starts at the point of greatest out-of-roundness.

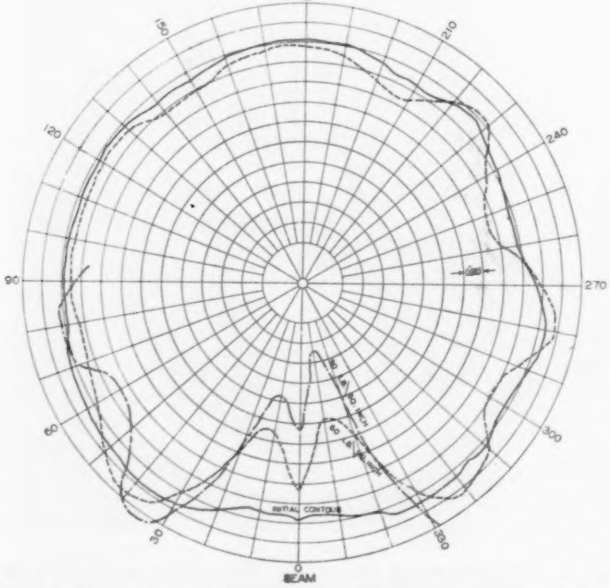

FIG. 5 VARIATIONS IN RADIUS OF CYLINDRICAL SHELL 16 IN. INSIDE DIAMETER AND 0.063 IN. THICK AFTER FABRICATION AND DURING EXTERNAL-PRESSURE TESTS
(Note that maximum variation in radius of the initial contour is only 0.010 in., about one-sixth the shell thickness.)

In using this or similar apparatus, it is essential that the axis of rotation of the radial arm be the geometrical axis of the model. Otherwise, since variations in radius are plotted to a greatly magnified scale, a true circle will appear distorted. Since we cannot be certain that the instrument axis is absolutely centered, especially for long models, the graphical contour thus obtained may show a greater out-of-roundness than actually exists. We are certain, therefore, that no model has a greater out-of-roundness than is indicated by these polar diagrams.

When models are made of identical materials and have about the same degree of out-of-roundness, they collapse at nearly equal pressures. Variations greater than 5 per cent of the collapsing strength can invariably be traced to irregularities in the shell, and premature collapse can usually be predicted by a close examination of the initial contour as shown on the polar diagram of the model.

THE CYLINDRICAL SHELL WITH STIFFENING RINGS AND ATTACHMENTS

The most economical design of a large cylindrical vessel subjected to external pressure requires closely spaced stiffening rings or frames. Moreover the stresses in the shell depend not only upon the spacing of the frames, but upon their rigidity as well. Although the theory underlying the stress distribution in such a structure has been rather carefully worked out (8), (9), we are compelled to rely upon model tests for final confirmation of design.

The problem of duplicating a section of a submarine hull or other large pressure vessel by a model 16 in. in diameter presents few additional difficulties, once the technic of fabricating the thin cylindrical shell has been developed. In actual practice, large pressure vessels are not fabricated from a simple plate in each circumferential belt or course, but from several plates which are generally connected (and reinforced) at the seams by longitudinal straps. A working plan of such a model is shown in Fig. 6.

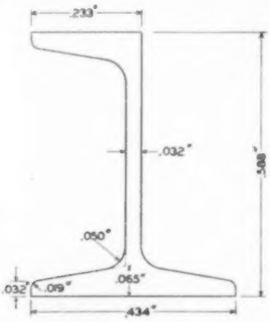

Fig. 7 Profile of Stiffening Frame for Models Shown in Fig. 6

Method of Fabricating Small Stiffening Rings or Frames

The stiffening frames are very small, having a depth of about $^1/_2$ in. with a web thickness of 0.032 in. Actual dimensions of the section are shown in Fig. 7 and the steps required in machining one or more frames from a forged circular ring are shown in Fig. 8. Two separate operations are employed. First, the flanges and the channel side of the frame are completely finished in a lathe and the remainder of the frame roughed out and cut off. Next, the finished side is fitted tightly in a chucking ring while the other side of the frame is finished to size.

The outside and inside diameters of the frame can be measured with micrometers, but the irregular parts must be made to fit templets. These templets are very accurately made on zinc sheets by photographic reductions of large-scale drawings. The correct web thickness is obtained by finishing the frame flush with the chucking ring. Using this method, a skilled mechanic can turn out a very accurate piece of work.

Methods of Attaching Stiffening Rings to Shell

The frames in most large pressure vessels are riveted to the shell, but this construction cannot well be duplicated in small-scale models. In more recent designs the frames are welded to the shell, but welding likewise imposes limitations upon the scale of the model.

Riveted construction can be satisfactorily duplicated with careful work down to about one-eighth scale, or until the rivets become as small as $^1/_8$ in. in diameter. The plates may be as thin as $^1/_{16}$ in., provided suitable material can be obtained and the holes are drilled.

The minimum thickness of plate which will permit fusion welding without objectionable warping is about 0.10 in., but best results are obtained with material at least 0.125 in. thick. The welding itself cannot well be reproduced in beads or fillets less than about $^1/_8$ in. in maximum dimension.

When frames or stiffening rings are internal and require only to be held in place, soft solder is entirely satisfactory, but when the frames are external, something more substantial must be provided to prevent the shell from tearing away from them.

Spot welding is a successful alternative for riveting on thin shells and frames. It can be applied with great facility to the fabrication of many parts of thin-walled models. Although the frame flanges illustrated in Fig. 7 are less than $^1/_4$ in. wide, perfect spot welds are possible by using small electrodes specially shaped to fit the frame. Wood forms and stands made for the purpose are used to hold the model accurately in position at the spot-welding machine so that the operator's whole attention can be devoted to the welding process. The strength of good welds, thus made, is quite comparable to that of riveted joints reduced to scale.

Construction and Testing of Two Similar Models

Two models were constructed according to the plan in Fig. 6. The first model was fitted with six longitudinal seam straps. The straps were made to butt against the ends of the pressure vessel and thus take their full share of the axial load. The second model was made exactly similar to the first, but with the addition of suitable longitudinal members to represent the keel and tank tops of a submarine.

Initial measurements showed a maximum variation from circular form (within the region of one lobe) of about 0.02 in. for each model; this variation was less than half the wall thickness of 0.05 in. In the first model, the greatest variations occurred near the seam, which was reinforced by a longitudinal strap, and near one of the upper longitudinal straps. These variations were undoubtedly caused by excessive heat or electrode pressure in the spot-welding operation. The variation from circular form was on the whole greater than would be expected in a submarine hull, but was likely of the same order of magnitude as would be found in a commercial pressure vessel of large diameter.

The two models, when tested, collapsed at equal external pressures. In the first model, a bulge was formed at 91 per cent of the collapsing pressure. At 98 per cent of the collapsing pressure the second bulge formed, although the model was able to hold that pressure without further damage. With a slight increase of pressure, other bulges followed in quick succession and the pressure fell off. Had the pressure been held, collapse would have been complete. The first bulge appeared near the seam where the variation from circular form was a maximum and the second bulge appeared near the longitudinal strap where the variation was almost as great.

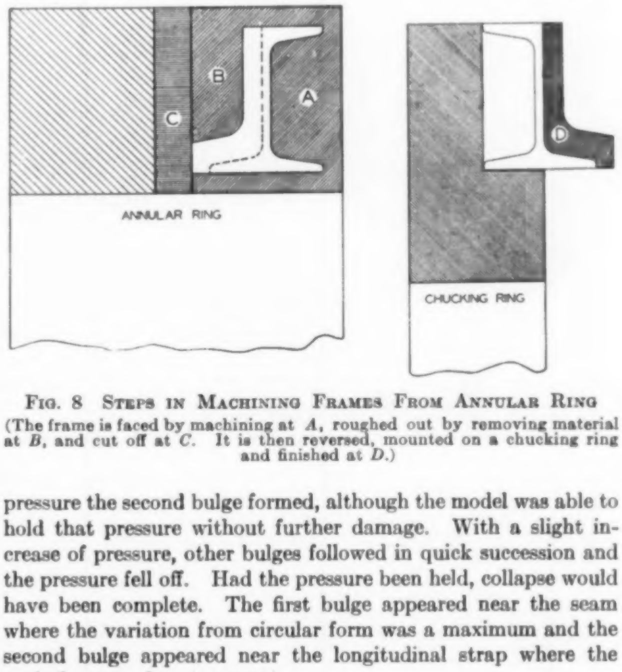

Fig. 8 Steps in Machining Frames From Annular Ring
(The frame is faced by machining at *A*, roughed out by removing material at *B*, and cut off at *C*. It is then reversed, mounted on a chucking ring and finished at *D*.)

In the second model, the greatest variations from circular form occurred near a longitudinal strap and near an upper longitudinal but not near the seam. These variations also were undoubtedly due to the spot welding. This model withstood a pressure of 98 per cent of the collapsing pressure before a bulge appeared. As before, this bulge was at the point of greatest variation from circular form. Four other bulges formed while the pressure was held constant, demonstrating that the element of time, as well as that of load, is directly associated with the failure of structures when stresses in the material reach the yield point. When the pressure was slightly increased the shell tore away from the frame at one of the bulges due to failure of the spot welds. Evidences of rivets pulling through the shell have been noted on similar tests to much larger scale.

THE FLAT, UNSTIFFENED, OR DIAPHRAGM BULKHEAD

A proposal to construct a light-weight compartment bulkhead in a submarine, in which stiffeners were to be partially or entirely omitted and in which reliance was to be placed upon the strength of a circular flat plate loaded as a diaphragm, afforded an excellent opportunity to utilize small-scale models. In this case, the design was too radical and embodied too many unknown features to warrant building a full-sized structure into a ship without thorough investigation, especially as the stresses in the diaphragm plate, in the event of accidental flooding, even at shallow depths, would exceed the yield point of the material. In cases of this kind theoretical considerations of elasticity are of little avail, and the best means of obtaining advance information is by model tests.

The model scale selected for preliminary tests required a flat-plate thickness, in the diaphragm portion of the bulkhead, of only 0.035 in. The diaphragm was to have an integral, substantial connection around its periphery to a relatively heavy ring, representing an elaborate construction in the full-scale design. The dimensions and form of the model bulkhead are shown in Fig. 9.

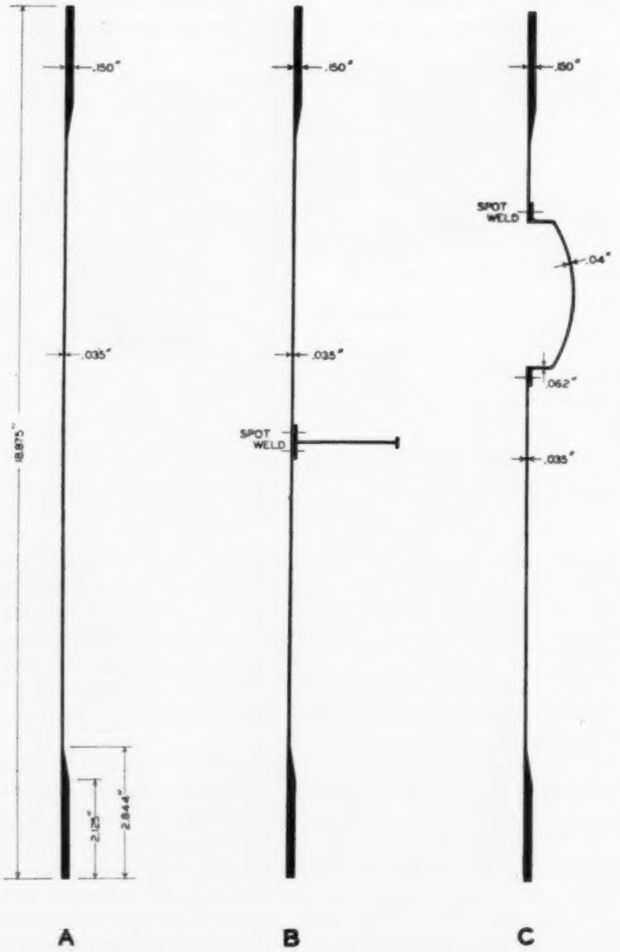

FIG. 9 SECTIONS OF THREE MODELS USED IN TESTING DESIGNS OF CIRCULAR DIAPHRAGM BULKHEADS

(*A* is a plain unstiffened bulkhead, *B* is stiffened by an I-beam across a diameter, and *C* is a bulkhead with circular door.)

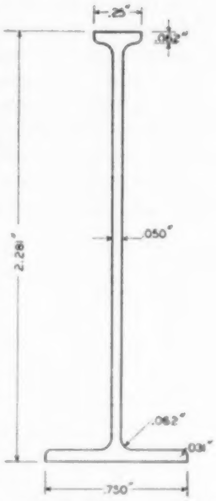

FIG. 10 PROFILE OF I-BEAM FOR MODEL DIAPHRAGM BULKHEAD SHOWN AT *B* IN FIG. 9

Since there was available no suitable magnetic chuck for holding the model while machining, the following method was employed to insure the required uniform thickness in the diaphragm. The bulkhead was first faced off to a plane surface and this face was then soft-soldered to the plane surface of a heavy backing plate. The entire bulkhead was then turned to the exact thickness of the rim. Using this rim surface as a reference plane, the central or diaphragm portion was readily turned to the proper thickness.

The model, when removed from its temporary mounting and calipered with micrometers, was found to have a uniform diaphragm thickness of 0.035 in., plus or minus 0.0005 in. This percentage variation in thickness is no greater than would be expected in the full-scale structure. It is only fair to state, however, that for this as well as for some other types of models such a degree of refinement in a machined model was reached only after building several models of much simpler construction having considerably heavier scantlings.

During hydrostatic tests the diaphragm deflected quite uniformly even when the deflection at the center reached one-sixth of the diameter of the diaphragm. It is of interest to note that the pressure at rupture exceeded the collapsing pressure of models representing the hulls of the same submarine design by nearly 50 per cent.

A modification of the full-scale design required a heavy stiffening member to be worked along a diameter of the bulkhead, breaking up the diaphragm into two semicircular panels, as shown at *B* in Fig. 9. This member was represented in the model by the modified I-section, illustrated in Fig. 10, which was machined from the solid and its wider flange spot-welded to the diaphragm plate.

The machining of this member presented no particular difficulties on account of its comparatively short length (about 14 in.). Both flanges were kept at the same width until the web was finished. When one side of the web was machined to size, the beam was turned over and the web surface supported by parallel bars while the other side was machined.

Another modification required the addition of a structure representing a door frame and a door, eccentrically placed on the diaphragm, as shown at *C* in Fig. 9. The model frame and door were machined as a unit from the solid, to a thickness of 0.04 in. in the door and 0.06 in. in the flanges. The flanges were spot welded to the 0.035-in. bulkhead plate and the latter was then cut out inside the door frame. This bulkhead model, after rupture, is shown in Fig. 11.

Deflections of the model bulkhead across a diameter were measured by an apparatus whose principal parts are shown in Fig. 12. The assembly is of very rigid construction and the bearing surfaces are extraordinarily large, to avoid all deflections in the measuring apparatus and to prevent rotation or rocking of the sliding block when in use. A measuring device of this kind with long or short straight-edge guides, is an inexpensive and useful piece of apparatus for numerous tests of thin-walled-model structures.

THE HOLLOW GIRDER, REPRESENTING AN ELEMENTARY SHIP STRUCTURE

It has long been felt that the present simple theory of determin-

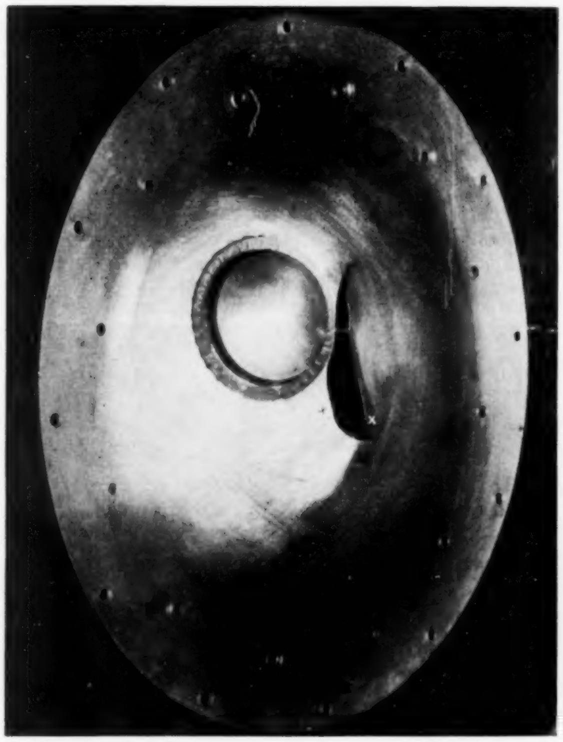

Fig. 11 Photograph After Rupture of Model Diaphragm Bulkhead Shown at *C* in Fig. 9

(Note spot welding around door frame and holes for attachment to test tank.)

ing the longitudinal strength of a ship's hull is far from satisfactory. Although many ships so designed have proved amply strong, they unquestionably possess excess strength in certain places, which of course represents excess weight. Some ships, on the other hand, have been found deficient in strength, owing to abnormally high local stresses or lack of column strength in the compression members, neither of which is indicated by the simple theory.

It is a long, complicated, and expensive job to test a full-sized ship under longitudinal bending load, and only three such tests have ever been made (10), (11). Furthermore, even though full-scale tests are carried to destruction, they show the weakness of the weakest part rather than the strength of the strongest. To be sure, elaborate strain-gage observations are taken, but these data are of no great significance except in tension members, as the additional displacement due to buckling in compression members cannot readily be separated from pure strain. Values of stress computed by ordinary methods, therefore, are erroneous and are certain to be misleading. Moreover the elastic effects are rather obscured by the design of the secondary structures in one ship which may not be duplicated in another.

Again, the naval architect who wishes, for instance, to determine the most economical distribution of material in hull plating and stiffening frames, is confronted with the possibility of obtaining reliable information from model tests. The subsequent paragraphs describe the beginning of a program now in progress at the U. S. Experimental Model Basin in an endeavor to solve this and related problems.

Hollow beams or girders $5^1/_2$ in. deep and 9 in. wide, built of sheet steel 0.031 in. thick, were chosen as suitable and inexpensive models for a general survey of the field. A cross-section of one of these models is shown in Fig. 13. All that has heretofore been said about adherence to true geometrical form in the construction of thin-walled cylindrical shells representing large pressure vessels applies equally to the building of these hollow-girder models; in fact, the problems are essentially the same. High-grade sheet steel is likewise employed to avoid irregularities in the plates which would cause buckling to begin at very low stresses.

The photographs, Figs. 14 and 15, illustrate the principal steps in the fabrication of these models. The sheet steel is first cut to the proper dimensions and bent to U-shape in a brake, following which it is pressed to very nearly exact shape in special metal dies. The male die is removed and a heavy plunger, shown in Fig. 15, analogous to the plunger used in the cylindrical shells, is placed inside the model at one end. A substantial steel plate is bolted over the female die to hold the plunger in position, and removable shims are placed between this plate and the die to regulate the pressure on the plunger as the latter is drawn through from end to end and as the model is worked more and more nearly to final size.

During these drawing operations, if such they may be called, the thin sheet forming the model must of course be held so that it is always in tension. The plunger and sheet are lubricated as for other drawing operations on sheet steel. Free movement of the plunger when the top plate is drawn down tightly on the female die indicates that the thin plate is exactly to shape and size.

The U-shaped sheet is now withdrawn from the die and the two edges for the attachment of the deck plate are formed at right angles to the sides in a brake. The deck or top plate is next applied and the model replaced in the die. A second clamping

(Note extremely rigid members employed to limit deflections to the mode only.)

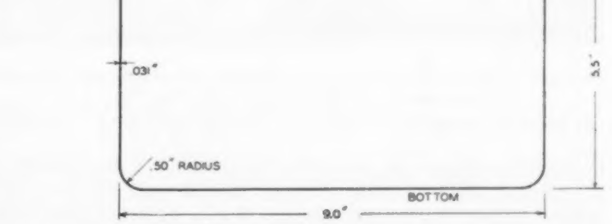

Fig. 13 Cross-Section of Hollow-Girder Model Representing Elementary Ship Structure

plate having notches at intervals along each side to correspond to the slots shown in the female die, holds the two parts of the model securely together while spot welds for tacking purposes are made at the edge of the deck. The plunger may be drawn through the model while these tack welds are being made, keeping the plunger always abreast the electrodes as each weld is made. After removal from the die, the rows of spot welds along the deck edges are completed as indicated in Fig. 13.

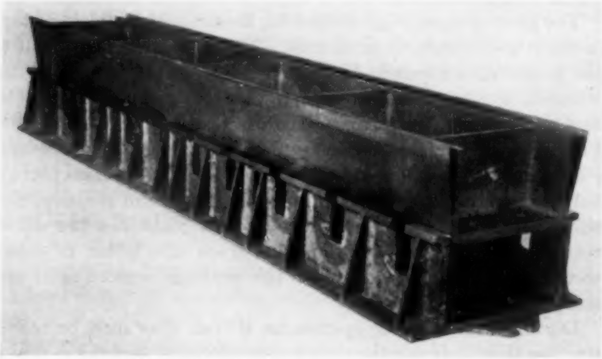

Fig. 14 Special Metal Dies for Forming Bottom and Sides of Model Shown in Fig. 13

(The slots in the lower die are to permit tack welding the deck plate to the sides of the model while the plates are held accurately in place by the forms.)

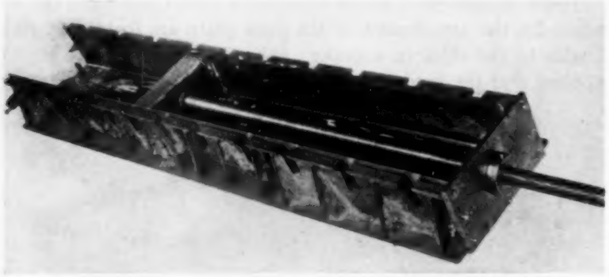

Fig. 15 Plunger and Drawbolt Used to Smooth Out Irregularities in Model While Held in Metal Form

[Note clamps at left for holding sheet in tension while plunger is drawn to right. A heavy clamping plate with clearance grooves cut for the plate edges (not shown in the photograph) holds the plunger in position.]

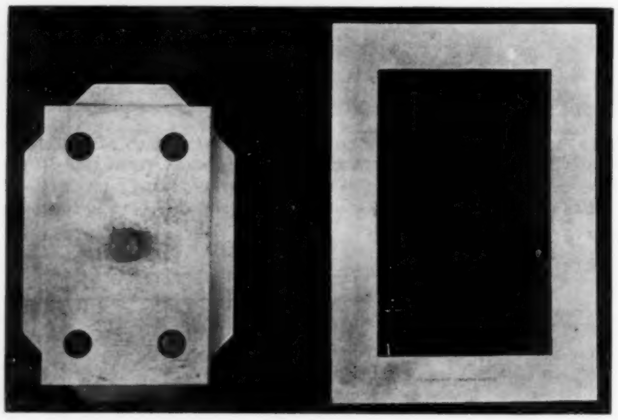

Fig. 16 Die and Punch for Accurately Flanging Bulkheads Fitted in Models Shown in Fig. 13

(At the left a bulkhead plate is secured to the punch preparatory to flanging.)

Bulkheads are placed at intervals inside the model to represent those occurring in all ship structures and to preserve the general form of the section. To prevent distorting the walls of the model when these bulkheads are spot welded in place, the flanges around their edges must be exactly square and the bulkheads must be of exactly the same shape as the model. Flanging all four sides of these bulkheads simultaneously in the simple die shown in Fig. 16 easily satisfies these conditions. Special ends are welded to the model to take the reactions in the testing machines.

The completed model is an extremely thin-walled structure with smooth, flat sides, in which the maximum departure from true shape and flatness is about one-half the plate thickness. Since collapse of these models is invariably caused by buckling of that portion which forms the compression flange of the girder, consistent results can be obtained only with models which possess the same degree of flatness.

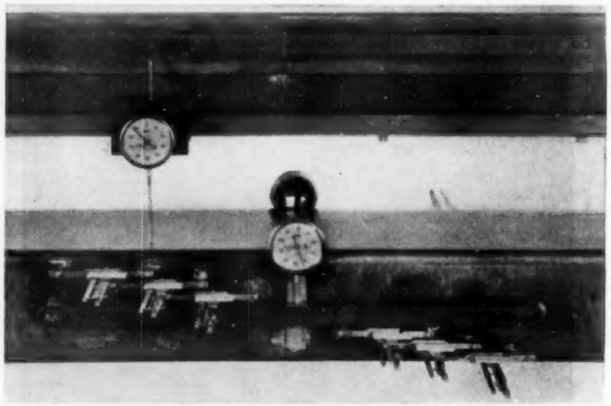

Fig. 17 Hollow-Girder Model Prepared for Longitudinal Bending Test

(The upper dial micrometer is carried by a block sliding on the straight edge and measures the longitudinal profile of the compression member. The two lower dial micrometers, one on each side, measure the deflection at the center bulkhead relative to the adjacent bulkheads. The Huggenberger tensometers measure strains in the side plating.)

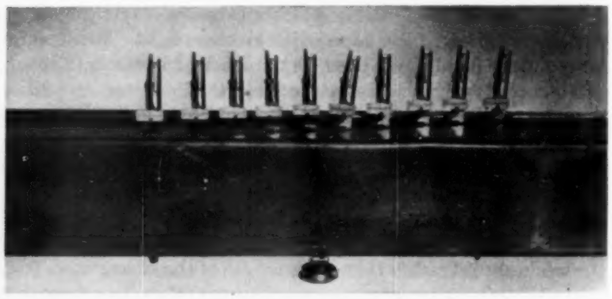

Fig. 18 Hollow-Girder Model After Collapse of the Compression Flange (Bottom)

(Note the three rows of spot welds indicating position of three transverse bulkheads. Holes for hand strain gages are staggered diagonally across the bottom; clamps for Huggenberger tensometers are likewise mounted in staggered positions to permit reading the scales. Note different types of strain-gage mountings shown in Figs. 17 and 18.)

The initial longitudinal profile of the compression flange, as well as the profile during subsequent loadings, is indicated by the sliding block and dial micrometer shown in Fig. 17. The part of the beam under test is the 24-in. midsection which contains three bulkheads spaced 12 in. apart, as shown by the lines of spot welds in Fig. 18. Deflection of the central portion of the beam with reference to the two end bulkheads is given directly by the two lower dial micrometers shown in Fig. 17.

During test, the model is loaded with uniform bending moment, shear being practically eliminated. An important feature to be investigated under these test conditions is the influence of the vertical sides in loading the top and bottom members throughout their entire breadth. Such an investigation requires, of course, a knowledge of the magnitude and distribution of stress over the section.

As previously stated, accurate strain observations are difficult to obtain in the compression members. Hand strain gages have been tried but are no longer used, since even small holes drilled into the thin material form lines of weakness and the pressure required for applying the gage points in the holes causes unnatural bending of the material and hastens collapse due to eccentricity in the compression members. Furthermore, most gages of this type have a base length entirely too great.

Huggenberger tensometers of 1 in. base length have been employed for strain readings. In the future Tuckerman optical strain gages of the same length will also be used. The latter instruments are extremely accurate and were designed at the U. S. Bureau of Standards especially for model-testing work. Both types of gages are sufficiently compact to be placed at close intervals for investigation of stress distribution as shown in Figs. 17 and 18.

Many different types of clamps have been tried for attaching these gages to the thin walls of the model. Although comparatively slight pressure is required to hold the contact points on the smooth steel plate without the necessity of drilling holes, cutting notches, or making special indentations, this pressure may be sufficient with an improperly designed clamp to cause imperceptible buckling of the plate and premature collapse. Some success has been attained by mounting a second strain gage or a dummy gage on the opposite side of the plate, but with a closed or box model this is not always possible.

CONCLUSIONS

The authors have endeavored to show that while the design and fabrication of models for determining the strength of thin-walled structures represent real problems in the attainment of the requisite degree of geometrical similarity and the use of identical materials, these problems are not at all insurmountable.

The authors cannot too strongly recommend the use of multiple models. In fact, it has become their practice to base definite conclusions as to the strength of any given design only upon the closely duplicated test results of not less than three identical models.

Since test results on similar models of thin-walled structures can be closely duplicated, models can be used for making comparative tests among themselves. Once a satisfactory basis for comparison has been established, the influence of systematic variations in scantlings and the effects of auxiliary structures can be evaluated.

Although models are built to a small scale and are usually made elementary in character, it must not be assumed that the care and thought expended upon them can be reduced in the same proportion. In fact, the smaller the scale of the model, the more exacting are the mechanical requirements imposed by the theory of similitude, and the greater the care and thought that must be used in conducting the tests and interpreting the results.

Discussion

T. McLean Jasper.[4] The writer notes with interest the authors' outline of tests applied to models in determining the strength of thin-walled structures. Models, however, whose dimensions are several times reduced from the actual, must be used with discretion, since in very thin sections representing the model of a thin full-sized vessel, the model may take on some of the characteristics of a thin diaphragm or film. The mechanics of diaphragms or films does not apply to that of plates with considerable stiffness. This brings to mind, therefore, that multiple models may not necessarily give the correct solution when they represent the foregoing general conditions.

Undoubtedly models can be of great help in solving certain problems, and there is no doubt that the authors have used such methods to acquire valuable information in design, and therefore they should be complimented for the untiring efforts that they have applied.

The writer would like to ask what measurements for out-of-roundness were made in the collapse work that they have performed, except the outside- and inside-diameter changes which indicate also the variation of thickness of the tube. Would not the outside diameter variation and the thickness-measurement variation give also an equal degree of knowledge of the test specimens?

Experiments carried out under references 5 and 6 measured both the outside diameters and the thickness of the cylinders along the periphery at many points. Specimens used under reference 4 were made on a mandrel and the turning was carried out with great precision, and it is believed produced specimens of the greatest degree of precision yet used for collapse tests.

These remarks are directed specifically to the statement made by the authors under "Measurements of Shell Contour."

It would be of great interest to learn how it is proposed to use the data contained in Fig. 5, in applying them to test results and also to commercial tolerances in design and construction.

R. G. Sturm.[5] The paper gives a clear demonstration of several cases where exact geometrical similarity between a model and its prototype are really necessary. The effect of small discrepancies, such as deviations from flatness of thin plates, certainly cannot be overlooked in most models and is of extreme importance in models where elastic instability is a factor contributing to failure. There are cases, however, where thin-walled structures may not necessarily behave in the same manner as the prototypes unless a number of similarity conditions in addition to geometric similarity are obtained.

---

[5] Research Engineer-Physicist, Aluminum Research Laboratories, New Kensington, Pa.

One of the greatest advantages of model testing is to verify a theory of the behavior of a type of structure when that theory is applied to the model, and to establish confidence in the application of the same theory to the prototype. From theoretical analyses applied to model tests it is often found that failure of the model depends upon some power of the scale ratio, as well as upon a number of other factors, including the physical properties of the model material and details of the structure.

An example of the use of a model for interpreting the behavior of its prototype in which the elastic properties of the model material, as well as the geometrical proportions, enter into the similarity conditions, is that employed in the studies of a model of an 11-ft-diameter pipe line.[6] In this case the stresses in the prototype were determined by a theoretical analysis and checked by actual measurement in the field. Various models were built and a more comprehensive study made of the deflections and stresses. It was indicated by the theory that the stresses themselves would vary as the scale ratio, thereby indicating that the elastic properties of the model material should bear the same ratio to the properties of the material in the prototype as the scale ratio in order to give an exact similitude in behavior. The theoretical analysis, however, furnished the medium for interpreting the test results, even though complete similitude was not obtained.

In many cases it is desirable to magnify the deflections and strains produced by given loads so as to facilitate accurate measurements. In the case of the model of the aforementioned pipe line, the model was made of aluminum sheet particularly for this purpose.

A model of an arch dam[7] has been built of blocks of special rubber compound so as to magnify the deflections and strains of the model, as well as to obtain certain other conditions of similarity, such as discontinuities in the structure.

In the case of the tests of the diaphragm mentioned in the paper, the ductility of the material, as well as the ultimate strength, would influence the ultimate strength of the diaphragm in resisting uniform pressures. The actual stress in the plate at failure will be influenced by the amount of distortion, and the amount of distortion at failure depends upon the ductility of the material; that is, the greater the bulge, the smaller the radius of curvature, and consequently a greater internal pressure is needed for a given ultimate stress in the material.

In the case of the models of ships indicated in the authors' paper for which the loads apparently would be reduced according to the scale ratio, one would expect the measured stresses to be in the same proportion as the scale ratio. Thus the observed stresses in the model would be expected to be only a small part of what would be expected in the prototype. If the structure were to fail by elastic instability at loads scaled down according to the scale ratio and the modulus of elasticity for the model was also reduced according to scale, directly comparable results would be expected. If the structure were to fail by plastic yield of the material, one would expect the model to show a strength many times the strength of its prototype unless the ratio of the strength of the material in the model to the strength of the material in the prototype was the same as the scale ratio. This appears to be another example in which all the physical properties of the model material, including the modulus of elasticity, should be reduced according to the scale ratio in order to maintain true similarity.

The use of models in studying thin-walled structures may be informative and valuable provided the significant factors in similarity are adequately considered. The nature of the particular structure to be tested and the type of loads applied will determine which of all the conditions of similarity are significant.

E. E. Shanor.[8] The work being done at the U. S. Experimental Model Basin, Navy Yard, Washington, D. C., as described in this paper, is very interesting. Engineering, before the development of the mathematical methods of analysis now used, depended largely on model building for a check on designs. Originally the Patent Office required models in connection with a patent application. Engineering then was largely by the cut-and-try method. With the greater use of mathematics by the engineer, it became less needful to confirm new designs by model building and testing, and it is now only in exceptional cases that resort to test by models is made. Such cases generally arise from the difficulty of a mathematical analysis or the uncertainty as to the starting hypothesis. For instance, all bidders on the penstocks required at the Boulder Dam are required to build small-scale models of the Y's and T's and test them to destruction to prove the design on which they are bidding—this because of the difficulty of the mathematical analysis involved.

The models discussed in this paper represent constructions that are hard to analyze mathematically and that involve uncertainties as to the agreement of the actual construction with the assumptions on which the analyses are based. This is especially true of the tube which collapses due to external pressure. Theoretically, the tube should be absolutely round, and the walls should be of uniform thickness and the material of uniform physical qualities. The variation in pressure at which failure will occur and the form of the failure will be determined largely by variations from perfection in form and thickness of wall. It is evident what a task the model builder sets for himself when he attempts to check theoretical formulas for collapse of tubes under external pressure by means of models.

The methods used by the authors in building their models are extremely interesting. One wonders if the soldered seam does not introduce objectionable inequalities; yet a better way is not apparent. Although possibly beyond the scope of the paper, it would have been of immense interest to have included illustrations showing the collapsed tubes and a comparison of actual and theoretical results.

The paper performs a valuable service in showing that accurate and dependable results can be secured through the use of models, provided the requisite accuracy in their building is attained.

W. P. Roop.[9] This admirable exposition of the devices found necessary to obtain compliance with the conditions of similitude in model tests of thin-walled structures well illustrates the specialized character of model work in general. Models have come in for rather wide application recently, and their usefulness is well appreciated. This paper will serve to emphasize the necessity of caution, and it is hoped that it will help to prevent disappointments that might occur from too great reliance on model tests of insufficient scope and detail. The authors' strong recommendation for multiple models is strongly seconded. Possibly there are engineers who have sufficient insight, experience, and skill to assure that information obtained from a single model is complete and exact enough for direct application, but an engineer who could meet this requirement would also be able to design a full-scale structure of novel type without models. For, as the authors well say, a successful model requires no less forethought than is expended on a full-scale structure.

Many existing structures have given long service which, from the point of view of present-day standards, might be rated unsuccessful due to overweight. It was largely by a process of approximation realized in such full-scale models that the design standards of an older generation were established. The model method is obviously a more economical method of obtaining similar results, but it is an error to press the model engineer too closely in the matter of economy. Models cost less to build, but no less to design, than full-scale structures. The full-scale models have one advantage in that they are capable, in most instances, of at least partial service, but even when due allowance is thus made for what might be called the salvage value of a full-scale model, the balance is all in favor of the small model as a means of progress in design. Where progress is desired, therefore, a generous expenditure for models is in order.

The analysis of model data is hardly less costly and surely not less necessary than forethought in model design; indeed, the two can hardly be separated. Yet it is the writer's belief that the relatively low cost of actual construction of models sometimes leads to an underestimation of the amount of the expenditure on model work, and especially of the study and interpretation of model data, which will lead to greatest overall economy.

The tests under discussion follow two divergent lines, dealing on the one hand with cylinders of circular section under external pressure, and on the other with beams of box section. Of these the first line has been followed much further, and the large number of models tested has resulted in the evolution of an elaborate but highly successful technique. These methods have been in part adapted to use in the box models since the occurrence of failure by instability leads to marked similarities between the cylinders under external pressure and the boxes under bending load. These are, however, important differences; and one would anticipate that with further extension of the box-model program even further divergences in technique would occur.

For example, no strain-gage data were taken on the cylinders. One might infer from what is said that since strain gages are of value only in plating in tension, and since these box girders invariably fail by compression, strain gages are of little value on the boxes. This would, however, be a hasty inference. Distribution of strain in tension may itself serve to indicate imminent occurrence of buckling in compression members. But it would be disappointing to be forced to the conclusion that "buckling in compression members cannot readily be separated from pure strain."

Box models so far tested appeared to have been all of the same bulkhead spacing; with stiffening members more closely spaced, the need of extreme accuracy with respect to flatness would appear to be somewhat diminished, or, in any event, a distinction would have to be made with respect to the extent of plating within which given deviations might occur, whether within the limits of one frame or of several frames. While the thin-walled cylinder under external pressure will always fail in the unstable mode, the thin-walled box girder presents a variety of elastic elements of which the flat plate under compression in its own plane is only one, though under most circumstances of proportion it is doubtless the most significant.

The allusion by the authors to the influence of secondary features of design deserves added emphasis.

It has long been customary to design a structure as a whole (in case of a ship, a tapered box girder with transverse diaphragms), and then attach secondary parts with little consideration of effects other than those of weight. As refinement of the design of the primary structure advances, more consideration must be given to the effect of such incidental features. The function of the present tests is to provide a secure basis for the refinement of the primary structure, and this can be done only by elimination of uncertainties proceeding from the incidental features. Thus while the models do not appear to resemble an actual ship very closely, they do present an idealized representation of the primary structure. When, by use of models, supplemented by full-scale tests, the limits of refinement of the primary structure are approached, a choice will have to be made between two procedures with respect to the incidental features. As a first step in advance, they may be so combined with the primary structure as to produce no interference with its elastic action. By following certain definite practices in design, this result can be rather accurately obtained. A further development, however, would consist in adaptation so as to obtain assistance for the primary structure. This will impose rather definite limitations on design of incidental structure. The safest guide in ascertaining these limitations would be found in tests on models incorporating the incidental structure.

C. O. Rhys.[10] The use of small-scale models undoubtedly offers an excellent method of determining how a full-sized structure will behave. As is well known, the principle has long been successfully employed in the design of ships, models of 12 ft or so in length being towed along in tanks. In this case, the main object is to ascertain resistance to motion through the water, and geometrical similarity is the paramount consideration.

As pointed out in the excellent paper under discussion, when strength considerations are involved, not only geometrical similarity, but identical materials and similarity of loading and fastening become equally important. The authors show in a clear and instructive way how these results are obtained, bringing out the point that, as might be expected, multiple models have great advantages over individual models.

On the fifth page it is stated that spot welding is a successful alternative to riveting for very thin plates. It would be of interest to know whether any tests have been made to compare the joint efficiencies of the two modes of fastening.

In the description of the behavior of two similar models under test, the time interval between the formation of bulges is emphasized. This confirms some recent experience of the writer's with the shell of a heat exchanger which deformed under stresses due to unequal temperatures. Calculation showed that a corrugated effect might be expected. Actually, however, only one corrugation appeared, though dimensionally it agrees with the theoretical result.

William Hovgaard.[11] This paper is of great importance, because it shows that it is possible to study the design of thin-walled structures by means of small models, a problem that hitherto has been unsolved, or solved only in certain cases. It indicates the methods by which such models can be manufactured satisfactorily, and since the information in this respect is the result of many costly experiments and much thought and ingenuity, it is of great value to the profession. In naval architecture as well as in several other branches of engineering the problem of weight saving has come to the front in recent years. Old rule-of-thumb methods and crude empirical formulas must be in many cases replaced by more refined calculations, based on the theory of elasticity, but even the best formulas cannot be safely applied without experiments which enable the designer to determine the physical constants. Full-scale tests can be carried out only in rare cases, and it is necessary to resort to model experiments; but with thin-walled structures and if relatively small models are to be used, an extreme accuracy in the manufacture of the models is required, involving great practical difficulties. As pointed out in the paper, it is necessary to use several identical models in each specific case, so as to obtain a reliable average. All this means high cost, unless special methods of manufacture are developed, and it is here perhaps that this paper has its greatest value by indicating practical and simple methods of manufacture.

[11] Professor, Department of Naval Architecture and Marine Engineering, Massachusetts Institute of Technology, Cambridge, Mass.

Thus the authors of this paper open up a field of research which hitherto has been cultivated in a somewhat fragmentary and unsatisfactory manner. The systematic and thorough way in which this difficult problem has been approached has yielded results which reveal the great possibilities of the method. It cannot fail to lead to much greater results in the future and a wider application by other investigators.

The Bureau of Construction and Repair of the Navy has here successfully initiated a development of this important line of research, which will be of benefit not only to the Navy, but also to the merchant marine and to several important industries in other fields.

AUTHORS' CLOSURE

It is difficult for the authors to believe that, as Mr. Jasper says, "the mechanics of diaphragms or films does not apply to that of plates with a considerable stiffness," providing the "diaphragms" and "plates" are *geometrically similar*. The "slenderness" of a rod and the "thinness" of a tube or plate depend upon their length, diameter, and breadth, respectively, as well as upon their absolute thickness. A so-called "thin" tube may be 0.05 in. thick or 5 in. thick, depending entirely upon its diameter. So also a "thin" plate or shell may be very thin or it may be very thick, depending upon its other dimensions. Practically, it may be impossible to obtain geometrical similarity in models "whose dimensions are several times reduced from the actual," but this is a purely physical limitation and in no way changes the underlying theory. To be sure, the thickness of model shells cannot be reduced indefinitely, say, to molecular dimensions, but practical limitations prevent an approach to such an extreme.

Concerning measurements of out-of-roundness, the record for each model tested includes a diagram similar to Fig. 5. From such a diagram, it is possible to measure directly not only variations in diameter of the shell, but also variations in radius. Measurements of diameter involve two irregular surfaces, and it is not uncommon to have the effect of irregularities on opposite sides neutralize each other. That is, an outward bulge on one side and an inward bulge on the opposite side may not be indicated by a measurement of the diameter.

Since short, thin tubes, or tubes with closely spaced frames, collapse in a large number of lobes, and since each individual lobe behaves in a manner somewhat analogous to a column or plate under compression, it seems reasonable that the eccentricity in each individual lobe should be significant in determining the resistance to collapse of that particular lobe section. Certainly this eccentricity should be considered independent of any eccentricity that might exist on the opposite side of the model.

Von Mises ("Stodola's Festschrift," Zurich, 1929, p. 429) states: "It is certain that in the case of buckling with a higher number of lobes, even very slight initial irregularities may have a decisive effect." Two tubes, one elliptical and the other containing a dent, may have the same difference in maximum and minimum radii, yet the elliptic shape would have a greater weakening influence than the dent on a tube long enough to collapse in two lobes, while the dent would have a greater weakening influence on a tube short enough to collapse in a large number of lobes. A tube is no stronger than its weakest lobe.

It is for this reason that variations in radii rather than variations in diameters have been employed by the authors in the measurement of out-of-roundness. The necessity for such a distinction does not become evident in dealing with long tubes similar to those mentioned in references 4, 5, and 6, which always collapse in a small number of lobes, but cannot be overlooked in analyzing data on short, thin tubes which collapse in a large number of lobes.

The authors wish to point out that they are always on the alert for evidences of a scale effect which might vitiate the results of their model tests, even where theory indicates that no such effect can be expected. It is for this reason that geometrically similar models of different scales and sizes are invariably built. Their plan has been to use smaller, simpler, and hence cheaper models for a general survey of the field to be covered, and to verify the conclusions thus obtained with larger and more accurately constructed models, eventually confirming results by tests on models of about half-scale. For example, their experiments on submarine strength hull models 6 in. and 16 in. in diameter were confirmed by tests at the Portsmouth Navy Yard on models 8 ft. in diameter, thus precluding the possibility of an unknown scale effect.

Evidently there is some confusion in Mr. Sturm's mind as to the method of applying load to the models of ships described in the paper. In the model arch dam referred to, the height of the dam and the pressure head are reduced according to the scale ratio; since the surface of the dam is reduced by the square of the scale ratio, the total load is reduced by the cube of the ratio. However, the ship models are not tested in water, but are supported by transverse knife edges on the platform of a testing machine. According to the simple theory of beams or columns, equal loads per unit area on the model and prototype, that is, total loads reduced according to the square of the scale ratio, produce equal stresses in the two structures. This is shown in the case of tubes subjected to external pressure, since the model and the full-sized structure collapse at equal hydrostatic pressures.

Concerning the objectionable features of a soldered seam, as pointed out by Mr. Shanor, the authors admit that the seam has proved a source of trouble and has caused considerable uncertainty in interpreting experimental results. The seam usually represents the region of greatest departure from circular form, and, as a rule, collapse begins in a lobe adjacent to the seam.

Various attempts have been made to improve these conditions. Models have been made, using no support whatever at the seam except solder; longitudinal straps from 0.25 in. to a semi-circumference in width have been tried; narrow straps transverse to the seam have also been used. The present method of reinforcing the seam was adopted as possessing the fewest disadvantages.

The authors have at hand many diagrams similar to Fig. 5, and many photographs of collapsed models. One such photograph was published as Fig. 3 in their 1931 paper (7), while Table 1 of the same paper gave a comparison of actual and theoretical collapsing pressures for a number of tube models.

Other photographs and data will be published in a subsequent paper.

It is indeed desirable, as Lieutenant Roop points out, to obtain reliable strain-gage readings on thin-walled structural models while under test. Such readings can be taken by using very sensitive gages of not more than 1 in. base length, clamped to the test member. Preferably, gages should be mounted on both sides of the plate with their points exactly opposite each other. This avoids the introduction of eccentric loading by the gage itself and makes the determination of strain at the middle surface of the plate very simple. When gages with a base length of 1 in. or less are used, the introduction of apparent strain due to buckling does not introduce serious error in stress calculations until the buckling becomes considerable.

The amount of buckling a plate can undergo and still continue to hold its load, as well as the permissible initial eccentricity in a compression member, are functions of the lobe length. Here again the analogy is very close between stiffened plates under edge compression and circular cylindrical shells under external hydrostatic pressure.

The length of the lobes in a plate is determined by the spacing of longitudinal stiffeners, that is, stiffeners which are parallel to the direction of loading. This corresponds to the spacing of transverse circular frames in a tube. Hence the effect of variation from flatness depends more upon the spacing of longitudinal than of transverse stiffeners.

Regarding the use of spot welding instead of riveting, as brought up by Mr. Rhys, the authors possibly should have said that spot welding is the only known alternative for riveting for very thin plates. Comparative tests of riveting, spot welding, and fusion welding on plates about 0.1 in. thick are contemplated in the near future, but it is not likely that any satisfactory comparison can be made on plates 0.05 in. thick or less.

The time interval occurring between the application of load and the formation of bulges in circular cylindrical tubes subjected to external pressure is very pronounced. The same may be expected on all models and structures where the stresses reach the yield point of the material. On some of the large tube models, bulges have appeared after the load had been held constant for several minutes. Likewise, bulges have appeared at intervals of several minutes at constant load, even though the bulges were not adjacent and seemed to have no direct connection with each other. This phenomenon is due no doubt to the gradual redistribution of loads when any small region has been stressed to the yield point and deformation has brought about a corresponding redistribution of stresses.

The experimenter should take care lest the test loads be applied too rapidly and the recorded ultimate collapsing load be too great.

Once the validity of model tests on thin-walled structures has been justified, an unlimited field of application is immediately opened up. Practically the only limitation is the accuracy with which models can be fabricated and the ingenuity with which test results can be interpreted. As previously pointed out, certain features such as riveting cannot be conveniently reproduced to small scale, and the experimenter is confronted with the necessity of providing a suitable alternative. Just how successful a given alternative may be, or how fully the results obtained by its use can be relied upon for full-scale design, are questions to be settled by experience and individual judgment. However, much if not all of the uncertainty is removed when final tests are performed on larger-scale models where the details of construction can be accurately reproduced to scale.

Stresses in Railroad Track

By S. TIMOSHENKO[1] and B. F. LANGER[2]

S. Timoshenko

With the constant tendency in railroad practice to increase the axle loading and the speed of locomotives, the problem of stresses produced in rails by moving loads becomes more and more important. In a study recently made by engineers of the Westinghouse Electric and Manufacturing Company, principally in connection with the study of the tracking characteristics of electric locomotives, there has been developed a method for experimental determination, not only of vertical but also of lateral forces produced on the rails by a moving locomotive, and it is shown that these lateral forces produce in rails very high stresses. In this paper the authors briefly discuss the theory which has been used as a guide in this experimental research work, and describe some recent experiments in the laboratory and in the field.

B. F. Langer

With the constant tendency in railroad practice to increase the axle loading and the speed of locomotives, the problem of stresses produced in rails by moving loads becomes more and more important. During the last fifteen years an important piece of work in this field has been done by the Special Committee on Stresses in Railroad Track[3] under the direction of Prof. A. N. Talbot. In this work a complete theory for the bending of rails produced by vertical loads has been given, and also an experimental method for determining these loads has been developed.

Further progress in determination of track stresses has been made by engineers of the Westinghouse Electric & Manufacturing Company,[4] principally in connection with the study of the tracking characteristics of electric locomotives. There has been developed in this study a method for experimental determination not only of vertical, but also of lateral forces produced on the rails by a moving locomotive, and it has been shown that these lateral forces produce in rails very high stresses.

In this paper a brief discussion of the theory which has been used as a guide in this experimental research work is given, and some recent experiments in the laboratory and in the field are described. Special attention is given to the local stresses in rails produced by vertical and lateral forces. It seems that this is the first time that these stresses have been studied. The importance of knowledge of these stresses for a logical design of rail profiles cannot be overestimated.

I—RAIL AS A LONG BAR ON ELASTIC FOUNDATION

1 Vertical Bending of Rails

The following theory of vertical bending of rails is based upon the assumption that the rail can be considered as a long bar continuously supported by an elastic foundation.[5] The rigidity of this foundation is defined by the magnitude k of the *modulus of foundation*, which is the load per unit length of the rail necessary to produce a deflection of the foundation equal to unity. The experiments show that the magnitude of the modulus can be always determined in such a manner that the deflection of the rail calculated on the assumption of the continuous foundation is in good agreement with the deflection of the actual rail supported by ties. Using the notations

EI = flexural rigidity of the rail

$$\beta = \sqrt[4]{\frac{k}{4EI}} \quad \ldots\ldots\ldots\ldots\ldots\ldots \quad [1]$$

and applying the equation for the deflection curve

$$EI\,\frac{d^4y}{dx^4} = -ky \ldots\ldots\ldots \quad [2]$$

we find[6] for the simplest case of a single load P acting in the vertical plane of symmetry on an infinitely long rail (Fig. 1):

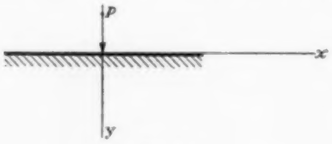

Fig. 1

$$y = \frac{\beta P}{2k} e^{-\beta x} (\cos \beta x + \sin \beta x) \ldots\ldots \quad [3]$$

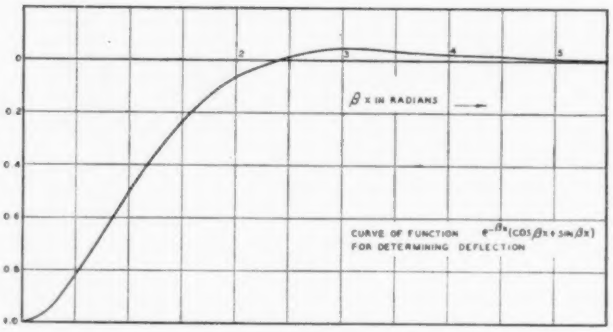

Fig. 2 Deflection Curve

The corresponding deflection curve is shown in Fig. 2. The maximum deflection is under the load P and is obtained from [3] by putting $x = 0$. Then

$$\delta = (y)_{x=0} = \frac{\beta P}{2k} \ldots\ldots\ldots \quad [4]$$

This equation is usually employed in calculating the modulus of foundation k from the deflection of an actual rail. Measuring the deflection of the rail produced by a known vertical load P and using Equation [1], we can easily calculate from [4] the magnitude of k. (See description of the calibration of the track, Section III.)

From the solution [3] it is seen that the deflection curve is a wavy line, the amplitudes of which are damped out with the increase of the distance x from the point of the application of the load P. The length of the wave is

$$L = \frac{2\pi}{\beta} = 2\pi \sqrt[4]{\frac{4EI}{k}} \ldots\ldots\ldots \quad [5]$$

Taking as an example a 130-lb. rail ($I = 72.8$ in.^{4}) and assuming $k = 1500$ lb. per sq. in., we find from Equation [1] that $\beta = 0.020$ in.$^{-1}$ Then from Equation [5] we find that the length of a wave is more than 300 in. If instead of an infinitely long bar a bar of a finite length $2l$ is loaded at the middle, the equation for deflection can be put in the form

$$\delta = \alpha_1 \frac{\beta P}{2k}$$

In which α_1 is a numerical factor depending on the length of the bar. The values of this factor for various values of βl are given in the second line of the following table.[7]

$l\beta =$	1	1.5	2	2.5	3	π
$\alpha_1 =$	1.18	1.09	1.08	1.04	1.02	1.01
$\alpha_2 =$	0.92	1.09	1.05	1.01	0.997	0.996

It is seen that if a bar of a considerable length (say, $l\beta > 2.5$) is taken, the maximum deflection is about the same as in the case of an infinitely long bar.

Having the deflection curve, Equation [3], the bending moment is easily calculated from the equation

$$M = -EI\frac{d^2y}{dx^2} = \frac{P}{4\beta} \epsilon^{-\beta x} (\cos \beta x - \sin \beta x) \ldots\ldots \quad [6]$$

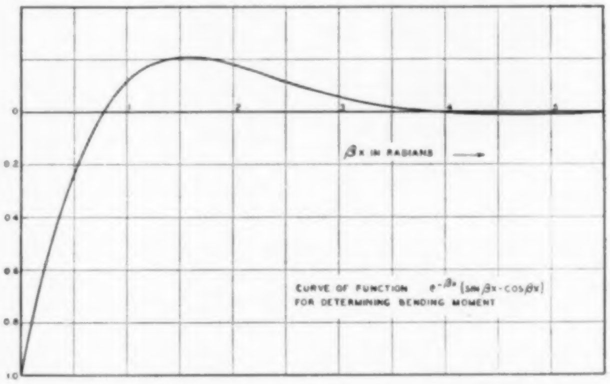

Fig. 3 Bending-Moment Curve

which moment is represented graphically in Fig. 3. The maximum bending moment is under the load. Substituting $x = 0$ in [6],

$$M_{\max} = \frac{P}{4\beta} \ldots\ldots\ldots \quad [7]$$

In the case of a bar of a finite length $2l$ loaded at the middle, the maximum bending moment is

$$M_{\max} = \alpha_2 \frac{P}{4\beta}$$

The numerical values of the factor α_2 for various values of $l\beta$ are given in the table above. It is seen that for $l\beta > 2.5$, the maximum bending moment for a bar of finite length is practically the same as in the case of an infinitely long bar. In our laboratory tests (see Section II) $2l = 240$ in. and $\beta = 1/50$ in.$^{-1}$ Hence the stress conditions near the point of application of the load are practically the same as for an infinitely long bar.

By using Equation [1] the maximum bending moment is

$$M_{\max} = \frac{P}{4} \sqrt[4]{\frac{4EI}{k}} \ldots\ldots\ldots \quad [7a]$$

and using the notation S for the section modulus of the rail, the maximum bending stress is

$$\sigma_{\max} = \frac{M_{\max}}{S} = \frac{P}{4}\frac{\sqrt[4]{I}}{S}\sqrt[4]{\frac{4E}{k}} \ldots\ldots\ldots \quad [8]$$

Since the right-hand member of [8] remains constant for geometrically similar cross-sections of rails, if E/k remains constant and P varies as the square of the linear dimensions of the cross-section, it can be concluded that $\sigma_{\max}$ remains unchanged if the weight of the rail per unit length increases in the same proportion as the load P. This conclusion gives a certain justification for increasing the weight of the rail in the same proportion as the axle load of the rolling stock that is to run over it.

---

[6] For derivation of formulas see S. Timoshenko, "Strength of Materials," vol. II, p. 401. Equation [3] is derived only for $x > 0$.

[7] See H. Zimmermann, "Die Berechnung des Eisenbahnoberbaues," 2nd ed.

The approximate value of the maximum pressure $R_{\max}$ on a tie is obtained by multiplying the maximum deflection, Equation [4], by the tie spacing a and by the modulus of foundation. Then

$$R_{\max} = \frac{\beta P}{2k}\, ak = \frac{P}{2}\sqrt[4]{\frac{ka^4}{4EI}} \quad \text{[9]}$$

It is seen from this that the pressure on the tie depends principally on the tie spacing a. It diminishes with a diminution of a and k, and with an increase in the flexural rigidity EI of the rail.

Having the solution for the vertical deflection produced by a single load P and using the principle of superposition, the deflection curve and the bending-moment diagram for any system of vertical loads can easily be obtained. For the purpose of illustrating the method of calculation, let us consider a 100-lb. rail with $I = 44$ in.^{4} and with $k = 1500$ lb. per sq. in. Then from [1], $\beta = 1/43.3$ in.$^{-1}$ Taking a system of four equal loads (Fig. 4) 66 in. apart, and fixing the origin of coordinates at the point of contact of the first wheel, the values of βx for four wheels are given in the following table.

Wheels	1	2	3	4
βx	0	1.52	3.05	4.57

By using now the curve in Fig. 3 and superposing the effects of all the loads acting on the rail, the bending moment under the first wheel is

$$M_1 = \frac{P}{4\beta}\,(1 - 0.207 + 0.051 + 0.008) = 0.75\,\frac{P}{4\beta}$$

i.e., the bending moment is 25 per cent less than that produced by a single load P. In the same manner, for the point of contact of the second wheel it is found that

$$M_2 = \frac{P}{4\beta}\,(1 - 2 \times 0.207 - 0.051) = 0.535\,\frac{P}{4\beta}$$

It is thus seen that, due to the action of the adjacent wheels, a considerable diminution of the bending moment under the second and the third wheels takes place.

In the same manner the bending moment at any other point can be calculated. For instance, at the point A, midway between the wheels 2 and 3, the bending moment is $-0.22\, P/4\beta$ and the rail is bent convex upward. From this we see that during the motion of such a system of loads as is shown in Fig. 4 the stresses change not only their magnitude but also their sign. Under the action of such cycles of stress, fatigue cracks in rails may occur. Many actual fractures in rails have a typical fatigue-crack appearance. The same kind of fracture occurs also in splice bars (Fig. 5). The cracks usually begin at the points mm, which are the most remote points from the neutral axis nn. Sometimes cracks begin at the holes or at the reentrant corners, where a high stress concentration takes place.

(Moment from one isolated load = unity.)

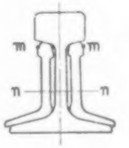

Fig. 5

By using the same method of superposition and the curve given in Fig. 2, the deflection produced by a system of vertical loads also can be easily calculated.

The inverse problem, i.e., of calculating the vertical pressures produced by locomotive wheels on the rail provided either the deflections or the stresses in the rail under the wheels have been determined by experiment, can also be solved without any difficulty. The application of such calculations to our experiments has always shown a good agreement between the sum of the calculated pressures and the actual weight of the locomotive used. This gives a certain justification to our assumption that the rail can be considered as a bar on a continuous elastic foundation.

2 Eccentric Vertical Load

If a vertical load P is applied with an eccentricity e, Fig. 6(a), it can be replaced by the load P centrally applied and by the torque Pe, Fig. 6(b). The central load produces vertical bending of the rail, discussed in the previous article, and the torque produces twisting of the rail.

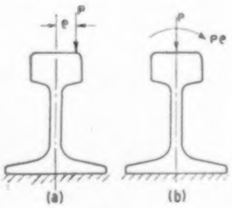

Fig. 6

If a rail with free ends is submitted to the action of two equal and opposite twisting couples M_t, the angle of twist may be roughly calculated from the known approximate equation of Saint-Venant, namely,

$$\phi = \frac{M_t l}{C} \quad \text{[10]}$$

In which l = length of the rail, and

$$C = \frac{A^4 G}{40 I_p}$$

where A = area of the cross-section
G = modulus of rigidity, and
I_p = polar moment of inertia.

To get a more accurate value for the torsional rigidity C, a direct torsion test is necessary. Such tests show that the actual value of the torsional rigidity is somewhat smaller than given by Saint-Venant's formula.

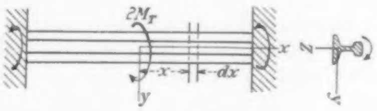

Fig. 7

If the ends of the rail are fixed and a torque $2M_t$ is applied at the middle (Fig. 7), the twist of the rail is accompanied by a bending of the head and base of the rail. At any cross-section at a distance x from the middle, the torque M_t is transmitted partly in the form of simple twist and partly by bending of the head and of the base of the rail. Let M_1 and M_2 represent the first and second parts, respectively, and ϕ denote the angle of twist shown in Fig. 8. Then

$$M_1 = -C\,\frac{d\phi}{dx} \quad \text{[11]}$$

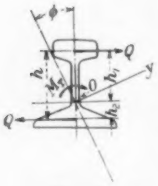

FIG. 8

The part M_2 is represented in Fig. 8 by the couple Qh, in which Q denotes the shearing force due to bending in the head and base of the rail, and h is the distance between the centroids of the head and base sections. Neglecting bending of the web, the position of the center of twist[8] O is determined by the distances

$$h_1 = \frac{hI_2}{I_1 + I_2}, \qquad h_2 = \frac{hI_1}{I_1 + I_2} \ldots\ldots\ldots\ldots [12]$$

in which I_1 and I_2, respectively, denote the moments of inertia of the head and of the base sections with respect to the axis of symmetry of the rail cross-section. The shearing forces Q are then determined from the equation

$$Q = EI_1 \frac{d^3y}{dx^3} = EI_1 h_1 \frac{d^3\phi}{dx^3}$$

which gives

$$M_2 = Qh = Eh^2 \frac{I_1 I_2}{I_1 + I_2} \frac{d^3\phi}{dx^3} \ldots\ldots\ldots\ldots [13]$$

Using the notation

$$\frac{EI_1 I_2}{I_1 + I_2} = D$$

the differential equation of twist becomes

$$M_t = M_1 + M_2 = -C \frac{d\phi}{dx} + Dh^2 \frac{d^3\phi}{dx^3} \ldots\ldots [14]$$

The solution of this equation for a long rail is

$$\frac{d\phi}{dx} = -\frac{M_t}{C}(1 - e^{-\gamma x}) \ldots\ldots\ldots\ldots\ldots [15]$$

in which

$$\gamma = \sqrt{\frac{C}{Dh^2}} \ldots\ldots\ldots\ldots\ldots\ldots [16]$$

It is seen that with an increase in the distance x from the middle cross-section of the rail, the second term in the parenthesis in the right-hand member of Equation [15] diminishes, and this equation approaches Equation [11] for simple torsion. The bending of the head and base of the rail have only a localized effect on the torsion of the rail. The results of the experiments made[9] are in very good agreement with Equation [15].

Imagine now that the rail shown in Fig. 7 is attached along its length to a continuous elastic foundation which resists the rotation of cross-sections of the rail during twist. Assuming that the resisting couple of the foundation per unit length of the rail is proportional at any cross-section to the corresponding value of the angle of twist ϕ and using for the factor of proportionality the symbol k_1, we find by differentiation of Equation [14],

$$\frac{dM_t}{dx} = -k_1\phi = -C\frac{d^2\phi}{dx^2} + Dh^2 \frac{d^4\phi}{dx^4}$$

and the equation for determining the angle of twist is

$$Dh^2 \frac{d^4\phi}{dx^4} - C\frac{d^2\phi}{dx^2} + k_1\phi = 0 \ldots\ldots\ldots\ldots [17]$$

The solution of this equation shows that the twist of a rail affixed to an elastic foundation may be represented by a wavy line, and that the amplitude of the waves decreases with an increase in the distance from the loaded cross-section.

3 LATERAL LOAD

A single lateral force H applied to a rail produces lateral deflection and twist in the rail. Let us assume again that the rail is continuously supported by an elastic foundation which resists the lateral deflection and twist of the rail. Let k_1 be the modulus of foundation with respect to twist (see Art. 2) and k_2 the modulus of foundation with respect to lateral deflection. Denoting by y the lateral deflection of the center of twist of the rail and by ϕ the angle of twist, the deflection at the base of the rail is, from Fig. 9, $y - g\phi$, and the corresponding lateral reaction at the base per unit length is

$$q = k_2(y - g\phi) \ldots\ldots [18]$$

The reactive twisting moment per unit length is

$$m = k_1\phi \ldots\ldots\ldots [19]$$

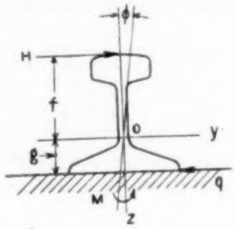

FIG. 9

Now the differential equation of lateral bending of the rail is

$$EI_1 \frac{d^4y}{dx^4} = -k_2(y - g\phi) \ldots\ldots\ldots\ldots\ldots [20]$$

in which EI_1 is the flexural rigidity of the rail in a horizontal plane.

In discussing the twist of the rail we find from statics that the rate of change of torque is given by the equation:

$$\frac{dM_t}{dx} = qg - m$$

Using now the Equations [14], [18], and [19], we find

$$-C\frac{d^2\phi}{dx^2} + Dh^2 \frac{d^4\phi}{dx^4} = k_2(y - g\phi) - k_1\phi \ldots\ldots [21]$$

The two simultaneous Equations [20] and [21] determine the lateral bending and twisting of the rail under the action of the force H. In integrating these equations, the following conditions at the loaded cross-section must be satisfied:

$$\left.\begin{array}{l} \left(\dfrac{dy}{dx}\right)_{x=0} = 0; \quad EI_1\left(\dfrac{d^3y}{dx^3}\right) = \dfrac{1}{2}H; \quad \left(\dfrac{d\phi}{dx}\right)_{x=0} = 0 \\ -C\left(\dfrac{d\phi}{dx}\right)_{x=0} + Dh^2\left(\dfrac{d^3\phi}{dx^3}\right)_{x=0} = \dfrac{1}{2}Hf \end{array}\right\} \ldots [22]$$

The other constants of integration must be chosen so as to make bending and twist of the rail disappear at infinity.

The application of this general theory in particular cases[9] shows that lateral bending and twist are of localized character; therefore if several lateral forces, such as lateral pressures produced by locomotive wheels, are acting on the rail, the maximum stress produced in the head of the rail by one of these forces is not substantially affected by the other forces.

4 EXPERIMENTAL DETERMINATION OF LATERAL FORCES, VERTICAL FORCES, AND THE ECCENTRICITY OF VERTICAL LOADS

In the most general case, the action of a force on the rail can be replaced by a vertical load P with a certain eccentricity e

---

[8] Further discussion regarding center of twist can be found in Timoshenko's "Strength of Materials," vol. 1.

[9] See paper by S. Timoshenko in Reports of Zürich Congress, loc. cit., footnote No. 4.

and by a lateral load. In discussing stresses in rails and tracking characteristics of locomotives, it is of practical importance to know all three quantities: P, H, and e. There is no difficulty in finding experimentally the vertical load P. It is clear from Figs. 10(b) and 10(c) that at the two points m and n at the two opposite edges of the base of the rail the stresses produced by a torque M_t or by a lateral load H are numerically equal and of opposite sign. Hence by taking the strain-gage measurements at m and n, the average of these two readings can be used for determining the magnitude of the vertical load. This calculation can be made by using Equation [8] or, with a greater accuracy, by making a preliminary calibration of the track by applying a known vertical load and taking readings at m and n. The effect of the adjacent vertical loads on the readings at m and n can be determined by using the curve in Fig. 3.[10]

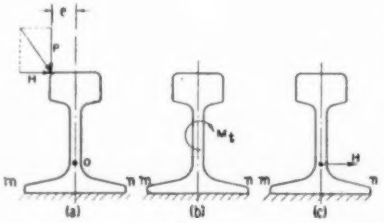

FIG. 10

In our field experiments, a Westinghouse magnetic strain gage[11] was used and the strains produced at m and n by locomotive wheel pressures were recorded to a certain scale on an oscillograph film. Taking readings under all the wheels of the locomotive, the vertical pressures of these wheels on the rail can be calculated as it was explained in Art. 1. In order to obtain a higher accuracy, the curve obtained by calibration was usually applied instead of the theoretical curve, Fig. 3. Figs. 11, 12, and 13 show the strain gages attached to the base of the rail.

To determine the magnitude of lateral force H, Fig. 10(a), the longitudinal strain-gage measurements at the height of the center line of the rail were made as shown in Fig. 12 (strain gage B). The preliminary tests in the laboratory (see Section II) showed that this longitudinal strain depends principally on the magnitude of the lateral force H. The effect of the vertical force P, Fig. 10(a), is small and practically independent of the magnitude of the eccentricity e. Subtracting this small effect from the total reading of the strain gage B, the difference represents to a certain scale the lateral force H. The scale is usually established by making the preliminary calibration tests on the track.

For determining the eccentricity e of the vertical pressure P, the vertical strain gage C (Figs. 11 and 13) was used. This strain gage measures the change in the distance between the head and the base of the rail, which depends principally on the eccentricity e of the vertical load P. Thus having the readings on the strain gages A, B, and C, the quantities P, H, and e, determining completely the pressure of a wheel on the rail, can be calculated provided a preliminary calibration test on the track has been made. Several examples of such calculations will be given in discussing field measurements in Chapter III.

5 DYNAMIC STRESSES IN RAILS

The dynamic deflection of the rail and the dynamic stresses under the action of the moving wheels of a locomotive may become much larger than those calculated on the basis of the static formulas discussed in Art. 1. There are various causes

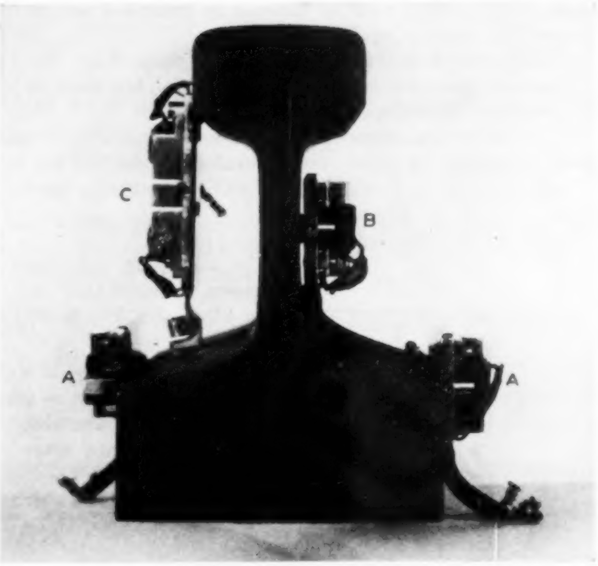

FIG. 11 STRAIN GAGES MOUNTED ON RAIL MODEL. END VIEW

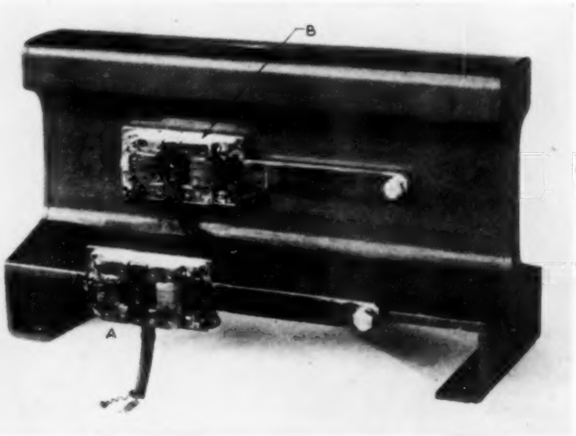

FIG. 12 STRAIN GAGES MOUNTED ON RAIL MODEL. GAGE SIDE OF RAIL

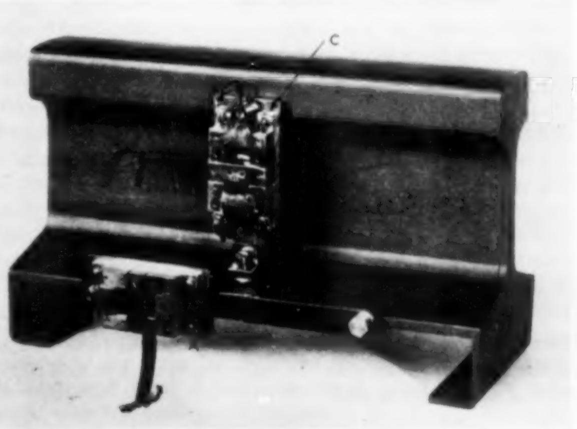

FIG. 13 STRAIN GAGES MOUNTED ON RAIL MODEL. OUTSIDE OF RAIL

which may produce such an increase in deflection and stress, the principal ones being:

---

[10] At the suggestion of J. P. Shamberger a method has been developed which will avoid the necessity of making corrections for the stress due to adjacent wheels when calculating vertical loads. Simultaneous measurements will be taken under each wheel of the locomotive.

[11] J. P. Shamberger, Proc. A.S.T.M., vol. 30 (1930), p. 1041.

a Different kinds of irregularities in the shape of the wheel or rail, such as flat spots on the rim of the wheel, low spots on the rail, and discontinuities at the rail joints.

b Variation in the forces acting on the rail caused by variable spring forces on the wheel, the vertical component of the centrifugal force of the counterweights, and the vertical component of the forces in the connecting rods.

c Vibration of the rail under moving loads.

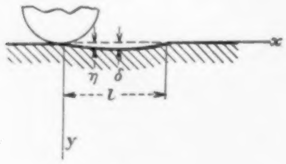

FIG. 14

In discussing the dynamic stresses produced in a rail by the effect of a low spot (Fig. 14), let

u = variable depth of the low spot, a given function of x

W/g = unsprung mass per wheel

$\alpha = 2k/\beta$, the vertical load necessary to produce a deflection equal to unity—see Equation [4]

y = additional deflection of the rail under the wheel due to the dynamic effect of the low spot.

Then the vertical displacement of the wheel due to the dynamic deflection of the rail and to the low spot is $y + u$, and the differential equation of motion of the wheel in the vertical direction is:

$$\frac{W}{g}\frac{d^2(y + u)}{dt^2} + \alpha y = 0 \qquad [23]$$

If v is the speed of the locomotive, then

$$\frac{du}{dt} = \frac{du}{dx}v; \qquad \frac{d^2u}{dt^2} = \frac{d^2u}{dx^2}v^2$$

and Equation [23] can be put in the form

$$\frac{W}{g}\frac{d^2y}{dt^2} + \alpha y = -\frac{W}{g}v^2\frac{d^2u}{dx^2} \qquad [24]$$

If the shape of the low spot and the speed v are known, the right-hand member of [24] can easily be expressed as a function of the time and we arrive at the known equation of forced vibration of a system with one degree of freedom, the solution of which can be easily obtained in each particular case. Take, for instance, the low spot the shape of which is given by the equation

$$u = \frac{\delta}{2}\left(1 - \cos\frac{2\pi x}{l}\right) \qquad [25]$$

in which (see Fig. 14)

l = length of the low spot, and

δ = depth of the spot at the middle of its length.

Then the right-hand member of [24] becomes

$$-\frac{W}{g}v^2\frac{\delta}{2}\frac{4\pi^2}{l^2}\cos\frac{2\pi x}{l}$$

Measuring the time from the moment when the point of contact of the wheel coincides with the beginning of the low spot (Fig. 14), $x = vt$ and [24] becomes

$$\frac{W}{g}\frac{d^2y}{dt^2} + \alpha y = -\frac{W}{g}v^2\frac{\delta}{2}\frac{4\pi^2}{l^2}\cos\frac{2\pi vt}{l} \qquad [26]$$

Using the notations

T = period of vibration of the wheel on the rail[12]

$T_1 = l/v$ = time it takes the wheel to cross the low spot, we obtain a solution of Equation [26] satisfying the initial conditions

$$(y)_{t=0} = \left(\frac{dy}{dt}\right)_{t=0} = 0$$

in the following form:

$$y = \frac{\delta}{2}\frac{1}{1 - \left(\frac{T_1}{T}\right)^2}\left(\cos\frac{2\pi t}{T_1} - \cos\frac{2\pi t}{T}\right) \qquad [27]$$

It is seen that the additional dynamic deflection is proportional to the depth of the spot δ and depends on the magnitude of the ratio T_1/T and on the position of the wheel. The variation of this deflection when the wheel is moving along the spot, i.e., in the interval $0 < t < T_1$ for different values of the ratio T_1/T, is shown in Fig. 15. At the beginning y is zero, and then becomes negative. This means that at the instant the wheel reaches the edge of the low spot the pressure on the rail and the deflection begin to diminish. This happens because the wheel, due to the low spot, begins to accelerate downward. When the wheel advances along the spot, the retardation of the vertical downward movement begins, and with it an increase in pressure and deflection, as seen from the figure. The values of the ratio of the maximum deflection $y_{\max}$ to the depth δ of the low spot, calculated from Equation [27] for different values of the ratio T_1/T, are given in the following table.

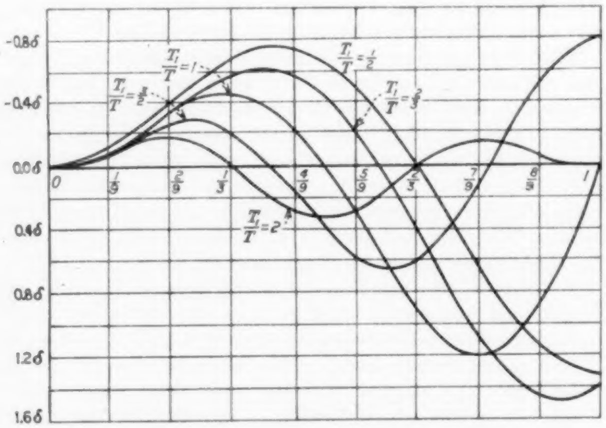

FIG. 15 ADDITIONAL (DYNAMIC) DEFLECTION PRODUCED BY FLAT SPOT ON WHEEL OR LOW SPOT ON RAIL

(δ = depth of flat spot; l = length of flat spot; T = period of free vibrations of wheel on rail; T_1 = time for wheel to cross flat spot.)

T_1/T	2	3/2	1	4/5	2/3	3/5	1/2
$y_{\max}/\delta$	0.33	0.65	1.21	1.41	1.47	1.45	1.33

A maximum additional deflection, equal to 1.47 δ, occurs at the speed corresponding to the ratio $T_1/T = 2/3$, i.e., when the time it takes the wheel to cross the low spot is equal to two-thirds of the period of natural vibration of the wheel on the rail. It can be concluded that the additional (dynamic) pressure due to the low spot is about equal to the load which produces a static deflection equal to 1.5 δ. Thus a comparatively small low spot produces, at certain speeds, a very appreciable dynamic effect, which must be added to the deflection calculated from the static Equation [4].

---

[12] The mass of the rail is neglected in this calculation. W/α is the static deflection of the rail under the action of the weight W of the wheel, then the formula for T coincides with the usual formula for the period of free vibration. See S. Timoshenko, "Vibration Problems in Engineering," p. 17.

Similar results can be obtained for low spots of different contours. In the general case, Equation [26] becomes

$$\frac{W}{g}\frac{d^2y}{dt^2} + \alpha y = F(t)$$

and its general solution is[13]

$$y = \frac{g}{W}\frac{T}{2\pi}\int_0^{t_1} F(t)\sin\frac{2\pi(t_1 - t)dt}{T} \quad\ldots\ldots\ldots[28]$$

Calculations made[14] for low spots of several different contours show that the ratio $y_{\max}/\delta$ does not depend substantially on the contour of the low spot provided it is represented by a continuous curve. Hence we can state that the maximum additional dynamic pressure on the rail due to a low spot is about 50 per cent larger than the load which produces static deflection equal to the depth δ of the low spot.

The calculation made above for the case of a low spot can be applied also to the case of a flat spot on the rim of the wheel, because such a flat spot produces exactly the same vertical movements of the wheel as a low spot of the same shape on the rail.

The question of the dynamic effect of clearances between the rail and the tie and the dynamic effect of rail joints can also be treated in a similar manner.

In considering the additional wheel pressure of a locomotive due to the centrifugal force Q of a counterweight, we can use the theory of forced vibration. In calculating this pressure, we take the centrifugal force and multiply it by the magnification factor.[15] Then the additional pressure on the rail is

$$Q\,\frac{1}{1-\left(\frac{T}{T_2}\right)^2}$$

in which T, as before, is the period of vibration of the wheel on the rail and T_2 is the time of one revolution of the wheel.

In this calculation the mass of the rail is neglected, which is justified because the time T_2 is usually large in comparison with the period of natural vibration of the rail.

To determine the period of lowest type of vibration, we note that this type of vibration consists of an oscillation of the rail in a vertical direction as an absolutely rigid body. Let q be the weight of the rail per unit length and k, as before, the modulus of foundation. The static deflection of the rail due to its own weight is q/k, and the period T_3 of the fundamental type of vibration is

$$T_3 = 2\pi\sqrt{\frac{q}{kg}}$$

Taking, for instance, a 130-lb. rail and $k = 1500$ lb. per sq. in.,

$$T_3 = 2\pi\sqrt{\frac{130}{36 \times 386 \times 1500}} = 0.0157 \text{ sec.}$$

This can be always considered as small in comparison with the time T_2 of one revolution of the wheels, and the magnification factor differs but little from unity.

II—LOCAL STRESSES IN RAILS

1 INTRODUCTION

In the previous section the rail was discussed as a beam on an elastic foundation, and it was shown that the usual theory for such bending can be applied to the rail as a whole. However, in the region near the point of application of the load the stresses deviate considerably from those that can be calculated from simple bending theory. In this section these local stresses near the load point will be discussed, and the results of some tests will be given.

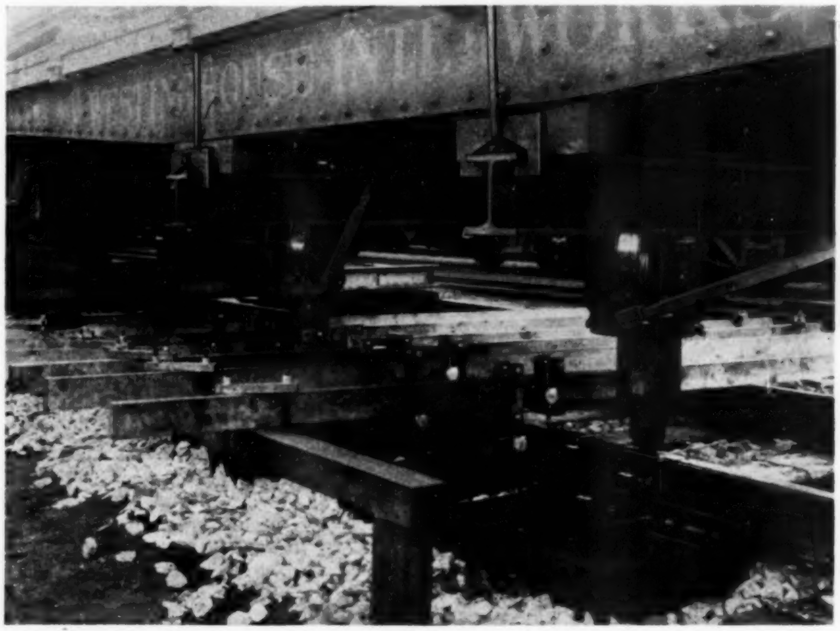

FIG. 16 EQUIPMENT FOR STATIC FIELD TESTS

The tests that will be mentioned were made partly on actual track and partly in the laboratory. The apparatus used for the static tests on actual track is shown in Fig. 16. A loaded flat car was supported from points outside the rail-tie structure. Hydraulic jacks were attached to the under side of the car directly over the rails in order to exert vertical loads. Lateral loads were produced by another hydraulic jack acting in such a way as to spread the rails apart. The magnitudes of the loads were read with hydraulic gages tapped into the high-pressure sides of the oil systems of the jacks. Deflections were measured with dial gages supported from outside the track, and stresses were measured with Huggenberger tensometers.

In the laboratory a 20-ft. length of rail was supported on cantilever springs spaced 21 in. apart to simulate track conditions. Fig. 17 shows the arrangement, and Fig. 18 details of one of the springs. The tests showed that the elasticity of these springs and the clamps holding the rail to them had a vertical modulus of foundation of 1500 lb. per sq. in. and a lateral modulus of 3000 lb. per sq. in. Lateral load was applied after turning the rail, springs, and base plate over on their sides so that the structure rested on the angles which were welded to the base plate.

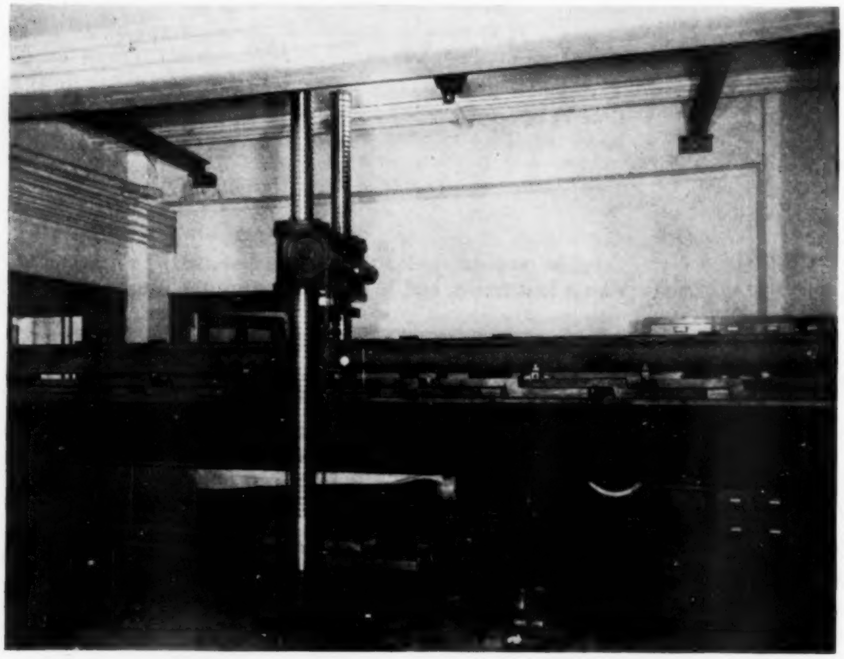

FIG. 17 EQUIPMENT FOR LABORATORY TESTS

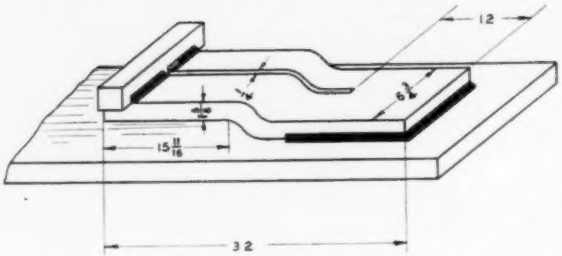

FIG. 18 SPRING USED IN LABORATORY TESTS

2 WEB AND FILLET STRESSES

General. The tendency of American rail design has been toward the increase of vertical rail stiffness, and a thin, high section has resulted. Considering the rail as a beam, it seems justifiable to remove material from the web and place it in the head or base in order to reduce the longitudinal stresses produced by vertical bending of the rail as a whole. However, if the web is made too thin it will compress vertically or else bend, as a narrow plate, away from the longitudinal vertical plane of the rail, and vertical stress in the web will result.

Experience and direct investigation have taught the stress analyst to beware of rapid changes in section. In the cross-section of a rail such rapid changes are to be observed at the points where the web meets the head and where it meets the base. The vertical stresses in the fillets at these points cannot easily be investigated by direct strain-gage measurements on a steel rail. The method used by the authors was that of measuring the stress in the web of an actual rail, after which photoelastic methods[16] were employed to find the relationship between the web stress and the fillet stress.

Concentric Vertical Load. A vertical load applied at the center of the head causes compression in the web. This vertical load, concentrated in a very small area at its point of application, spreads out along the rail as it progresses downward. In the case of a two-dimensional problem the pressure on a semi-cylindrical section of radius *r* and thickness *b* (see Fig. 19) produced by a load *P* is[17]

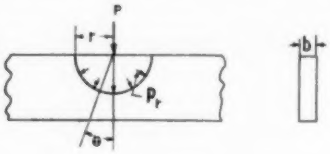

FIG. 19

$$p_r = -\frac{2P\cos\theta}{\pi b r}$$

If we consider only the section of the rail directly under the load, then $\theta = 0$, $\cos\theta = 1$, and the compression in the web varies in inverse proportion to the thickness *b* of the web, and the distance *r* from the load. The applicability of this theory is demonstrated in a qualitative way by the test results shown in Fig. 20. Here, among other data, the vertical web stress produced by a centrally applied vertical load (*A*) is shown for different points along the height of the web. It will be observed that the stress near the bottom of the web is much less than that near the top.

Eccentric Vertical Load. When a vertical load is applied nearer one edge of the head than the other, it produces vertical bending in the web as well as compression. In Fig. 20 one of the curves shows the vertical web stress produced by an eccentric vertical load (*B*). Note that at the top of the web, on the side of the rail at which the load is applied, the stress produced by this type of loading is the highest of any found in the web. Fig. 21 shows the vertical web stress $3^3/_4$ in. above the base of a P. S. 130-lb. rail in actual track produced by centrally applied and eccentrically applied vertical loads. The maximum compression is somewhat higher than that shown in Fig. 20, probably due to the greater stiffness of the foundation (k = 3000 lb. per sq. in.).

Because it caused the most severe condition in the web, the eccentric vertical type of loading was investigated photoelastically. The photoelastic method was applied to thin celluloid models of rail sections.[18] A thin section to which only a single concentrated load is applied does not completely represent a rail because it takes no account of the spreading of the load in the longitudinal direction nor of the torsional rigidity of the head.

This torsional rigidity, in a full rail, opposes the rotation of the head at the section where the load is applied. In the loading arrangement used in the photoelastic tests (see Fig. 22) the force applied to the extension of the head at *A* acted in the same way on the celluloid model. In the tests on steel rails it was found that the rotation of the head was $^1/_7$ of what it would have been if a section only 1 in. thick had been used. Therefore the force at *A* and its moment arm were adjusted so as to reduce by $^6/_7$ the twisting moment on the head produced by the main part of the eccentric load at *B*.

[17] See Timoshenko, "Strength of Materials," vol. I, p. 147.

[18] The photoelastic tests described here were made by R. V. Baud of the Westinghouse Research Laboratories.

The spreading of the load along the length of the rail was taken into account by correcting the readings in accordance with the amount of spreading found in tests on steel rails. That is, the slope of the curve was adjusted to conform to the slope of curve *B*, Fig. 20.

Fig. 23 shows the results of photoelastic tests on a model representing the P. S. 130-lb. rail. The stress along the boundary of the cross-section was measured. It will be noted that the highest stress occurs in the fillet under the head, and that the stresses near the bottom of the web are comparatively low because of the correction for the spreading of the load along the length of the rail. These results suggested that a more favorable stress distribution could be obtained if material were removed from the bottom of the web and placed nearer the tops. A model of such a rail was made and tested, with the result shown in Fig. 24. The redistribution of material in the web lowered the maximum stress by about 22 per cent.

The photoelastic results were not considered reliable in the

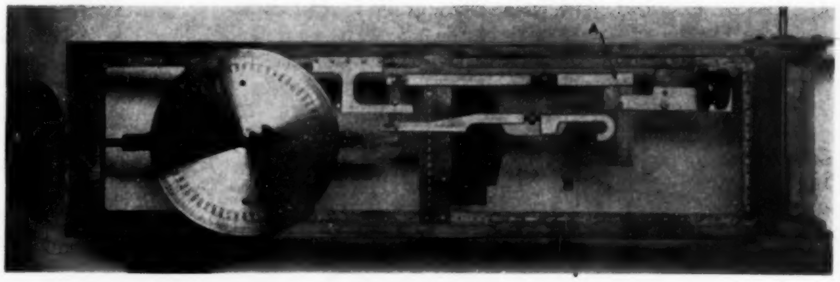

Fig. 22 Loading Arrangement Used in Photoelastic Tests

Fig. 20 (upper left-hand column) Vertical Web Stress Produced by Various Types of Loading. P. S. 131-Lb. Rail in Laboratory

Fig. 21 (lower left-hand column) Vertical Web Stress Produced by Various Locations of Vertical Load. P. S. 130-Lb. Rail in Track region of the base and the fillet at the bottom of the web because the method of attachment of the base of the celluloid model was not similar to that of an actual rail. A few measurements were made of lateral base stress in the base of a P. S. 130-lb. steel rail under the conditions shown in Fig. 25. Strain was measured between points *a* and *b*. The results showed that fairly high lateral stresses in the direction *ab* can be expected in the base of the rail. The conditions represented the most severe possible locations of vertical and lateral load, and were made directly over a tie. The stress thus measured was 28,000 lb. per sq. in. compression.

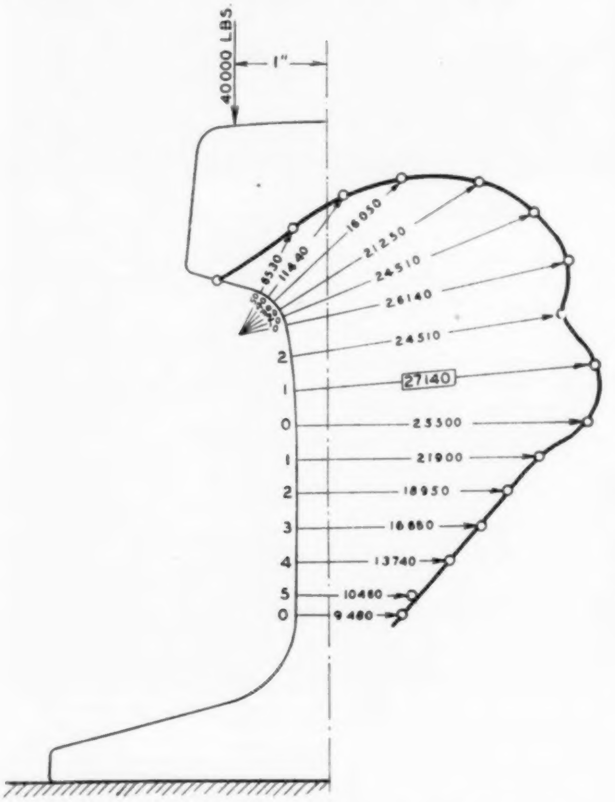

FIG. 24 RESULTS OF PHOTOELASTIC TEST. RAIL WITH UPPER PART OF WEB THICKENED

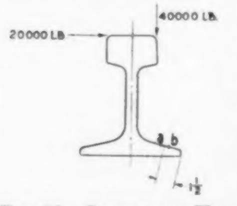

FIG. 25 CONDITIONS UNDER WHICH LATERAL BASE STRESS WAS MEASURED

Lateral Load. When a lateral load is applied to the head of a rail, the web bends, but not in the same manner as it does under the influence of an eccentric vertical load. One of the curves in Fig. 20 shows the distribution of vertical web stress produced by lateral load along the height of the web. The torsional rigidity of the head almost completely prevents rotation of the top of the web, and the curvature is of the type shown in Fig. 26 (*a*) instead of that shown in Fig. 26(*b*). Because of this reverse curvature, the stress in the fillet under the head is compression on the side near the lateral load

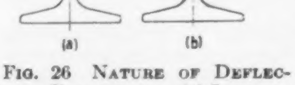

FIG. 26 NATURE OF DEFLECTION PRODUCED BY (*a*) LATERAL AND (*b*) ECCENTRIC VERTICAL LOAD

Summary. For the magnitudes of vertical and lateral load found in practice (see Section III) the highest vertical web stress is produced by a vertical load applied near one edge of the rail head. In most rails this maximum stress is located in the fillet under the head, and the stress in the lower part of the web is comparatively low. The vertical web stress produced by lateral load is usually not excessive. This stress is important because, for the most usual combination of high vertical and lateral load (vertical load applied eccentrically on the gage side of the head and lateral load directed away from the center of the track), the stresses from the two load components (vertical and lateral) are additive, both being compression.

The points brought out by these tests that are of value to the rail designer are that a more uniform stress distribution can be obtained by thickening the upper part of the web at the expense of the lower part, and that bringing the wheel load nearer the center of the rail will lower the stress in the fillet under the head.

3 LONGITUDINAL STRESSES NEAR THE POINT OF LOAD APPLICATION

At points within about 10 in. of the load, the longitudinal stresses are quite different from those that could be calculated from the ordinary bending theory, as may be seen from the experimental data plotted in Figs. 27 and 28. These show the distribution of head and base stress along the length of a P. S. 130-lb. rail in track. The base stress was measured 0.25 in. above the bottom of the rail and the head stress 1.2 in. below the top.

In order to account analytically for this distribution of stress near the load, it is necessary to add to the usual bending stress the effects due to four different phenomena:

(*a*) Torsion (Produced by lateral or eccentric vertical load)
(*b*) Bending of the head alone on the elastic foundation formed by the web (Produced by any type of vertical or lateral load)
(*c*) Reverse bending due to the concentration of the load (Produced by any type of load)
(*d*) Contact stress (Produced mostly by vertical load).

(*a*) *Torsion.* In a rail in pure torsion a cross-section originally plane does not remain so after the twisting moment has been applied. A rail built into a track, however, may be considered as an infinitely long bar with a twisting moment applied at some section along its length. (See Section I, Article 5.) In this case, due to symmetry, the section at which the load is applied cannot deform. But since the cross-sections at a little distance from the load do deform, there must be longitudinal tensions and compressions set up in the rail. A rail twists when a lateral or an eccentric vertical load is applied to the head.

The differential equation for a rail in torsion has been given in Section I, Equation [14], and its solution in Equation [15]. The longitudinal stresses set up near the load are such as would be produced by the forces *Q* in Fig. 8. The lateral deflection of the head is $h_1\phi$. Therefore the bending moment in the head is

$$M_H = EI_1h_1\frac{d^2\phi}{dx^2}$$

Differentiating the expression already obtained for $d\phi/dx$ in Equation [15] with respect to x, we obtain

$$\frac{d^2\phi}{dx^2} = -\gamma\frac{M_t}{C}e^{-\gamma x}\ldots\ldots\ldots\ldots\ldots [29]$$

At the load point, $x = 0$ and $e^{-\gamma x} = 1$, therefore,

$$M_H = -EI_1h_1\gamma\frac{M_t}{C}\qquad\text{[30]}$$

and similarly, the bending moment in the base is

$$M_B = -EI_2h_2\gamma\frac{M_t}{C}\qquad\text{[31]}$$

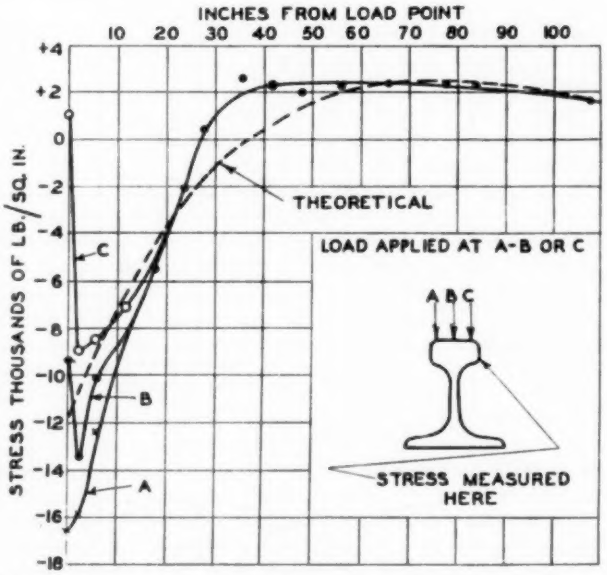

Fig. 27 Longitudinal Head Stress From 30,000 Lb. Vertical Load. P. S. 130-Lb. Rail in Track

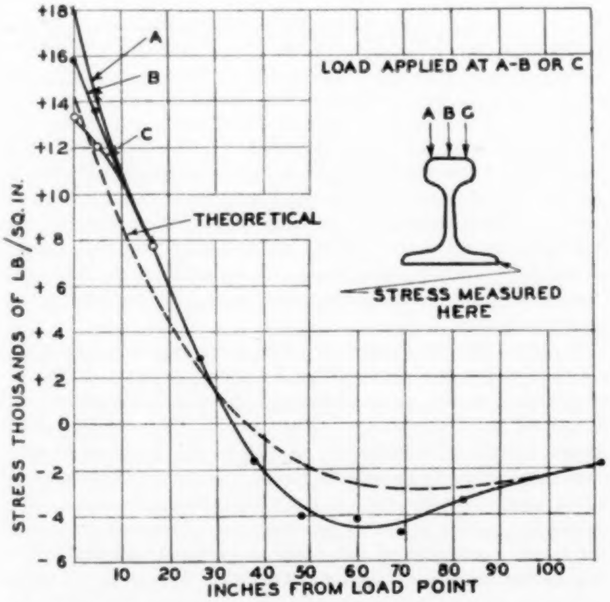

Fig. 28 Longitudinal Base Stress From 30,000 Lb. Vertical Load. P. S. 130-Lb. Rail in Track

From these expressions and the dimensions of the head and base of the rail, the longitudinal stresses set up by the forces Q (Fig. 8) can be calculated.

(*b*) *Bending of the Head Alone.* If the base of a rail were rigidly supported and a vertical or lateral load applied in the usual way, there would still be bending stresses set up in the head. Since the head is much wider than the web, it may be roughly considered as a beam bending on the elastic foundation formed by the web. The theory for this type of bending is similar to that already given for a rail bending on the elastic foundation formed by the ties, ballast, and ground. The only difference is in the calculation of the elasticity of the web foundation. The modulus of foundation, k, is by definition the load per unit length necessary to produce unit deflection at the union between the head and the web.

When the load is vertical, only the compression of the web need be considered. For vertical load, the modulus of foundation of the web is

$$k = \frac{tE}{d}\qquad\text{[32]}$$

where t = average web thickness,
d = web height, and
E = Young's modulus for rail material.

When the load is lateral the bending of the web must be taken into account. In the measurements of vertical web stress described above it was seen that the web bends, not as a cantilever, but in the manner shown in Fig. 26(*a*), without rotation of the top of the web. The deflection at the end of a cantilever, the end of which is prevented from rotating, is one-fourth that of a simple cantilever. Therefore, for lateral load, the modulus of foundation of the web is

$$k = \frac{Et^3}{d^3}\qquad\text{[33]}$$

(*c*) *Reverse Bending Due to Concentration of Load.* Consider a small hemispherical region concentric with the point of load application (see Fig. 29). The pressure on each element of the hemispherical surface has a component in the direction of the length of the rail. These components add together to form the forces F, which cause a bending moment in the rail as well as a uniform tension. The integration of these longitudinal components over the hemispherical area shows that $F = P/\pi$. The uniform tension produced by this effect is F/A, where A is the cross-sectional area of the rail. The bending moment that it produces is F times the distance of the point of application of the load from the neutral axis of the rail. The effect of the forces F should be considered for both vertical and lateral bending.

(*d*) *Contact Stress.* The contact pressure between the rail and the wheel is of importance in the study of the plastic flow of the rail head and the tire. The stress inside the head produced by contact pressure may also be a factor in hastening certain types of rail failure.

The solution for the pressure between the surfaces of two elastic bodies in contact was first given by Hertz, and can be found in most books on elasticity.[19] The solution for the state of stress inside a body produced by a concentrated load on its surface is also well known.[20] However, the calculation of the state of stress inside a body produced by a distributed load on its surface is exceedingly complicated, and is one that must be solved in each particular case of surfaces of contact for a complete, accurate study of the conditions in a rail. Two such solutions have been made independently, and are in perfect agreement. One was made by Prof. N. M. Belajef, Mechanical Laboratory, Institute of Ways of Communication, Leningrad, Russia. The solution best available to American readers is that of H. R. Thomas and V. A. Hoersch.[21] They have put their solution into a very usable form, and have also checked it experimentally by means of the Fry strain-etch method. The problem of the rail and the wheel is considered as that of two crossed cylinders.

---

[19] See "Strength of Materials," by S. Timoshenko. For the consideration of the tangential component of contact stress such as can be produced by tractive effort, see Fromm, "Schlupfberechnung beim Rollen Deformierbarer Schieben," *Zeitschrift für Angewandte Mathematik und Mechanik*, 1927, p. 27; also, R. Lorenz, "Schiene und Rad," Z.V.D.I., no. 6, 1928, p. 173.

[20] See A. E. H. Love, "Mathematical Theory of Elasticity," p. 190.

The approximate formula given by Thomas and Hoersch for the maximum shear in two crossed cylinders in contact is

$$\text{Max. shearing stress} = \frac{11{,}750\ P^{1/3}}{(R_1/R_2)^{0.271} R_2^{2/3}} \ldots\ldots [34]$$

where P = load in pounds
R_1 = radius of larger cylinder in inches
R_2 = radius of smaller cylinder in inches
$1 < R_1/R_2 < 8$, and
Poisson's ratio = 0.25

The contact pressure between the two elastic bodies and the maximum shearing stress inside the bodies are functions of the load and the radii of curvature of the bodies. Thus a small wheel with a light load may produce just as much plastic flow in the rail head as a larger wheel with a heavier load. Thomas and Hoersch give the following two numerical examples to illustrate this point.

Wheel diam., in.	Radius of rail head, in.	Load, lb.	Depth to point of max. shear, in.	Area of contact, sq. in.	Max. shearing stress, lb. per sq. in.
33	14	25,000	0.121	0.215	56,500
80	14	60,000	0.179	0.502	59,800

Comparison Between Calculated and Experimental Results. The longitudinal stresses in the head and base produced by eccentric vertical load were calculated for the cross-section directly under the load and compared with experimental results from measurements on an actual track. (See Figs. 27 and 28.) The calculated stresses for concentric load were assumed, perforce, to be equal to the experimental values, since the modulus of foundation of the track could be determined only from the experiments themselves, and there was no purely theoretical method of calculating the stresses from simple bending.

The local stresses produced by eccentric vertical load were calculated according to the theories already outlined. The lateral bending due to twist was calculated from Equations [30] and [31], and modulus of foundation of the web from [32]. The forces F, Fig. 29, were considered to produce uniform tension and bending. The contact stress was calculated according to a theory in which it is assumed that the load is concentrated instead of distributed over a small area. The rail used was P. S. 130-lb.

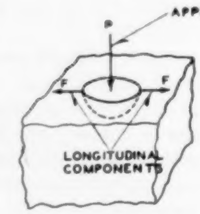

Fig. 29

Fig. 30 presents a comparison between the calculated and the experimental results. The very good experimental confirmation of the calculated stress values shows that the theories outlined above are well founded.

4 Transverse Fissures

Transverse fissures are fatigue cracks which form inside the heads of rails in the transverse plane. They have become increasingly prevalent in America during the past score of years, and are particularly dangerous because they cannot be detected by the usual methods of inspection.

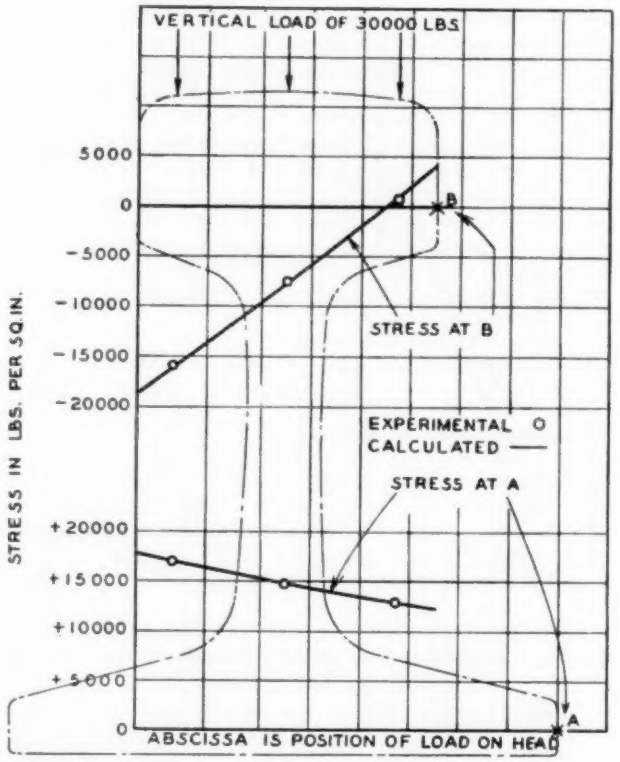

Fig. 30 Comparison of Calculated Longitudinal Stresses With Experimental Results

A long step toward the elimination of accidents from transverse fissures was made when E. A. Sperry introduced his fissure-detector car,[22] by means of which track can be inspected for the presence of such internal flaws. The method is an electrical one. A current is passed through the rail and used to detect changes in resistance such as occur when a transverse fissure is present. Cars of this type have already been used with good success on several railroads.

The detection of fissures in track is at best not a complete solution of the problem. What is really necessary is the determination of the cause of fissures and the development of a means for their prevention. The work of Freeman and others at the Bureau of Standards,[23] as well as the evidence of other observers, points to the conclusion that transverse fissures occur when, and only when, the rail head has internal cracks produced during the cooling period of manufacture. Freeman has studied the tensile properties of rail steels at elevated temperatures as well as the process of cooling of the rail. The study of tensile properties showed that some steels have, around 500 to 650 deg. cent., a ductility less than at normal atmospheric temperature. The study of the cooling process showed that tensile stresses are apt to be set up in the head at the time that the metal on the inside of the head is passing through this brittle range. If, then, we have the combination of a steel subject to brittleness at about 550 deg. cent. and a fairly rapid cooling of rails rolled from that steel, we are apt, according to Freeman, to find internal cracks in the head of the rail which will develop into transverse fissures under the action of wheel loads. There is some question as to whether the amount of the increase in brittleness found by Freeman is sufficient to account for the appearance of cracks during cooling. It may be that the cracks are due to the stresses on the inside of the head being tension in three dimensions (see Fig. 31), which is a very severe stress condition. It appears, then, that a complete solution of the problem may come with the development of an economical method for the slow cooling of rails.

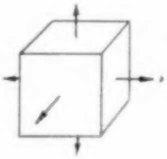

Fig. 31

Attempts have been made to place the entire blame for transverse fissures on the stresses in the rail head produced by bending and contact pressure. There are, undoubtedly, high stresses in the head, and there is no question but that they cause a fissure to grow after it has once started. It seems unlikely, however, that these stresses ever start cracks in sound material, since fissures seldom, if ever, start where the bending and contact stresses are a maximum.

It is seen that transverse fissures are connected with the shape of the rail cross-section only in so far as the ratio between the volume and surface of the head affects the rate of cooling. The evidence now available indicates that the problem is one that can best be solved by the metallurgist and the manufacturer. A suggested line of attack would be the study of residual stresses and the effect upon them of different methods and rates of cooling.

III—FIELD TESTS

1 Methods and Apparatus

The field tests made were primarily for the purpose of studying the action of various types of locomotive running gear on curved and tangent track. The results that were obtained are of major importance in the study of rail stresses because they tell what the forces are which can be exerted on rails in actual operation.

On the basis of the information obtained from the static tests (see Sections I and II), a method was devised whereby strain-gage measurements could be taken under dynamic conditions in such a way that they could be used to determine vertical and lateral wheel loads. This method is described in Section I.

At each test location a short static calibration was made to determine the relationship between vertical load and average base stress, and that between lateral load and web stress, for the particular spot where the tests were being made. The load was also applied at various distances from the gages to determine what correction should be made for the stress due to adjacent wheels. The apparatus used for these static calibrations was similar to that used in the static-stress studies. It consisted of a loaded car to which hydraulic jacks were rigidly attached, so that by moving the car the jacks could quickly be spotted over the point on the track where the calibration was to be made. Lateral loads were applied by means of a jack lying crosswise between the rails.

The calibration car was placed with the hydraulic jacks directly over the magnetic strain gages. Vertical and lateral loads were applied, and readings taken from all the gages. (Figs. 11, 12, and 13 show the location of the instruments.) The car was then moved to two or three locations, 3 to 10 ft. distant from the gages, and the procedure was repeated. At each location the car body was raised off the center pins with jacks in order to isolate the load applied at the center of the car as nearly as possible.

The deduction of wheel loads from stress data can best be explained by means of a simple example. Suppose we have a record of strain-gage measurements from a four-wheeled vehicle which has passed over the test spot, and wish to find the vertical loads. The axle spacing is 60 in. The static calibration has given us the two necessary curves, which are:

Curve No.	Abscissa	Ordinate
(1)	Distance from load	Average base stress from vertical load
(2)	Vertical load	Average base stress at load point

The peak base-stress readings on the north rail are:

	1st axle	2nd axle
Inner base.......	9,600	8,000
Outer base.......	10,800	6,000
Average..........	10,200	7,000

From curve (1) it is found that at 60 in. from the load the rail is in reverse bending and the base stress is —15 per cent of the base stress directly under the load.

Let A = maximum stress due to 1st wheel alone
B = maximum stress due to 2nd wheel alone

Then

$$10{,}200 = A - 0.15B$$

and

$$7000 = B - 0.15A$$

Solving for A and B,

$$A = 11{,}500, \text{ and } B = 8730$$

From curve (2) we can find the wheel loads corresponding to A and B, the corrected base stress values.

The method used for finding lateral loads is similar, with the web stress used in place of the average base stress. Ordinarily, due to the shorter wave length of the stress distribution from lateral load, no correction need be made for adjacent wheels, and curve (2) can be used directly.

For vehicles with more than two axles the calculations are more complicated, but the method is the same. When each stress reading has to be corrected for the effects of three or four adjacent wheel loads, it is best to solve the simultaneous equations by trial and successive approximations rather than by a direct method.

A typical oscillograph record of rail stress is shown in Fig. 32.

tests were made on the Great Northern Railway during the months of August and September, 1929. Track stresses were measured at three locations between Merritt and Berne on the electrified portion of the Cascade Division, and for all types of locomotives operating over the Division, namely,

Electric, 1-D$_0$-1 (Mikado), G. N. Class Z-1
Electric, 1-C$_0$ + C$_0$-1 (Mallet), G. N. Class Y-1
Steam, 2-8-2 (Mikado), G. N. Class O-4
Steam, 2-10-2 (Santa Fe), G. N. Class Q-1
Steam, 2-6-0 + 0-8-0 (Mallet), G. N. Class M-2

The three test locations included a tangent, a 2-deg. 30-min. curve, and a 10-deg. curve, all on a 2.2 per cent grade. The tangent and the 10-deg. curve had P. S. 130-lb. rail and the 2-deg. 30-min. curve had Great Northern 110-lb. rail. The speeds were mostly low, and never exceeded 30 m.p.h. As a consequence, the only severe conditions were found on the 10-deg. curve.

FIG. 37 WHEEL LOAD DIAGRAM

Results. Figs. 33–37 give the results from one representative test of each of the five locomotives on the 10-deg. curve. The directions of the arrows opposite the wheels indicate the directions of the lateral guiding forces exerted on the wheels, and so help to visualize the manner in which the locomotive is made to follow the curvature of the track against the resistance of friction and inertia. A minus sign preceding the value of lateral load indicates a force on the rail directed away from the center of curvature of the track.

Vertical Loads. Although the sum of all the vertical loads for any one test is always practically equal to the static weight of the locomotive, it will be observed that there is considerable non-uniformity in the loads on separate wheels. This non-uniformity is due to six different phenomena:

(1) Oscillations set up by unevenness in the track
(2) Rotation of counterbalance
(3) Angularity of connecting rod
(4) Longitudinal weight transfer. This is due to the height of the drawbar above the rail. The tractive effort at the level of the rail is resisted by the drawbar force, which produces a moment tending to lift the front of the locomotive into the air when it is pulling
(5) Centrifugal or superelevation force, when the locomotive is not traveling at the speed for which the curve is superelevated
(6) Lateral forces at the rims of the wheels, either flange pressures or friction. The lateral forces at the wheel rims are resisted at the wheel hubs, which causes a turning moment on each axle which can only be resisted by an unbalance in the vertical loads.

In low-speed operation, such as these tests represent, (5) and (6) are by far the most important effects, and they occur only on curves. The tests on the tangent stretch did show some irregularity in the vertical loads, but this may have been due largely to friction in the equalization system not allowing the wheel loads to readjust themselves after the active unbalancing forces had been removed. The effect of lateral force on vertical load distribution can be observed in Figs. 33–37 wherever the lateral forces are particularly high. See, for example, the third driving axle in Fig. 33, or the first driving axle in Fig. 35. On the third driver in Fig. 33 the total lateral force on the axle is 23,500–2250 or 21,250 lb. On a 56-in. driver this produces a turning moment of $28 \times 21{,}250 = 595{,}000$ in-lb. The vertical forces producing the resisting couple are 58 in. apart and so must be 59,500/58 or 10,250 lb. This would produce a difference between the vertical loads of 20,500 lb. Actually, there was a difference of 34,300 lb., the remainder of which must have been due to superelevation and other effects.

Lateral Loads. The tests showed that the lateral forces were negligible on the tangent location and fairly small on the 2-deg. 30-min. curve, as might be expected for low-speed operation. Figs. 33–37 show the lateral forces on the 10-deg. curve.

The importance of lateral wheel loads in the study of rail stress has already been made obvious in Sections I and II. However, when we come to study the action of the locomotive itself, two new factors present themselves which increase still more the importance of the lateral load. One is the sixth of the causes mentioned for non-uniformity in the vertical loads. A lateral load not only produces rail stress by itself, but it increases the accompanying vertical load with a consequent increase in stress. The other factor is that the magnitude of the lateral load, together with the manner in which it is applied, is a measure of flange wear and rail side wear.

The study of the manner of application of the lateral load involves answering two questions: (1) How much of the lateral load is due to friction at the tread and how much to direct flange pressure? and (2) What is the angle between the vertical plane of the wheel and the vertical plane of the rail? (angle of incidence). In order to answer these questions it is necessary to make a detailed study of the action of the locomotive, which is beyond the scope of this paper. However, such a study has been made for a few of the test conditions used, and some of the results will be given. It can be shown that the amount of wear should be roughly proportional to the actual flange pressure and the angle of incidence of the wheel.[24] If we multiply these two values together we get a "wear factor" which can be used for a comparative study of the wear produced by various wheels. Table 1 presents a few typical results.

Table 1 shows that a high lateral load does not necessarily mean excessive flange and rail wear, since the wear depends so much on the actual flange pressure and the angle of incidence. In the first example given in the table the actual lateral load was quite low, but analysis showed that it was made up of a high flange pressure and a large friction force acting in opposite directions, and that the angle of incidence was large. It may be observed that the highest wear factors always occur on leading outer drivers. The last three examples in the table give the highest wear factors found on the locomotives to which they belong. It may be said that in general a high lateral force at the leading outer wheel of a multi-axled wheel base is indicative of excessive flange wear, whereas a high lateral force at one of the rear inner wheels is no cause for alarm.

Stresses. The only stresses which were measured directly were those in a longitudinal direction in the base and in the web of the rail. The longitudinal web stresses were very small and were used only as a means of measuring lateral forces. The highest base stresses measured at the three locations were as follows:

Test location	Position	Stress, lb. per sq. in.
Tangent	Outer base	12,200
2° 30′ curve	Outer base, outer rail	19,400
10° curve	Outer base, inner rail	50,700

These results are typical of the general trend of the stresses found at the three locations and illustrate the importance of the lateral load as a stress producer.

After the forces and eccentricities were determined from the field tests, the head and web stresses were found by using the static-stress measurements described in Section II. The static-load tests showed that the longitudinal base stress is not apt to be the highest stress in the rail. It was found that a lateral flange pressure of 25,000 lb. would produce a stress of about 45,000 lb. per sq. in. compression on the gage side of the head. The maximum base stress found in the dynamic tests produced by a purely vertical load did not exceed 15,000 lb. per sq. in. The point of maximum bending stress on the head, which is the top of the gage side, is very nearly the same distance from the neutral axis as the point where the strain gage was located on the base in the dynamic tests, and so 15,000 lb. per sq. in.

TABLE 1 WEAR FACTORS FOR VARIOUS LOCOMOTIVES

Locomotive	Service	Driver	Lateral load, lb. (exp.)	Wear factor
Electric, 1–D_o–1	1st of 2 cabs pulling	1st outer	1,000	971
Electric, 1–D_o–1	1st of 2 cabs pulling	3rd inner	23,500	72
Electric, 1–C_o + C_o–1	1 cab pulling	3rd outer	21,250	495
Electric, 1–C_o + C_o–1	1 cab pulling	4th outer	5,500	1870
Electric, 1–D_o–1	Regenerating at head end	1st outer	11,750	2540
Electric, 1–C_o + C_o–1	Regenerating in train	4th outer	11,000	2640
Steam, 2–10–2	Pushing at rear end	1st outer	25,250	4800

---

[24] Based on the assumption that the wear between two surfaces is proportional to the pressure between the surfaces, the rubbing velocity, and the coefficient of friction.

can be used for the head also. Thus the compression on the gage side of the head due to bending may be said not to have exceeded 60,000 lb. per sq. in.

High stresses may also be expected in a vertical direction in the fillet under the head. The static tests showed that these stresses are produced mostly by vertical load and are affected quite considerably by the location of the vertical load on the head. This position of the vertical load was determined roughly in the dynamic tests by the use of a gage measuring vertical deflection of the head relative to the base. (See Section I, Art. 4.) It was found that this particular deflection was produced by vertical load much more than by lateral load, and was also affected by the position of the vertical load on the head. It could therefore be used as a rough measure of this position. A combination of the data obtained in the static tests, the photoelastic tests, and the dynamic tests led to the conclusion that for the maximum values of vertical and lateral load (60,000 lb. and 25,000 lb., respectively) and the most usual position of the vertical load ($^3/_4$ in. from the gage side of the head), the stress in the fillet under the head attains a value of 60,000 lb. per sq. in.

3 Tests on the Pennsylvania Railroad

Description of Locomotives and Operating Conditions. Field tests were made on the Pennsylvania Railroad during the months of September and October, 1930. The two test locations were both near Claymont, Del., on the Maryland Division.

Stresses were measured for three types of locomotives, which were:

Electric, 2-B_0-2 (4-4-4), P. R. R. Class O-1
Steam, 4-6-2 (Pacific), P. R. R. Class K-4s
Steam, 4-8-2 (Mountain), P. R. R. Class M-1a

The two test locations included a tangent and a 1-deg. curve, with practically no grade. The rail was P. S. 130-lb. Interest was centered chiefly on the high-speed tests, and maximum nominal speeds of 80, 90, and 100 miles per hour were attained with the Mountain, Pacific, and electric locomotives, respectively.

Results. The maximum stresses were found to be produced by dynamic effects at high speed, and were most severe at the tangent location.

It was observed that here, as in the tests on the Great Northern, the sum of the vertical wheel loads for a single test is about the same as the static weight of the locomotive, even though there was considerable non-uniformity in the loads on separate wheels. The non-uniformity was, however, due principally to oscillations and dynamic augments from the counterbalance.

The effect of oscillations on vertical loads is twofold. First of all, lateral oscillations produce lateral wheel loads at the rims which are resisted at the hubs and produce unbalance of the vertical loads as described earlier, in the discussion of the vertical loads found in the Great Northern tests. Secondly, slight unevennesses in the track can, at high speeds, start a rolling motion of the sprung weight of the locomotive, which results in a periodic shifting of the weight from one rail to the other. Studies of the vertical and lateral wheel loads on individual axles showed that the unbalance in the vertical loads could not all be due to the effect of lateral load, and consequently a considerable amount must have been due to rolling.

The tests showed that the highest lateral forces were produced, not by the guiding of the locomotives around the 1-deg. curve, but by lateral oscillations on the tangent.

The general importance of lateral loads has already been sufficiently discussed. From the point of view of rail study these tests serve to point out another cause of lateral wheel loads, that is, locomotive oscillations at high speeds. Flange wear and rail side wear are not of importance in operation on tangent track and low-degree curves because of the small angles of incidence involved.

IV—CONCLUSIONS

1 Properties of Rails

In this paper an attempt has been made to point out some of the functions that a rail is called upon to perform, and to give what information is available on the factors which help it to perform those functions with a maximum of safety and economy. Let us consider for a moment some of the properties that a rail should possess.

Vertical Stiffness. The rigidity of a rail in the vertical plane is a very important factor. On it depends the pressure transmitted to individual ties, and hence it affects the amount of work necessary to maintain the track surface. The impact at the joints also depends partly on the vertical rigidity of the rail, but the problem of rail joints has not been dealt with in this paper.

Another factor which should be kept in mind when considering vertical rigidity is the damage to rolling stock caused by impact. As shown in Section I, Art. 5, the additional (dynamic) pressure due to a low spot on the rail or a flat spot on the wheel increases with the rigidity of the track.

Lateral Stiffness. Lateral stiffness is of importance in the study of locomotive oscillations at high speed as well as the study of operation on sharp curves at low speed. At high speed the problem is that of the lateral oscillations of the locomotive on the spring formed by the elasticity of the track and running gear. The problem is extremely complicated, and nothing definite can be said about the advantages or disadvantages of high lateral rigidity. In low-speed operation on sharp curves, the amount of lateral deflection of the rail will often affect the distribution of the flange pressures that guide the locomotive through the curve.

Soundness of Material. The recent prevalence of transverse fissures shows that there is a great deal of work to be done in improving the initial condition of rail steels. Manufacturers should study the cooling process with particular reference to the formation of residual stresses and internal flaws.

Hardness of Material. It is known that contact stresses produce plastic flow in the rail head, particularly at the joints. The very high axle loads used in America therefore make hard rail material a necessity. A large rail is given less mechanical work during the rolling process than a small one, which results in a coarser grain structure in the large rail. In order to have the same hardness as the small rail, it must have a higher carbon content. This tendency has resulted in carbon contents of 0.75 to 0.80 per cent in rails for main-line use, with consequent increase of brittleness. It is possible that the solution will be found in heat treatment, either of the whole rail or of the wearing surfaces.

Uniform Strength. There are several places in a rail where the stresses may be high. The optimum condition is to make all such places equally strong, and the experiments described in this paper give data which are helpful in designing a rail for uniform strength.

In considering the stress at any point of a rail, due thought should be given to whether the stress is of a cyclical and frequently repeated variety, or only occasional. If of the former the criterion of safety should be based on the fatigue limit of the material. If of the latter, the yield point can be used.

Studies in the fatigue of metals[25] have shown that the conditions of safety for repeated stress are well represented by a curve such as that shown in Fig. 38. In this diagram the abscissa represents "steady" stress and the ordinate, "alternating" stress. Any given stress cycle can be analyzed into a steady and an alternating component, much the same as is a fluctuating direct current in electrical theory. A stress cycle can therefore be represented by a point on the diagram, the coordinates of which are the steady and alternating components of the cycle. The limit of safety is determined by drawing a line from the yield point of the material on the steady-stress axis to the endurance limit on the alternating-stress axis. Points lying between this line and the axes represent safe conditions, and points lying outside the line represent unsafe conditions.[26]

[25] See Soderberg, C. R., "Factor of Safety and Working Stress," Trans. A.S.M.E., APM-52-2 (1930).

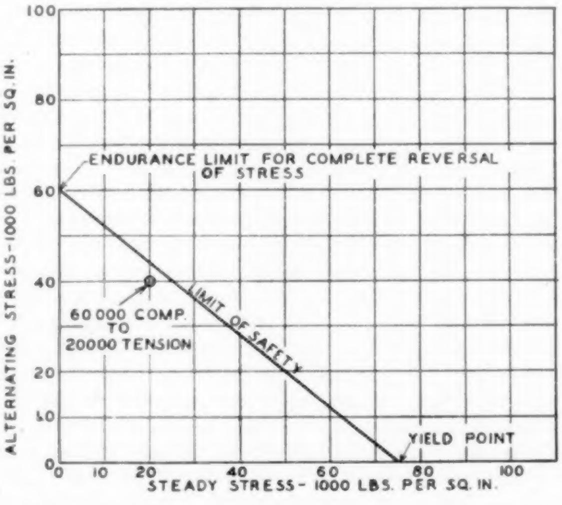

Fig. 38 Diagram Showing Limit of Safety of Stress Cycles

As an example, take a stress range of 60,000 lb. per sq. in. compression to 20,000 lb. per sq. in. tension. The algebraic average of these two is 20,000, which is taken as the steady component. The variation from this point is plus and minus 40,000, which is the alternating component. Thus, for a steel with a yield point of 75,000 lb. per sq. in. and an endurance limit of 60,000 lb. per sq. in., such a stress is safe, but very near the border line, and slight defects in the material can easily cause failure.

Let us discuss some of the stresses mentioned in this paper from the viewpoint of their liability to cause failure. The values given are for 130-lb. rail.

Stresses Produced by Centrally Applied Vertical Load. This type of load produces vertical bending of the rail, compression of the web, and contact stress in the head. It is repeated often enough during the life of the rail to necessitate the consideration of fatigue.[27]

The stress due to vertical bending goes from tension to compression. The range is not apt to be more than from 15,000 lb. per sq. in. in one direction to 5000 lb. per sq. in. in the other.

The compression in the web directly under the load is produced by vertical bending of the head on the elastic foundation formed by the web. Therefore it changes to tension a few inches away from the load, and the maximum tension is 20 per cent of the maximum compression (see Fig. 3). The wave length of this distribution is too short to allow the reversed stress between wheels to be more than 20 per cent of the maximum stress under one wheel. The highest compression that is apt to be found in the web due to centrally applied vertical load is 10,000 lb. per sq. in., so the stress range is from 10,000 lb. per sq. in. compression to 2000 lb. per sq. in. tension.

The contact stress produced by vertical load varies from zero to a maximum and is undoubtedly very high. However, it is also highly localized, and produces mostly plastic flow in the rail head.

Stresses Produced by Eccentrically Applied Vertical Load. This type of load produces all the stresses that are produced by centrally applied vertical load, with the addition of torsion, vertical bending stress in the web (see Section II, Art. 2), and lateral stress in the base (see Fig. 25). Its frequency of application is of the same order of magnitude as that of the centrally applied vertical load.

The torsion produced by this type of load is not severe, due to the shortness of the moment arm of the applied force. The lateral stress in the base is only high when the vertical load is eccentric on the outside of the head and accompanied by a high lateral flange pressure, which is an unusual condition.

The serious condition produced by eccentric vertical load is in the fillet under the head, and is due to bending of the web out of the vertical longitudinal plane. This stress goes from compression to tension, the same as the vertical web stress produced by centrally applied vertical load. Its maximum range is about 50,000 lb. per sq. in. compression to 10,000 lb. per sq. in. tension. When accompanied by a high lateral flange pressure, its maximum increases to about 60,000 lb. per sq. in. compression.

Stresses Produced by Lateral Load. Lateral load produces torsion, vertical stress in the web, lateral stress in the base, and lateral bending, principally in the head. The frequency of application of lateral load only approaches fatigue conditions on curves, where it is applied continuously during the passage of a locomotive. On tangent track the lateral forces are due to locomotive oscillations and they attain high values only occasionally.

The torsion is important only in that it produces lateral bending of the head and base [see Section II, Art. 3(*a*) and so can be considered along with the lateral bending. The vertical stress in the web produced by lateral load is not excessive, but is important because it must usually be added to the stress produced by eccentric vertical load.

The high stress produced by lateral load is that due to lateral bending of the head. This has a maximum of about 45,000 lb. per sq. in. and a reversal of 20 per cent of the maximum. On the gage side of the head, the maximum is compression and must be added to the stress produced by vertical load. Thus the maximum stress range in the head is about 60,000 lb. per sq. in. compression to about 15,000 lb. per sq. in. tension.

The work described in this paper shows that the weak points of present rails are the fillet under the head and the head itself.

2 Acknowledgments

The authors wish to thank the officials of the Westinghouse Electric & Manufacturing Company for having sponsored and guided the development and application of the test methods that were used. The field tests were all made in cooperation with the Westinghouse Railway Engineering Department, represented by Mr. J. P. Shamberger.

---

[26] Fatigue tests show that the true limit of safety is a curve and not a straight line. The line shown on the diagram is a convenient simplification of the actual data, and is known to err on the safe side.

[27] An exception must be made here for the augments of vertical load produced by some dynamic effects originating in the locomotive. For example, the augment produced by the rotation of the counterweight of a locomotive will not occur often enough at any one spot in a rail to produce fatigue.

Discussion

R. **Bernard.**[28] Experiments similar to those described in the paper are being carried on in Germany, and a large number of stress measurements on rails have already been performed. For this purpose a carbon-pile instrument, analogous to that first used by the Bureau of Standards in Washington, has been further developed, and by means of it stresses, frequency of vibration, and modulus of foundation have been determined. Some experiments have also been made with magnetic strain gages similar to the one described in the paper.

For German "Reichsbahn" track it has been found that the stress fluctuates from 1200 kg. per cu. cm. to —900 kg. per cu. cm. and the frequencies from 6 to 400 per sec., and that the modulus of foundation is about 10 kg. per cu. cm.

If the different conditions, in America are taken into account, it can be concluded that the foregoing results obtained are in satisfactory agreement with those given in the paper.

C. B. **Bronson.**[29] On page 3, and with reference to Fig. 5, the authors comment on the failure of splice bars, which they call fatigue cracks. Failure originates at the mid-distance of the top fishing or bearing surface and is induced by the notch effect from the sharp angle or edge of the rail head digging into the splice bar. Undercutting or filing of the rail-head bearing, rolling a notch or depression in the bar, and increasing the strength of the bar are all partially effective in overcoming this difficulty. Heat treatment of the splice bars has been very effective in reducing splice-bar failures.

In several places the authors call attention to the high stresses in the fillet joining head and web, and indicate that these are the most severe in the rail section. Rail failures, however, do not so indicate. In the Dudley rail sections, with fairly wide fillets joining head and web, failures of this type are practically unknown. Furthermore, with the greater and almost universal use and installation of canted tie plates, eccentric loading is being very much reduced, with more nearly center-bearing application.

In Section IV, under "Hardness of Material," the authors call attention to the fact that a large rail receives less work in rolling than a small one. While this is in part true, it must be remembered that the rail mills have faced the problem of heavier rail sections by rebuilding and modernizing their plants to keep pace with the changing conditions. As a result of this, much heavier mills are now in use, which produce very effective rolling pressures through the members of the heavy rail sections.

In particular, the New York Central Lines have continued the practice established by the late Dr. P. H. Dudley of using a broad, thin head on all of their rail sections, varying slightly from one weight to another. This has made it unnecessary to step up the carbon and other hardening elements in rolling the heavier rails, which the authors mention as being essential.

B. S. **Cain.**[30] It may be of interest to compare some of the results of this valuable paper with results obtained in somewhat similar work done by the General Electric Company during several years' study of locomotive design and operation.

Equation [27] shows some theoretical basis for the observation made in practice that the vertical forces due to balanced unsprung weight do not increase unduly with increase of speed on good track. In fact, at very high speed the weight does not have time to drop into soft spots. Similar observations are made by the Special Committee on Stresses in Railroad Track.[31] Fig. 15 also shows that the maximum impacts do not occur at the center of the depression or at a joint, but some distance away.

The strain gages used by the General Electric Company were originally of the McCollum-Peters type[32] depending on the compression of carbon piles. Some good results have been obtained with these gages, but experience has led to the preference for an electromagnetic gage of the same general type as that described in this paper. The gage is a development of the electric micrometer,[33] is constructed for a 2-in. gage length, and operates on 2000-cycle current with compact and portable equipment.

When using track-stress measurements to calculate the lateral pressures of locomotive wheels, it has occasionally been found that the rail will slip on the tie plate and may be prevented by vertical load from immediately slipping back. This action must be watched for, as it does not correspond with the theory of lateral bending and, if not detected, may give incorrect values of lateral force. Track-stress measurements at one or two isolated points cannot be relied upon to yield maximum values of stress or load, the records being not even simultaneous on different wheels. With the object of obtaining records over a greater distance, the Pennsylvania Railroad equipped a special track with hardened balls and plates to support the rail and to register maximum forces by indentation of the plates.[34] An instrument which makes continuous records of both vertical and lateral pressures simultaneously on a number of ties has been constructed and used by the General Electric Company[35] and has given many valuable results, especially of vertical pressures on the rail. It has shown particularly the importance of oscillations of certain types of locomotives at high speed in producing high rail stresses, showing that the maximum stresses are indicated by rail-stress gages only if these happen to be located at the exact spots where the maximum stresses occur.

Another attack on the problem of continuously recording wheel pressures has been to mount gages on the locomotives or cars themselves so that the lateral pressures on axles are recorded, either the maximum by means of a hardened ball and plate, or continuously by an electromagnetic strain gage. Records of this sort have recently been obtained. It is to be hoped that these continuous records of forces will ultimately be correlated with the local stresses in the rail section which form the chief subject of this paper.

The authors use in Table 1 a so-called wear factor, based on the assumption that the wear between two surfaces is proportional to the pressure between the surfaces, the rubbing velocity, and the coefficient of friction. Actually, it is also assumed that the coefficient of friction is the same for all cases. The writer does not believe that this factor is necessarily a good indication of wear, because rapid wear is often due to concentration of pressure on a small area, particularly in the familiar cases where incorrect contours are used, leading to cutting. In fact, the term "cutting" indicates a common source of rapid tire and rail wear which is not indicated by the so-called wear factor.

In the particular instance of the electric locomotives of the Great Northern Railway, as given in Table 1, there is a small difference between the maximum wear factors on different locomotives and considerable difference between individual wheels, even after averaging for both directions of motion. On the other hand, data obtained from the railway company covering tire wear on electric locomotives for the last two years, show that an even tire mileage is obtained on both classes of locomotives and "there is no measurable difference between tires wearing, regardless of position." It therefore appears that the "wear factor," while an interesting index of possible high wear in some cases, is not to be relied on as indicating relative performance, even qualitatively.

R. Eksergian.[36] This paper is a very important and valuable contribution to the literature of stresses in rails. Very little study up to this time has been given as to the effect of lateral loads in producing stresses in the rail, and the authors' analysis of stress concentration in the rail is extremely interesting.

Some years ago the late Prof. G. Lanza made a critical analysis of the effect of the spacing of the ties as concentrated elastic reactions under vertical wheel loads, and came to the conclusion that, due to the long wave length of the elastic depression of the rail, the assumption of an elastic distributed reaction for the actual concentrated tie reactions was a sufficiently good first approximation. The writer believes that Professor Timoshenko himself had made a similar analysis and come to the same conclusion.

But now in the study of lateral loads on the rail, the authors themselves state that lateral bending and twist are of a localized character, and sufficiently localized so that the lateral pressures of adjacent drivers have no mutual effect. In such a case the writer would like to ask the authors to what degree the assumption of a continuous torsional and lateral elastic reaction given by Equations [17] and [18] is justified when compared with the actual spacing of the tie reactions.

If the vertical loading has no eccentricity it would appear the lateral and vertical loading stresses can be separated, so that, due to the localized condition of stress produced by lateral loadings, stresses can be calibrated for a unit lateral load so that we can quantitatively measure the lateral forces of a wheel base. On the other hand, the authors point out the importance of eccentric vertical loading in producing both torsion and additional bending in the rail. If the flange is bearing up against the head the eccentricity will differ from that when the flange is away from the head. A study of such eccentricities for different configurations of the wheelbase may possibly be of importance in order that we may differentiate experimentally for the obtaining of lateral forces separately. Or can the effect of eccentricity of vertical loading be neglected with reasonably large lateral loads?

The consideration of a distributed elastic torsional reaction at the base of a rail has suggested a torsional elastic track (per pair of rails) reaction in conjunction with unequal loadings for individual wheels per pair of wheels. Such conditions occur wherever lateral forces are exerted, as in the rolling of a locomotive, as seen from an analysis of the phase relations in the dynamic augment of steam locomotives. Any combination of these conditions resolves into a couple exerted on the axle and wheels, together with the total axle loading, which latter divides equally on both rails, and the couple augments the mean axle wheel loading on one side and decreases it on the other. The couple reaction on the track (i.e., per pair of rails) causes a distributed elastic torsion reaction of the roadbed, if we can assume the tie itself as rigid. Actually the flexibility of the tie itself with the assumption of a distributed elastic tie reaction results in a more complicated torsional track elastic reaction. The mutual effect of tie reactions per pair of rails for unequal wheel loadings for the right rail as compared with the left rail, considering the distributed elastic reaction supporting the ties, would appear to be an interesting problem for study in connection with the vertical stresses in the rail.

The writer has made many calculations for the lateral forces exerted by various types of locomotives. A general discussion of the nature of these lateral forces is given in a paper by H. Uebelacker, and in the writer's "Static Adjustment of Trucks on Curves." It is interesting to note that with several pairs of drivers the largest lateral force for a locomotive with several pairs of drivers usually occurs on the next-to-the-rear driver, and the lateral reaction is exerted on the inner rail. Frequently the loadings may range from 20,000 to 30,000 lb. Such high loadings on the basis of the authors' analysis for stresses due to lateral forces must result in excessive rail stresses.

Such large lateral loadings are due to a considerable extent to the lateral guiding reactions of the front and rear trucks, and with swing-link trucks such loadings increase with the curvature. The authors' paper therefore reopens the question from another angle, i.e., that due to lateral rail stress limitations as to the type of truck-guiding apparatus such as a constant-resistance truck in preference to a swing-link truck and the use of an articulated wheelbase versus a completely rigid wheelbase.

In connection with vertical rail stress, the writer, in a paper on "The Balancing and Dynamic Rail Pressure of Locomotives," attempted to place the limitation of the counterbalance problem on the limiting rail stress. In connection with this the various phase angles of the dynamic augments for adjacent wheels were evaluated and the corresponding stresses estimated. The authors' paper has pointed out a further idea along this line, i.e., the estimating of the range of stress for the endurance or fatigue life of a rail. Using the master diagram of the bending moment, it is possible to construct an influence line for the passage of several drivers, and then, considering the phase relations of the dynamic augments of adjacent drivers, the complete variations of stress at a particular section can be estimated.

The relation of flange wear and angle of incidence have been recognized for some time. This relation has usually been stated by the equation, $W = kR\phi^n$, where W is the flange wear, R the lateral force, and ϕ the angle of incidence. It would be very interesting to establish experimentally the exponent n. The idea that flange wear depends essentially on the angle of incidence explains why the large lateral force of the next-to-the-last driver on the inner rail causes no appreciable flange wear.

F. M. Graham.[37] The designer of improved rails for heavy steam or electric service is confronted by a serious lack of available theoretical and experimental knowledge from which to project a rail section of greater dimensions than previously used. He will desire to produce a rail of increased stiffness and with such proportions of dimensions as will insure lateral stability against overturning under maximum combinations of forces which may be exerted in the actual service for which the rail is intended. The section must lend itself to suitable joint connections and conform to necessary manufacturing processes to produce sound steel and also permit heat treatment, if desired. The shape of the head of the rail must conform to the necessary requirements of wheel contacts, and such contacts should be made with the lowest possible unit pressure.

As opposed to the foregoing requirements, the following conditions are known to exist:

---

[36] Consultant, Engineering Dept., E. I. du Pont de Nemours & Co., Wilmington, Del. Mem. A.S.M.E.

[37] Assistant Engineer of Standards, Pennsylvania Railroad, Altoona, Pa.

1 Speeds approaching 100 m.p.h. develop very large forces exerted on the rail which cannot be calculated and which have only been observed in very limited tests.

2 Hidden defects in rails raise stresses in service to the point where their frequent repetition results in ultimate failure.

3 The cost of rolling experimental, or trial, sections is prohibitive, and therefore dependence must be placed on experience and the limited theoretical and test data available.

4 Wheel pressures on rails develop unit compressive stresses entirely beyond the elastic capacity of ordinary rail steel, as is shown by the observed cold flow of rail tops throughout their length, and especially at rail ends.

5 The supporting character of subgrade ballast and ties varies continuously from point to point, and especially so as between wet and dry seasons and during the winter season when roadbed and ballast are deeply frozen so that the ties provide supports with widely varying spans and resultant stresses.

The paper under discussion will be helpful in solving some of the above-mentioned difficulties.

The writer disclaims ability to criticize the more difficult mathematical analyses included in the paper, but wishes to call attention to some of the bases of calculations and other practical considerations.

Referring to Section I, wherein the elastic constant k is involved in all longitudinal stress values, it is impractical to determine this value generally on account of the elaborate equipment required, the tedious measurements to be made, and necessary occupation of the track interfering with its use during a single determination. Very low values of k occur at different times and places, resulting in permanent deformation of rails, if actual failure does not occur.

In this section the suggestion is advanced that the weight of the rail should be directly proportioned to the axle loads, disregarding speed, counterweighting, and shape of rail section. In designing a stronger rail section, the height is increased to provide greater stiffness; however, in doing so the size of the head is not increased—it may be decreased. To provide equal stability against lateral forces, it is necessary to increase the width of the base, also its thickness, tending to retain a low position of the center of gravity and thus relatively increasing the distance between the neutral axis and the top of the rail. Calling this distance c, it is suggested that where two different rail sections are assumed to have the same extreme fiber stress, their relative strengths are as $I^{3/4}/c$ for each section.

From the above it can be noted that two rail sections properly designed are not of similar shape.

Referring to Fig. 5 and the accompanying text in regard to joint bars breaking at the center of their length and cracking from the top downward, and stating that this is due to the greater distance from neutral axis to top of bar compared to the distance from the neutral axis to the bottom of the bar, resulting in higher unit tensile stress at top of bar in reverse bending, this explanation seems hardly adequate in view of the relatively low value of the reverse bending moment as shown in Fig. 3. May not this type of failure be brought about by reverse bending stress combined with the large unit pressure of the head of rail on the joint bar at this point, and the resultant severe abrasion and cold working causing considerable distortion or cold movement of the metal?

In the last paragraph of Section II the existence of a couple is assumed which assists in preventing the rotation of the rail from external forces. This assumption is doubtless based on the holding-down capacity of the spikes on the base of the rail. This is an unsafe assumption as spikes are not usually in contact with the top of the base of the rail and a very considerable actual rotation of the base of the rail would be necessary to bring them into action. Even if the spikes should act in this way, their effect would not be of a dependable elastic nature.

Similarly, in the first paragraph of Section III the resistance to lateral movement of the rail is assumed to be of an elastic character. Such movement is actually resisted by friction on the tie plates, which is of course not of an elastic nature, and also by contact of the rail base against spikes or shoulders of the tie plates. Such reactions are irregularly spaced and are of variable strength so that they do not provide a condition which can be properly included in a theoretical determination of rail stresses.

Referring to the tests on the Pennsylvania Railroad, the writer is not aware that simultaneous values of vertical and lateral forces exerted by each wheel have ever been measured. Such measurements have been made as the successive wheels arrive at a point of measurement, and it is probably not correct to assume that these are equal to simultaneous values.

The foregoing comments on some portions of the paper are only offered from a practical standpoint and are not of a constructive character.

The writer wishes to express his appreciation of this very interesting discussion of a difficult subject. It deals with stresses arising from the interaction of such diverse materials as dirt, stone, wood in various stages of decay, and steel when acted upon by modern locomotives at high speeds. The maximum forces often arise from accidental conditions which cannot be foreseen and which cannot be determined theoretically. Safe railroad operation is a question of maximums, not averages.

The writer suggests that the field work outlined by the authors be much extended to include the use of various types of modern locomotives (both steam and electric) at high speeds, using a large number of strain- and vibration-recording instruments so as to cover a considerable length of track instead of a single point. The track conditions should be varied so as to include all maintenance conditions which may be reasonably possible in actual service.

R. Grammel.[38] The authors' investigations provide a splendid example of fruitful cooperation between theory and experiment. The writer ventures to present some additional considerations which may perhaps be of use in furthering these investigations and in their practical application.

When the rail, as is usual, is attached to cross-ties which themselves are bedded on an elastic foundation, there obtains an interrelation between the vertical deflection [3] and the torsion ϕ. This is due to the fact that the loading of the tie near the two ends produces an upward bending of the tie in the middle, and hence a tendency of the ends to incline outward (except in the case when the parts of the tie under the rails themselves rest on some kind of a foundation but not in the middle). For an initial calculation we may assume that the moment of torsion which acts from the tie to the rail is proportional to the vertical deflection z of the rail and appears in Equation [21] as an additional member k_3z on the right-hand side. Here k_3 is a sort of coefficient of bedding, while z has the value given in [3]. A more exact calculation will take into consideration the connection between ϕ and z, and in addition the values of k_3 must be expressed in terms of the coefficient of bedding k. This can be done approximately in the following way. Instead of an infinite number of ties let us assume a single elastically supported "plate" having a coefficient of bedding k, but no bending rigidity in the longitudinal direction of the rail. If we then measure x lengthwise to the rail, y crosswise to the rail horizontally (which means along the tie), and z vertically, we have then to load the "plate" lengthwise to the rail with the unknown forces $Z(x)$ and the unknown moment $M(x)$. In addition to the known loads P (vertical) and H (horizontal) the rails then also carry the reactions $-Z(x)$ and $-M(x)$. In this way we obtain four linear differential equations, namely, for the deflection z' and inclination ϕ' of the "plate," for the vertical deflection z of the rail, for its torsion ϕ, and for its horizontal deflection y. These four equations are mutually interconnected by the magnitudes $Z(x)$ and $M(x)$, which may be omitted by the employment of an auxiliary condition to the effect that z and ϕ are the same as the values of z' and ϕ' at the locus of the rail. The actual calculation is rather complicated, but numerical results can be obtained. It would be of interest to compare them with results of actual measurements.

[38] Professor Dr.-Ing. Dr. R. Grammel, Stuttgart, Germany.

Walter M. Haessler.[39] Regarding the lateral rail forces mentioned by the authors, the writer would like to ask how this factor varies according to the height of the center of gravity of the locomotive above the rail. He is cognizant of the fact that these quantities—the lateral rail forces and the height of the center of gravity—are roughly in inverse proportion to each other. Have any experiments been made to indicate in a quantitative manner the relationship existent between these two quantities?

J. J. Karpinski.[40] The tendency of rail design, as stated in the paper, has been toward increasing the vertical stiffness. This was effected by increasing the height of the cross-section and placing more material in the head or base, while making little or no change in the thickness of the web. Thus the 80-lb. Am. Soc. C.E. Standard rail has a web $^{35}/_{64}$ in. thick, while the 85-lb., 90-lb., 95-lb., and 100-lb. rails have the same thickness of web, namely, $^{9}/_{16}$ in. This is an indication that the rail designers have already felt that material in the web was not being properly utilized.

After thorough theoretical and experimental investigations the authors point out that a more favorable stress distribution could be obtained if material were removed from the bottom of the web and placed nearer the top.

It seems to the writer that it would be of interest to extend these investigations to a case of a rail having the web perforated at regular distances near the bottom. In this way it would be possible to form an idea whether it would be possible to treat the rail as a Vierendeel girder. In this case, if necessary, extra thickness could be given to the verticals representing the unperforated part of the web because of the economy of metal attained by punching the web. The stronger verticals would permit increasing the height of the rail cross-section without fear of excessive stresses resulting from an eccentric vertical load, and therefore they would make it possible to diminish the amount of metal in the head, thus facilitating the process of cooling and consequently diminishing the chances of transverse fissures occurring.

C. F. Dendy Marshall.[41] With regard to the question of longitudinal weight transfer when in "motion" which is due to what the writer calls "trim," the authors give as the reason the pull of the drawbar. There are in addition two other factors which they omit to mention, namely, the upward pressure on the slide bars, and the frontal air resistance (with regard to the latter it is true that they were only dealing in that part of their paper with moderate speeds). The slide-bar pressure is a very serious disturbing force. Imagine for a moment that the stroke was increased until it was nearly equal to the diameter of the wheel. Suppose the crankpin to be at the bottom, brakes hard on, and steam admitted in front of the piston. It is obvious that there is a pressure downward on the rail under the driving wheels, and upward on the slide bars, tending to lift the front of the engine.

There is a point in connection with rail joints on which, though not touched on in the paper, the writer would like to lay his opinion before American engineers. In England they are set in line with one another; in the United States, he believes, they are usually alternated. Coming as they do at regular intervals, they are a potential danger if, at any attainable speed, their impacts can coincide, or harmonize, with the natural periods of the vehicles. With rails 45 ft. long, at 61 miles an hour a joint is met every second. The period of pitching, which is induced by parallel joints, is probably far quicker than this. But it has been found in England that the period of rolling (which alternate joints tend to produce) of a heavy tank engine is from 1 to $1^{1}/_{4}$ seconds, and rather less in the case of a tender engine. It would therefore appear that there is some risk about the alternative method, because the impulses, though small, are regular, and the writer is inclined to think that in this lies the explanation of the fact that elaborate and costly spring-compensating arrangements are found necessary in America, although not required in England: the reason being that they distribute the impulses and break up the rhythm.

S. Matsunawa.[42] In Japan, as well as in other countries, the study of stresses in railway track is regarded as of great importance from the economical viewpoint of railway operation, and the writer is very glad to have been afforded the opportunity of reporting some results of the investigations of similar subjects which were carried out by the Japanese Government Railways.

Statistical investigations of rail failures in 1929 covering a total operating track length of some 17,000 km. of the said railways have shown that 65 per cent of the total rail failures occurred within 1.6 meters from rail joints.

In view of this fact we think that investigations of rail stresses should be focused upon the effects of rail joints. In this connection the paper, "On the Strength, Design, and Maintenance of Rail Joints" by Mr. I. Horikoshi,[43] may be worth noting.

Measurement of the stress in railway rails under moving loads is one of the most important tasks imposed upon those who are interested in scientific research on rail stresses, though it is attended with great difficulties. The electric telemeter as devised by Mr. H. Shibata, engineer, of the writer's office, may be numbered among the best apparatus for the purpose, and the attention of experts is called to the descriptions in his paper entitled "Measuring the Stress and Depression of Rails by Means of an Electric Telemeter."[44]

In this apparatus the amount of stress (that is, the strain within a given gage length) and of the depression of rails to be measured is read in terms of electric current which varies proportionally to the amount of stress or depression. The slide-wire method is adopted, and the record is obtained by means of a portable six-element oscillograph designed for the purpose.

A chief advantage of the apparatus is that the stresses at four different points and the depressions at two different points can be recorded at the same time, and that the record can be easily magnified any number of times, as there is no considerable inertia mass of the recording part.

In Fig. 39, AB is a resistance wire, and a current from a battery E is adjusted by the rheostat R. A point C is soldered on AB, and D is a contact point which slides a distance in proportion to the strain or depression of the rail under rolling load. There is some potential difference between C and D according to the amount of current flowing through the resistance wire AB, and to the value of the resistance between C and D. The current in the shunt circuit DVC will therefore vary with the amount of the strain or the depression. Thus, we can measure the strain or depression by recording the variation of this current by means of the oscillograph at any required magnification, which is made possible by adjusting the rheostats R and r.

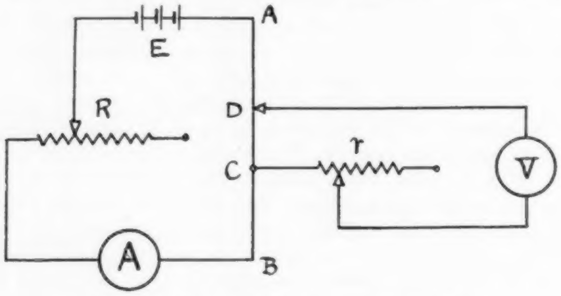

FIG. 39 ELECTRIC TELEMETER CIRCUITS

Thus the longitudinal, lateral, and any other stresses in rail can be measured by applying a proper attachment which reduces different amounts of strain to proper variations of the electric current in the shunt circuit DVC.

H. F. MOORE.[45] The authors have given an interesting discussion of transverse fissures in rails, although their experimental methods are not such as to detect such fissures or to determine the complex stresses beneath the surface of a rail under a wheel load. They refer to Bulletin 212 of the University of Illinois Engineering Experiment Station. In that bulletin a mathematical analysis is developed for internal stresses, and it is found that theoretically there exist very high shearing stresses, which are a maximum beneath the surface of the rail. Whether these stresses are sufficiently great to start a fissure in sound rail steel is as yet a matter of uncertainty. Experiments are now in progress in the Materials Testing Laboratory of the University of Illinois, in connection with the Joint Investigation under the auspices of the American Railway Association, the Technical Committee of the Association of Steel Rail Manufacturers, and the University. Already a transverse fissure has been produced in the laboratory in a shatter-cracked rail which has never been in track service, and tests on specimens of sound rails are now under way. Until further experimental results have been obtained the writer does not believe that it can be safely assumed that it is unlikely that wheel-load stresses can ever start internal fissures in sound rail steel. Further tests may, or may not, show this to be the case.

A. ONO.[46] The calculation of stresses in rails and the experiments in the laboratory and field have so thoroughly and successfully been carried out by the authors that there appears nothing to be added except one thing relating to the rail joint. Some results given in or deduced from a note on the calculation of the joint[47] will be introduced here in the hope that they will prove of interest to engineers interested in the present paper.

The joint is considered to consist of compound beams, and the relative displacement of the rail and fishplates, say, $y_1 - y_2$, is assumed to be represented by an equation such that $\mu = K_1 (y_1 - y_2)$, where μ is the intensity of pressure between the rail and fishplates induced by the action of load, and K_1 is the modulus of joint. In the calculation another constant α may be conveniently taken instead of K_1, viz.,

$$\alpha = \sqrt[4]{\frac{K_1}{4}\left(\frac{1}{E_1J_1} + \frac{1}{E_2J_2}\right)}$$

where E_1J_1 and E_2J_2 are the flexural rigidities of the rail and plates, respectively. As the modulus of elasticity of carbon steel is practically independent of the carbon content, E_1 and E_2 may be taken as equal. It is to be remarked that α plays a similar part to that of the constant β, which depends on the modulus of foundation as well as on the rigidity of rail.

The value of K_1 is unknown, but α may be determined by measuring the deflection of rails jointed together, and comparing this result with that observed on rails without joint. This was done in the laboratory of the Steel Works at Yawata, Japan, by taking specimens supported at both ends and loaded at the middle. Of course the value of α may vary greatly according to the tightness of the joint.

Now the greatest bending moment induced at the joint by a load P may be approximately found by the following equation:

$$M_b = \frac{P}{\beta\,(4 + q)}$$

where

$$q = \frac{4\beta J_1}{\alpha J_2}$$

The numerical value of q for a very tight joint was found to be 0.925 for 37-kg. rails (weight per meter) and 0.725 for a certain 50-kg. rail, used in Japan. Accordingly, the greatest bending moment in fishplates is a little less than that in rails without joints, while the stress in the former is very considerable as compared with that in the latter owing to the relatively small value of the section modulus.

Next the stress in rails may be considered by extending the calculation of the joint. For this purpose we find the positive and negative moments, and then the maximum and minimum values of the bending stress at a certain section of the rail. In this way we obtain the average stress and the alternating stress, as were also mentioned by the authors. Taking these stresses as factors determining the safety of material and assuming, e.g., a straight-line relation between these two for the fatigue limit, an equivalent alternating stress with the average stress zero may be found. Then the breaking section may be determined by finding a section in which the equivalent stress is a maximum.

Such calculation being performed, it can be shown that the fracture of a rail is likely to take place near a joint, so far as the bending stress is concerned, but when the joint is very tight, the straining action is only slightly greater than in long rails without joints. When the joint is so loose that it is quite unable to transmit force and moment, the calculation should be partly modified, as the magnitude of the negative moment is greatest when the load is at an end of the rail. In this case the straining action becomes much higher, say, some 33 per cent over that in long rails, and the distance between the breaking section and an end of a rail is some 76 cm. in 37-kg. rails and 88 cm. in 50-kg. rails. A report made by the research staff of the Steel Works at Yawata states that the transverse fissure of rails is rather localized in a region near an end. This seems to support the result of the calculation, although the writer does not mean to imply that the stress may be conclusively calculated by taking the bending only, as there are many other things to be considered, which were dealt with by the authors of the present paper.

C. Richardson.[48] It is interesting to note the effect of lateral forces on rail stresses. Eccentric loads also tend to increase the unit stresses. In canting one rail it is frequently found that the load is delivered on the outside of the head. In this case the lateral forces plus the vertical forces combine to produce an abnormally high unit stress.

The actual tests cover moderate speeds. It is hoped that further papers will disclose stresses involved at maximum speeds.

Continuation of the research work started should show whether a redesign of the rail is necessary to meet stresses actually incurred. Originally freight-car side frames were designed primarily for vertical stress. Investigation of failures showed that the lateral forces were the actual causes of failure. When the side frames were redesigned for both vertical and lateral forces, the life of side frames was increased to the point where they now outlive the car.

E. Schwerin.[49] This paper extraordinarily enriches our knowledge of the complicated stresses which arise in railroad tracks. The authors show that the probable stresses may be calculated with great accuracy, and that the weak points of the rails now used are the fillet under the head and the head itself; this last result seems to be extremely important for the development of new, more suitable forms of track.

With regard to this research the writer would like to know the opinion of the authors concerning the rise of grooves ("Riffelbildung") on the head of the rail. This phenomenon, which is especially observed at the entrance of stations, and which leads to quick destruction of the head of the rail, was much discussed some years ago. Has the Westinghouse Company already investigated this phenomenon, or are such experiments projected? As far as the writer knows, the cause of this phenomenon has not yet been fully explored, and he would be glad if the authors would express their opinion on this point.

Dr. Ing. Saller.[50] Some months ago the writer submitted an article entitled "Einheitliche Berechnung des Oberbaues" to the *Organ für die Fortschritte des Eisenbahnwesens* for publication, in which he gives simpler equations for the axle sequence than those offered by the authors. This article appeared in No. 2 of that journal for 1932.

Equation [5] of the present paper, as the writer sees it, is incorrect. The value of y in Equation [3] becomes zero when $(\cos \beta x + \sin \beta x)$ equals zero, and this is the case when $\beta x = 3\pi/4$, and hence the total length $2 \times (3\pi/4\beta) = 1.5\ \pi/\beta$.

Referring to Equation [9], the writer would say that it seems to him that here the longitudinal-tie-construction theory is applied to cross-tie construction. The longitudinal-tie construction employs no cross-ties. In the application of the longitudinal-tie theory to cross-tie road construction, the cross-tie and longitudinal-tie widths are often interchanged.

The writer has made a few tests with Thoma's electrical capacity extensometer at the rail base in straight sections, and has found that the influence of the lateral forces is not as great as the authors indicate. This work is still being continued.

A more specific reference to the table in Zimmermann's book (footnote 7) would be appreciated.

A. Spoliansky[51] and J. Lamoen.[52] The mathematical introduction to the paper gives as clear an insight into the stability of rail as may possibly be obtained when one restricts oneself to analytical methods. The theory used (of bending of bars continuously supported by an elastic foundation) has proved to be one of the most useful theories in applied mechanics, especially with reference to foundation problems. The most exhaustive work from this point of view is probably that written by Hayashi.[53] One of the present writers has also treated this question,[54] and has applied the theory to the computation of the horizontal reactions between piers and bridge in a weir consisting of a great number of slender piers supporting a bridge reaching from one abutment to the other.[55] The reactions of the piers on the bridge are in fact concentrated forces, but he has likened the bridge to a bar on an elastic foundation. The results of the approximate computation, assuming continuous support, were 0.5 per cent higher than those obtained by the exact calculation, considering concentrated reactions. This fully corroborates the presumption that the rail of Fig. 17 of the paper is, practically speaking, continuously supported.

Fig. 40

On page 3, second column, the authors say: "The inverse problem, i.e., of calculating the vertical pressures produced by locomotive wheels on the rail provided either the deflections or the stresses in the rail under the wheels have been determined by experiment, can also be solved without any difficulty." The writers quite agree as to the deflections, these being but feebly affected by the contact effects. But to make this method hold for stresses measured under the wheels, it would be necessary that the observed stresses—which are of course the existing stresses—be approximately equal to the stresses computed from the bending formula $M/\sigma = I/v$, M being measured on verticals passing through the wheel centers (see Fig. 4). But as the contact stress intervenes, these calculated stresses will be entirely different from the real stresses. (See Figs. 27 and 28.)

The writers are much interested in Figs. 27 and 28 showing the effect of contact stress. They have obtained similar results when experimenting with the arrangement shown in Fig. 40 (*a*). Their observations are roughly sketched at (*b*) for the compression in the upper flange, and at (*c*) for the extension in the lower flange. One might think that at a certain distance from the points of contact the computed and the observed stress diagrams would become identical. This is only true, however, for sufficiently great values of l/h, i.e., the transverse dimensions must be sufficiently small as compared with the longitudinal dimensions. When this condition is not satisfied, the ordinary theory of bending is contradictory to the theory of elasticity.

H. R. Thomas.[56] Referring to Fig. 30 and the accompanying text, the relative magnitude of the various local stresses might well have been indicated; and the method of calculating the contact stresses as well as the reason for assuming that the load makes contact at a point instead of over an area would be of interest.

The introduction of a discussion of transverse fissures into Section II—Local Stresses in Rails, does not seem warranted. The kind of repeated stress involved in the statement "Transverse fissures are fatigue cracks which form inside the heads of rails in the transverse plane," is not stated, nor are there any results presented which would indicate the presence of a repeated stress in the interior of the head sufficient in intensity to cause a fatigue crack to form and spread. Practically the whole of this discussion involves matters on which the evidence available (both in this paper and elsewhere) is not conclusive.

As suggested above, there does not seem to be anything in this paper which would warrant the paragraph on Soundness of Material.

Referring to Fig. 38, the use of the expression "Limit of Safety" is unfortunate, since any stress condition approaching this curve is certainly approaching the point of actual destruction.

In dismissing contact stresses as having only the effect of producing "mostly plastic flow in the rail head," the possibility that such cold working of the head may result in high internal residual stresses or may contribute to the start of surface cracks is being disregarded.

In presenting stress measurements and calculations, only locomotive-wheel loads seem to be considered. On account of the much greater frequency of application of car-wheel loads, it would seem that on the whole these loads might be even more important. This is especially the case if their effect in producing plastic flow and wear of the rail head is considered.

Hans Fromm.[57] The investigations which are discussed in the paper give important information regarding the magnitude of the stresses in rails, regarding the causes producing these stresses, and the calculation of the stresses. These investigations showed that it is possible, by using a simple theory, to calculate with sufficient accuracy stresses produced by vertical and lateral forces. It is possible furthermore to obtain from a few suitably chosen strain measurements in the field the system of forces acting on the rail. Combining these two kinds of investigation it is possible to determine the static and dynamic forces acting between the wheels and the rail and to establish in this manner an important foundation (1) for the design of locomotives and cars, and (2) for the design of rail profiles and of railway track.

Especially interesting is the action of lateral forces, which in general consists of the pressure of the flanges and of the lateral friction forces. The lateral forces produce a very considerable increase of stresses in the rails (1) by direct action and (2) by producing changes in distribution of the vertical loads between the wheels.

The wear on the rail depends, in the writer's opinion, principally on the magnitude of the work of friction which is obtained as the product of the friction force and the corresponding magnitude of sliding (*Gleitschlupf*). We have to consider here (1) the wear between the flange and the rail, which is approximately proportional to the acting pressure of the flange, to the coefficient of friction, and to the height of the flange, and (2) the wear of the upper surface of the rail and of the surface of the wheel rim, for which not only lateral but also longitudinal friction forces must be considered. These longitudinal forces appear partially as the reaction against friction between the flange and the rail, but principally they represent the necessary circumferential forces acting on the driving wheels and the forces acting during braking. The work of friction can be calculated[58] in the case of a conical surface of the rim of the wheel as is usually the case in railways. It gives the friction losses due to sliding and also the lever of the rolling friction.

The longitudinal friction forces have only a negligible influence on stresses in the rail at a considerable distance from the point of contact of the wheel and of the rail. But at the surface of contact and near this surface the friction forces can have a considerable effect on the stresses. The calculations[59] in the case of a rim with the usual conical surface and a flat surface of the rail give an increase of the reduced stresses[60] up to 70 per cent. This increase depends on the dimensions, the magnitude of the load, and the coefficient of friction. In the case of a curved contact surface of the rail we have the case of contact of two cylinders with perpendicular axes, for which we have not yet a solution. We must expect here a similar increase in reduced stresses as for the above-mentioned case of a flat contact surface of the rail. Moreover, with continuous wear the contact surface of the rail approaches a flat surface. There exist also some profiles which have the flat surface from the very beginning.

So long as the reduced stress is far below the yield point the wear depends essentially upon the work of friction forces. When the reduced stress approaches the yield point, the hysteresis work becomes noticeable. This is shown by increase of rolling losses above the work of friction forces and on the other hand by the acceleration of wear due to fatigue. If the point of the maximum reduced stress is not on the contact surface but at a certain depth below the rolling surface of the rail, the well-known "pitting" phenomenon may occur.

$$\sigma_{\text{red.}} = \sqrt{2(\tau_1^2 + \tau_2^2 + \tau_3^2)}$$

proposed by von Mises, in which τ_1, τ_2, and τ_3 are the principal shearing stresses.

AUTHORS' CLOSURE

S. TIMOSHENKO. In closing the discussion the present author will consider only questions concerning the introductory theoretical part of the paper and the general arrangement of field measurements. Those concerning field experiments and laboratory tests will be answered by Mr. Langer.

In the theoretical part of the paper the authors begin with the discussion of the action on the rail of vertical loads. A more detailed investigation of this problem has shown[61] that the isolated elastic supports can be replaced with sufficient accuracy by a continuous elastic foundation (see discussions by Dr. R. Eksergian and Dr. Saller). Although the actual support of the rails is very far from this ideal condition, the theory based on such an assumption proved a very useful one, and the authors were guided by this theory in planning their experiments. It was found also that by using this theory vertical loads could be calculated with sufficient accuracy from strain measurements if only the modulus of foundation k were determined by the preliminary calibration tests.

In investigating lateral bending and twisting of the rail, the authors applied the same assumption of continuous elastic support. Due to the simultaneous action of large vertical loads, it can be assumed that all clearances are taken up and that the rotation and lateral deflection of the rail are producing the corresponding elastic deformation of the ties (see discussion by F. M. Graham). The theory developed in this manner gives only a general picture of the deformation of the rail produced by lateral forces and by eccentric application of vertical loads. To obtain the numerical values of lateral forces and of eccentricities from their tests the authors did not use the theoretical equations but based their calculations on the results of the preliminary calibration of the track (see discussion by R. Eksergian) so that the defects of their theory do not affect the calculated values of lateral forces. The arrangement adopted for strain measurements makes it possible to measure the effect of lateral forces separately from the effect of eccentric application of vertical loads (see discussion by R. Eksergian).

The authors made their measurements only in two cross-sections, and in general they cannot be relied upon to yield maximum values of stress or load (see discussion by B. S. Cain and F. M. Graham), but their experiments showed that in the curves and at moderate speeds there is a steady distribution of vertical and lateral forces between the locomotive, wheels, and rails. Under such conditions, their measurements give a true picture of acting forces. In the case of a tangent track, it is necessary to take simultaneous readings in many cross-sections. The possibility of mounting the gages on the locomotive was also considered in this case.

The problem of stress conditions in joints was not investigated by the authors, and they mentioned the cracks in joint bars only because they show that there must be reverse bending stresses which can be explained if the rail be considered as a bar on an elastic foundation. The large local pressures of the head of the rail on the joint bar may also have an effect on the development of the above-mentioned fatigue cracks (see discussions by F. M. Graham and C. B. Bronson). The deformation of a joint depends greatly upon the tightness of the joint, and is affected also by friction. It would be very interesting to determine experimentally with what accuracy the bending moment acting in a rail joint can be calculated (see discussions by S. Matsunawa and A. Ono). In conclusion, the author would like to note that it was not suggested in the paper that the weight of the rail should be directly proportioned to the axle loads (see discussion by F. M. Graham). It is shown only that if the rail profiles are geometrically similar, the maximum bending stress produced by an isolated force remains constant if the "weight of the rail per unit length is proportional to the load."

B. F. LANGER. Mr. Cain criticizes the use of the "wear factor" mentioned in Table 1 because it does not consider high concentrations of pressures due to incorrect contours. The wear factor is not intended to cover the whole subject of flange wear and rail side wear, but merely shows how this wear is affected by the layout of the wheelbase and the distribution of the guiding forces.[62] The fact that it does do this is demonstrated by the side wear of the outer instead of the inner rails on curves and the common practice of interchanging tires between end drivers and inner drivers to equalize the wear over the whole locomotive. A good article on flange wear, with particular reference to the shape of flange and rail contour, may be found in Heumann's "Spurkranz und Schienenkopf.[63]

Dr. Saller's method of finding the wave length of the deflection from Equation [3] is not correct, since he incorrectly assumes that the distance from the point where y is maximum to the point where y is zero is one-half of a wave length. The true wave length is found by putting the variable angle βx equal to 2π. This results in the value given in Equation [5].

Regarding Dr. Saller's criticism of Equation [9], the whole paper considers only cross-tie construction, and not longitudinal-tie construction. Equation [9] is correct for the former, but meaningless for the latter, since it does not consider the stiffness of the tie in bending.

The table referred to in Zimmerman's book (footnote 7) may be found on page 289 of the 2nd edition (1930).

The authors were very much interested in the information given by Messrs. Spoliansky and Lamoen on the effect of localized stress on stress distribution in beams. It was on account of this effect that they avoided the use of stresses in the head of the rail, near the point of contact, in calculating wheel loads. In the base and the web, the localized stresses are present, but do not introduce an error because the wheel loads are calculated from the experimental and not the purely theoretical relationship between stress and load.

Referring to Professor Thomas' discussion, the details of the calculations whose results are shown in Fig. 30 were not considered of sufficient importance to be included. The deformations from contact pressure were calculated from a formula given in A. E. H. Love's "Mathematical Theory of Elasticity," p. 192.

The appropriateness of a discussion of transverse fissures in this paper is apparently a matter of opinion. The authors felt that even though they had not done any original work themselves, it was a subject of such great importance that it could not be completely ignored, and therefore mentioned such work of other investigators which seemed to offer most hope of an ultimate solution. They will look forward with great interest to the completion of Professor Moore's work and its final answer to the question of whether or not fissures can be produced by wheel loads in sound rails. The evidence now available may not be conclusive, but it certainly indicates very strongly that the initial condition of the rail and not the loads imposed on it in service is the factor which determines whether or not it will develop fissures.[64]

In Fig. 38, the expression "Limit of Safety" should not be construed as meaning a safe working stress for design purposes. The well-known "factor of ignorance" should be applied.

[64] In addition to the work referred to in the paper, see also "Effect of Controlled Cooling and Temperature Equalization on Internal Fissures in Rails," by C. P., O. F. A., and N. P. P. Sandberg, *Metals and Alloys*, vol. 3, no. 4, April, 1932.

The authors were very much interested in the strain gage mentioned by Dr. Matsunawa, and hope to be able to obtain a more detailed description of it. The mechanical construction must be quite ingenious to translate such small motions into electrical variations by the simple means of a slide-wire resistance.

Mr. Dendy Marshall mentions two causes of longitudinal weight transfer in addition to the pull of the drawbar. One is frontal air resistance, which was not considered in the paper, but which is negligible at moderate speed. The other he calls "slide-bar pressure," which is the same as the authors referred to as non-uniformity in vertical load due to angularity of the connecting rod. (See section on Vertical Loads, under III—Field Tests.)

Mr. Bronson mentions that the high stresses in the fillet joining the head to the web have been overcome by widening the fillet and canting the rail. This is quite in line with the authors' ideas on correct rail design, although they feel that the canting of the rail, while desirable, should not be relied on entirely to reduce the eccentricity of the vertical load. The fillet should be adequate to withstand the eccentric load in case it does occur.

The determination of the modulus of foundation, k, need not be as difficult as Mr. Graham thinks. If this one value is all that is required, it can be found with sufficient accuracy by measuring the deflections under the wheels of a locomotive of known axle loading by means of a surveyor's level.

Mr. Haessler asks how the height of the center of gravity affects the lateral rail forces. This is a subject on which opinions differ and no experimental work has been done, to the author's knowledge. The commonly accepted idea is that a high center of gravity introduces elasticity between the spring mass and the rail, and hence reduces the lateral forces. This is of importance only at the moment of entrance to a curve or else during severe lateral oscillations. If the motion is steady, the height of the center of gravity can have no effect on the lateral rail forces.

Professor Schwerin asks an opinion regarding the formation of grooves (*Riffelbildung*) across the head of the rail. The authors have not done any work on this subject and can offer no new suggestions as to their cause.

Mr. Graham criticizes the theory of torsion of the rail, since it assumes the existence of a couple which opposes the rotation of the rail. This assumption is not, as Mr. Graham supposes, based on the holding-down capacity of the spikes, but merely on the existence of a vertical load. If there is pressure between the base of the rail and a tie plate, then a resisting moment can take the form of a redistribution of this pressure, without any spikes being used at all.

It is not stated in the paper that simultaneous records of vertical and lateral load under all the wheels of a locomotive have already been made. In footnote 10, it is merely stated that this is contemplated.

The authors heartily welcome Mr. Graham's suggestion that the methods outlined here be extended to the use of more gages and a greater variety of operating conditions. A burning problem at the present time is that of oscillations at high speed. Theories and models can be and are being used, but the final proof of any theory will always depend on full-scale tests. The authors believe that such tests can best be made by developments of the method outlined in this paper. The Otheograph of the General Electric Co. is not satisfactory for the following reasons:

1 The recorded values of lateral load are unreliable since the mounting of the rail is such that purely vertical load can produce lateral deflection and hence record as lateral load. It makes no attempt to record lateral forces directed toward the center of the track.

2 The recorded values of vertical load are in error at high speed due to the inertia of the steel ties supporting the spring mechanism.

Resistance of Slender Bodies Moving With Supersonic Velocities, With Special Reference to Projectiles

By THEODOR VON KÁRMÁN[1] and NORTON B. MOORE,[2] PASADENA, CALIF.

T. von Karman

The hydrodynamical equations for the steady flow of a compressible fluid with axial symmetry are applied to the case of a slightly disturbed parallel flow with velocity higher than the velocity of sound. The linear equation obtained in this way is integrated by a numerical method, and the solution applied to an approximate calculation of the pressure distribution at the head of a projectile. The question of the drag of projectiles is discussed and the results of the theoretical calculations compared with the values obtained from ballistic experiments. The numerical calculations have been carried out by the junior author, using the methods suggested by the senior author.

N. B. Moore

The present investigation deals with an approximate calculation of the resistance of bodies of revolution, moving through the air with a velocity superior to the velocity of sound. A number of investigations already exist on two-dimensional flow problems involving supersonic velocities, but there have been very few attempts to find solutions of the hydrodynamical equations in the three-dimensional case. On the other hand, most of the experimental data refer to bodies of revolution, in connection with the problem of the resistance of projectiles. This question has aroused the interest of a great number of scientists and engineers, and military institutions have also carried out quite a large number of experiments on the problem. In the present paper very slender bodies of revolution are considered, so that the results give only a first approximation to the case of actual projectiles. However, the pressure distribution on the front part of the bodies seems to be represented in a fairly correct way, and it is hoped that this first approximation will be useful to obtain further and closer approximations.

1—The Equations for Steady Flow With Axial Symmetry in a Compressible Fluid

The authors establish the fundamental equation under the following assumptions:

(*a*) The viscosity of the fluid can be neglected
(*b*) The pressure is a given function of the density
(*c*) The flow is a vortexless motion.

Assumption (*a*) implies that the frictional resistance of the body be neglected; this is of course not quite justified from the practical point of view. However, it seems that the frictional resistance and the "wave resistance" due to the effect of compressibility can be considered separately; in other words, it can be assumed that the shape of the compressibility waves and their contribution to the resistance is not altered very much by viscosity. Assumption (*b*) enables us to consider two limiting cases: the adiabatic and the isothermic compression or dilatation of the fluid elements. The first case corresponds to no heat conduction at all; the second postulates that the heat conduction is so perfect that there is no temperature change whatever in the part of the fluid involved in the flow around the body. The first case is nearer to reality, so the adiabatic hypothesis will be used, putting $p/\rho^k = p_0/\rho_0^k$, where p denotes pressure at an arbitrary point, and p_0 the value corresponding to the undisturbed part of the fluid, the respective densities being ρ and ρ_0; k is the ratio of specific heats and for air has the value $k = 1.41$ approximately.

According to the Helmholtz laws of vortex motion, no vorticity can be created in a perfect fluid if the external forces are conservative and the pressure is a function of the density only. Therefore assumption (*c*) is justified by the two previous assumptions, (*a*) and (*b*).

Introducing cylindrical coordinates x, r, and denoting the velocity components in the x and r directions by v_x, v_r, these velocity components can be expressed by the potential $\Phi\ (x, r)$, putting

$$v_x = \frac{\partial\Phi}{\partial x},\ v_r = \frac{\partial\Phi}{\partial r} \qquad [1]$$

in which case the dynamical equations are identically satisfied if we write

Presented at the National Applied Mechanics Meeting, New Haven, Conn., June 22–25, 1932, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

$$\frac{1}{2}(v_x^2 + v_r^2) - \frac{1}{2}V^2 = \int_p^{p_0} \frac{dp}{\rho} \ldots\ldots\ldots\ldots [2]$$

and assume that $v_x = V$ and $v_r = 0$ for $x = -\infty$.

The only differential equation to be satisfied is the "continuity equation," written in the vectorial form as

$$\mathrm{div}\,(\rho v) = 0 \ldots\ldots\ldots\ldots\ldots\ldots [3]$$

or in cylindrical coordinates, assuming axial symmetry, as

$$\frac{\partial}{\partial r}(r\rho v_r) + \frac{\partial}{\partial x}(r\rho v_x) = 0 \ldots\ldots\ldots\ldots [3a]$$

Introducing the potential Φ in Equation [3a],

$$\frac{\partial^2\Phi}{\partial r^2} + \frac{1}{r}\frac{\partial\Phi}{\partial r} + \frac{\partial^2\Phi}{\partial x^2} + \frac{1}{\rho}\left(\frac{\partial\Phi}{\partial r}\frac{\partial\rho}{\partial r} + \frac{\partial\Phi}{\partial x}\frac{\partial\rho}{\partial x}\right) = 0 \ldots [4]$$

We now calculate $\frac{\partial\rho}{\partial r}$ and $\frac{\partial\rho}{\partial x}$, using Equation [2]. First we write $\int \frac{dp}{\rho} = \int \frac{dp}{d\rho}\frac{d\rho}{\rho}$, where $\frac{dp}{d\rho}$ is a given function of the density. The physical significance of $dp/d\rho$ is well known: it is equal to the square of the "local" velocity of sound c, corresponding to the given density ρ. Differentiating [2],

$$\left.\begin{aligned} \frac{c^2}{\rho}\frac{\partial\rho}{\partial r} &= -\left(v_r\frac{\partial v_r}{\partial_r} + v_x\frac{\partial v_x}{\partial_r}\right) \\ \frac{c^2}{\rho}\frac{\partial\rho}{\partial x} &= -\left(v_x\frac{\partial v_x}{\partial x} + v_r\frac{\partial v_r}{\partial x}\right) \end{aligned}\right\} \ldots\ldots\ldots\ldots [5]$$

Introducing these values into Equation [4],

$$\left(1 - \frac{v_r^2}{c^2}\right)\frac{\partial^2\Phi}{\partial r^2} + \frac{1}{r}\frac{\partial\Phi}{\partial r} - \frac{2v_rv_x}{c^2}\frac{\partial^2\Phi}{\partial r\partial x} + \left(1 - \frac{v_x^2}{c^2}\right)\frac{\partial^2\Phi}{\partial x^2} = 0 \ldots\ldots [6]$$

Assuming $p = \frac{p_0}{\rho_0^k}\rho^k$, then $\frac{dp}{d\rho} = k\frac{p_0}{\rho_0^k}\rho^{k-1} = k\frac{p_0}{\rho_0}\left(\frac{\rho}{\rho_0}\right)^{k-1}$

On the other hand, $\int_p^{p_0}\frac{dp}{\rho} = k\frac{p_0}{\rho_0^k}\int_\rho^{\rho_0}\rho^{k-2}\,d\rho = \frac{k}{k-1}\frac{p_0}{\rho_0^k}(\rho_0^{k-1} - \rho^{k-1})$.

Introducing this expression in [2],

$$\frac{1}{2}(v_x^2 + v_r^2 - V^2) = \frac{k}{k-1}\frac{p_0}{\rho_0^k}(\rho_0^{k-1} - \rho^{k-1}) \ldots\ldots [7]$$

or

$$\frac{1}{2}(v_x^2 + v_r^2 - V^2) = \frac{1}{k-1}\left(k\frac{p_0}{\rho_0} - c^2\right) \ldots\ldots\ldots [8]$$

and finally

$$c^2 = k\frac{p_0}{\rho_0} + \frac{k-1}{2}(V^2 - v_x^2 - v_r^2) \ldots\ldots\ldots [8a]$$

If this expression for c be introduced into the differential Equation [6], the latter will contain only the one unknown variable Φ and its derivatives. Hence the problem is reduced to one of finding solutions of [6] which will satisfy certain boundary conditions at the surface of the body.

2—Assumption of Small Perturbations

In order to obtain a first approximation for the solution of Equation [6] it is assumed that v_x differs slightly from V and that v_r is small compared with V. This will be approximately the case if the body is a slender one, i.e., if the inclination of the tangents to the meridian curve with respect to the x-axis is small at every point. According to this assumption we put

$$\left.\begin{aligned} v_x &= V + u = V + \frac{\partial\varphi}{\partial x} \\ v_r &= v = \frac{\partial\varphi}{\partial r} \end{aligned}\right\} \ldots\ldots\ldots\ldots [9]$$

and consider u and v small compared with V. Introducing the expressions [9] into Equation [6] and retaining only the first-order terms in φ, u, v, and their derivatives,

$$\frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} + \left(1 - \frac{V^2}{c^2}\right)\frac{\partial^2\varphi}{\partial x^2} = 0 \ldots\ldots\ldots [10]$$

As for the velocity of sound, it will be seen that according to [8a], c can be considered as a constant with the same degree of approximation, since c is approximately equal to $k(p_0/\rho_0)$.

Equation [10] is a linear equation much employed in the theory of sound waves. In fact, if the time t be introduced, putting $t = x/V$,

$$\frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} = \left(\frac{1}{c^2} - \frac{1}{V^2}\right)\frac{\partial^2\varphi}{\partial t^2} \ldots\ldots\ldots\ldots [11]$$

or

$$\frac{\partial^2\varphi}{\partial r^2} + \frac{1}{r}\frac{\partial\varphi}{\partial r} = \frac{1}{c'^2}\frac{\partial^2\varphi}{\partial t^2} \ldots\ldots\ldots\ldots\ldots [12]$$

where $\frac{1}{c'^2} = \frac{1}{c^2} - \frac{1}{V^2}$.

In case $V > c$, Equation [12] is identical with the equation for a two-dimensional wave motion, with a "source" at the origin $r = 0$; hence for velocities higher than the velocity of sound the steady flow around a body of revolution can be interpreted as a two-dimensional circular wave motion, with a variable source at the origin. Using this analogy it is necessary to assume that the intensity of the source is a function of the time t, depending on the shape of the body. The problem of computing the stationary motion around a body of given shape can be reduced to that of computing the "source distribution" as a function of the time or of the coordinate x.

3—The Solution of the Approximate Differential Equation

The general solution of Equation [10] for the case $V > c$ is given by the following definite integral:[3]

$$\varphi(x, r) = \int_\infty^0 f(x - \alpha r\cosh z)\,dz \ldots\ldots\ldots [13]$$

where $f(\xi)$ is an arbitrary function of $\xi = x - \alpha r \cosh z$ and $\alpha = \sqrt{[(V/c)^2 - 1]}$. It can be shown that [13] is a solution of Equation [10] by differentiation; however, it is preferable to show this by interpretation of the solution. First it is noticed that the value of φ at a given point x, r, depends only on the values of $f(\xi)$ between $\xi = -\infty$ and $\xi = x - \alpha r$. If ξ be measured along the x-axis, the point $\xi = x - \alpha r$ is found by drawing a straight line through the point x, r, with the inclination $\beta = \tan^{-1}(1/\alpha)$, the intersection of this straight line with the x-axis giving the point $x - \alpha r$. β is called Mach's angle, and the cone with the point $\xi = x - \alpha r$ as origin and with the vertex angle 2β, Mach's cone. Obviously, the flow outside of Mach's cone depends only on the values of $f(\xi)$ corresponding to $\xi < x - \alpha r$; in other words, the influence of the values of $f(\xi)$ for $\xi > x - \alpha r$ is restricted to the interior of Mach's cone.

---

[3] Cf. H. Lamb, "Hydrodynamics," Cambridge, 1930, p. 278 and p. 498.

Assume now that $f(\xi) = 0$ for $\xi \leqq 0$ and that $f'(0)$ is finite. In this case the integral occurring in Equation [13] can be written as

$$\varphi(x, r) = \int_{\cosh^{-1}\frac{x}{\alpha r}}^{0} f(x - \alpha r \cosh z)\, dz \ldots\ldots [13a]$$

or introducing $\xi = x - \alpha r$ as the variable and substituting $z = \cosh^{-1}\dfrac{x - \xi}{\alpha r}$,

$$dz = \frac{-d\xi}{\sqrt{\left(\frac{x - \xi}{\alpha r}\right)^2 - 1}}\,\frac{1}{\alpha r} = -\frac{d\xi}{\sqrt{(x - \xi)^2 - \alpha^2 r^2}}$$

we obtain

$$\varphi(x, r) = -\int_{0}^{x - \alpha r} f(\xi)\,\frac{d\xi}{\sqrt{(x - \xi)^2 - \alpha^2 r^2}} \ldots [14]$$

The solution [14] corresponds formally to the solution of the potential equation, assuming sources distributed along the x-axis. In fact, putting $\alpha r \sqrt{-1} = q$; then Equation [10] can be written formally as

$$\frac{\partial^2 \varphi}{\partial q^2} + \frac{1}{q}\frac{\partial \varphi}{\partial q} + \frac{\partial^2 \varphi}{\partial x^2} = 0 \ldots\ldots\ldots\ldots [15]$$

which is exactly the potential equation. Furthermore, assume that the sources of the intensity $f(\xi)/4\pi$ are distributed along the x-axis between the points $\xi = 0$ and $\xi = x - \alpha r$. The solution of Equation [15] corresponding to this source distribution is given by

$$\varphi(x, q) = \frac{1}{4\pi}\int_{0}^{x - \alpha r} f(\xi)\,\frac{d\xi}{\sqrt{(x - \xi)^2 + q^2}} \ldots\ldots [16]$$

It follows that the corresponding expression [14] satisfies the original Equation [10].

Corresponding to this analogy $f(\xi)$ is also called the intensity of the source distribution in the present case and the calculation of an example is then undertaken, employing the simplest assumption for $f(\xi)$.

4—THE FLOW ALONG THE SURFACE OF A CONE

Assume that $f'(\xi) = a$, where a is a constant which has the dimension of a velocity. In this case, the integration involved in Equation [13a] is easily carried out, giving

$$\varphi = a\int_{\cosh^{-1}\frac{x}{\alpha r}}^{0} (x - \alpha r \cosh z)\,dz \ldots\ldots\ldots\ldots [17]$$

or

$$\varphi = -ax \cosh^{-1}\frac{x}{\alpha r} + a\sqrt{x^2 - \alpha^2 r^2} \ldots\ldots [17a]$$

The velocity components are

$$\left.\begin{aligned} u &= \frac{\partial \varphi}{\partial x} = -a \cosh^{-1}\frac{x}{\alpha r} \\ v &= \frac{\partial \varphi}{\partial r} = a\alpha\sqrt{\left(\frac{x}{\alpha r}\right)^2 - 1} \end{aligned}\right\}\ldots\ldots\ldots\ldots [18]$$

It is seen that the velocity components are functions of x/r only, so that the velocity is constant along straight lines passing through the origin. Obviously, Equation [18] can be used to describe the flow along the surface of a cone with small vertex angle.

Superposing the velocity components given by [18] on the parallel flow with the velocity V, we obtain

$$\left.\begin{aligned} v_x &= V - a \cosh^{-1}\frac{x}{\alpha r} \\ v_r &= a\alpha\sqrt{\left(\frac{x}{\alpha r}\right)^2 - 1} \end{aligned}\right\}\ldots\ldots\ldots\ldots\ldots [19]$$

In order to obtain the flow along the surface of the cone with the vertex angle 2γ, we write $x/r = \cot\gamma$ and put

$$\tan\gamma = \frac{v_r}{v_x} = \frac{a\alpha\sqrt{\left(\frac{x}{\alpha r}\right)^2 - 1}}{V - a\cosh^{-1}\frac{x}{\alpha r}} = \frac{a\sqrt{\cot^2\gamma - \alpha^2}}{V - a\cosh^{-1}\frac{\cot\gamma}{\alpha}} \ldots [20]$$

or with $\alpha = \cot\beta$ (β = Mach's angle), assuming $\gamma < \beta$,

$$a = \frac{V\tan\gamma}{\sqrt{\cot^2\gamma - \cot^2\beta + \tan\gamma\cosh^{-1}\frac{\cot\gamma}{\cot\beta}}} \ldots\ldots [21]$$

It is interesting to calculate the pressure acting on the surface of the cone. According to Equation [2],

$$\int_{p_0}^{p}\frac{dp}{\rho} = \frac{1}{2}\left[V^2 - (V + u)^2 - v^2\right] = -Vu - \frac{u^2 + v^2}{2} \ldots [22]$$

On the other hand, according to our assumption of an adiabatic process

$$\int_{p_0}^{p}\frac{dp}{\rho} = \frac{k}{k - 1}\,\frac{p_0}{\rho_0}\left[\left(\frac{p}{p_0}\right)^{\frac{k - 1}{k}} - 1\right] \ldots\ldots\ldots [23]$$

Introducing this expression in [22],

$$\frac{p}{p_0} = \left[1 + \frac{k - 1}{k}\,\frac{\rho_0}{p_0}\left(-Vu - \frac{u^2 + v^2}{2}\right)\right]^{\frac{k}{k - 1}} \ldots [24]$$

Developing the right-hand member of the equation,

$$p - p_0 = \rho_0\left(-Vu + \frac{u^2 + v^2}{2}\right)\left[1 + \frac{\rho_0}{2kp_0}\left(-Vu - \frac{u^2 + v^2}{2}\right)\right] \ldots\ldots\ldots [25]$$

and putting $c^2 = kp_0/\rho_0$

$$p - p_0 = \rho_0\left(-Vu - \frac{u^2 + v^2}{2}\right)\left(1 - \frac{Vu + \frac{u^2 + v^2}{2}}{2c^2}\right) \ldots [26]$$

or

$$\frac{p - p_0}{\frac{\rho_0 V^2}{2}} = -\left(\frac{2u}{V} + \frac{u^2 + v^2}{V^2}\right)\left(1 - \frac{2Vu + u^2 + v^2}{4c^2}\right). [27]$$

Fig. 1 represents $(p - p_0)/(\rho_0/2)V^2$ as a function of the ratio V/c for different values of the vertex angle. It is to be remarked that the approximation does not hold for small values of α

(V/c near to 1) and for values of α near to or greater than cot γ. An exact solution for the flow along a cone can be obtained by integrating the ordinary differential equation which results from the partial differential Equation [6], if it be assumed that all the velocity components are constant along straight lines through the origin of the cone. This differential equation has been discussed by Busemann[4] and more recently by G. I. Taylor,[5] but no numerical solutions are available at the present time which can be compared with the approximate solution given in this section. It would be of great value to compare the two solutions, and especially to investigate whether the exact solution involves a discontinuous change in the velocity and pressure (shock wave) even for small angles γ, as Busemann assumes, or whether this phenomenon appears only in the case of cones with larger vertex angles.

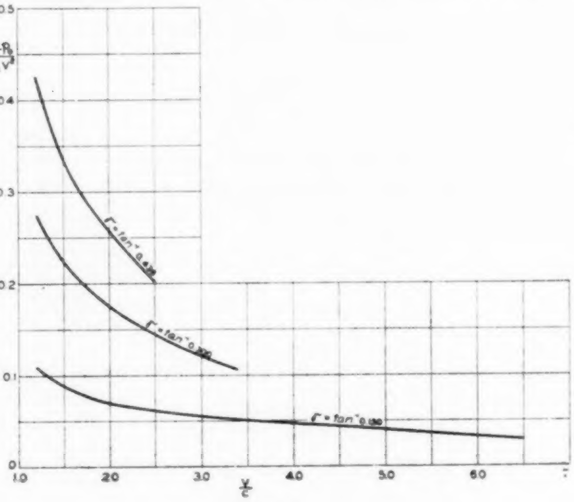

FIG. 1

It is interesting to compare our three-dimensional case with the two-dimensional flow along the two sides of an edge. Assuming small perturbations in the latter case, we have to integrate the equation

$$\frac{\partial^2\varphi}{\partial y^2} = \alpha^2 \frac{\partial^2\varphi}{\partial x^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots [28]$$

The solution for the edge is very simple. We obtain $\varphi = 0$ for $x < \alpha y$ and $\varphi = -a(x - \alpha y)$ for $x > \alpha y$, where a is a constant as above. Hence the additional velocities are

$$u = \frac{\partial\varphi}{\partial x} = -a, \quad v = \frac{\partial\varphi}{\partial y} = a\alpha$$

and the boundary condition gives

$$\tan\gamma = \frac{a\alpha}{V - a}$$

or

$$a = V\frac{\tan\gamma}{\alpha + \tan\gamma} \quad\ldots\ldots\ldots\ldots\ldots\ldots [29]$$

It will be noticed that a discontinuity in the velocities along the line $x = \alpha y$ is always obtained, even for small values of γ.

In the three-dimensional case the discontinuity as far as the approximate equation is concerned is restricted to the point of origin.

Let us consider the velocity distribution along a cylindrical surface r = const. and put $x = \alpha r + x'$. Then, from Equation [18], it is easily seen that

$$\left.\begin{aligned} u &= -a\cosh^{-1}\left(1 + \frac{x'}{\alpha r}\right) = -a\sqrt{\frac{2x'}{\alpha r}}\,(1 + \ldots) \\ v &= a\alpha\sqrt{\left(1 + \frac{x'}{\alpha r}\right)^2 - 1} = a\sqrt{\frac{2\alpha x'}{r} + \frac{x'^2}{r^2}} \end{aligned}\right\} \quad\ldots\ldots [30]$$

It is seen that u and v do not show any discontinuity at the conical surface $x = \alpha r$; however, the derivatives of u and v are infinite at points of this surface. Fig. 2 shows the pressure distribution along the cylindrical surface.

5—THE FLOW ALONG A "SEMI-FINITE BODY" (PROJECTILE)

Proceeding now to the computation of the source distribution for a body of revolution with a sharp point at the origin and cylindrical shape at infinity, we assume that the radius r is a monotonic function of x.

Referring to Fig. 3, the source-distribution curve $f(\xi)$ is approximated by a curve composed of straight segments, so that $f'(\xi)$ is replaced by the "step-shape" function shown.

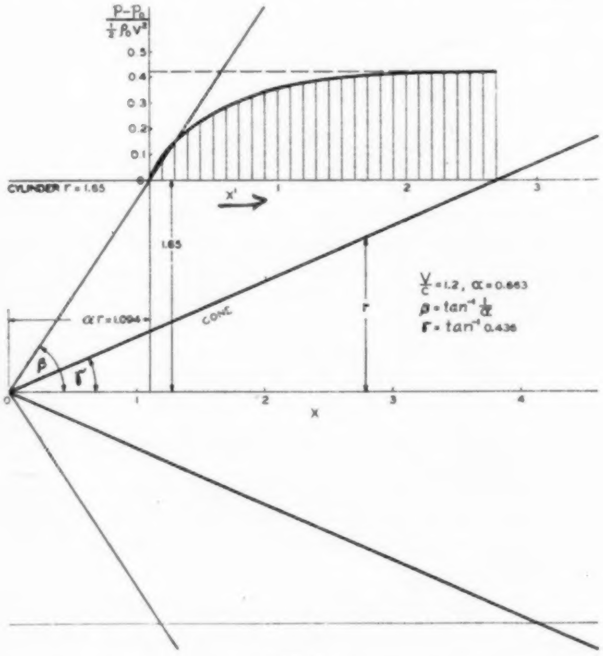

FIG. 2

The expressions for the additional velocities are

$$u = \int_{\cosh^{-1}\frac{x}{\alpha r}}^{0} f'(x - \alpha r\cosh z)\,dz,$$

$$v = -\int_{\cosh^{-1}\frac{x}{\alpha r}}^{0} f'(x - \alpha r\cosh z)\,\alpha\cosh z\,dz \ldots [31]$$

Consider now the points $P_1, P_2, \ldots\ldots P_n$ of the meridian line of the body in question; their coordinates may be designated by $x_1, r_1;\ x_2, r_2, \ldots x_n, r_n$ and the corresponding values of ξ by $\xi_1, \xi_2, \ldots \xi_n$. Denote the constant value of the derivative $f'(\xi)$ between ξ_{i-1} and ξ_i by A_i. Obviously then we can carry out the integrations in [31] and obtain for the velocity components at the point P_n

---

[5] Private communication from Mr. Taylor.

$$\left.\begin{aligned} u(x_n, r_n) &= -\sum_{i=1}^{n} A_i \left(\cosh^{-1} \frac{x_n - \xi_i}{\alpha r_n} - \cosh^{-1} \frac{x_n - \xi_{i-1}}{\alpha r_n} \right) \\ v(x_n, r_n) &= \sum_{i=1}^{n} \frac{A_i}{r_n} \left(\sqrt{(x_n - \xi_i)^2 - \alpha^2 r_n^2} \right. \\ &\qquad \left. - \sqrt{(x_n - \xi_{i-1})^2 - \alpha^2 r_n^2} \right) \end{aligned} \right\} \quad \ldots\ldots\ldots [32]$$

The boundary condition for the meridian line can be written

$$\frac{dr}{dx} = \frac{v_r}{v_x} = \frac{v}{V + u} \quad \ldots\ldots\ldots\ldots\ldots\ldots [33]$$

Introducing the expressions [32] in [33] and applying the equation consecutively to the points $P_1, P_2, \ldots$ we obtain linear equations for the constants $A_1, A_2, \ldots$. These equations can be solved consecutively because every one of them introduces a new variable which does not occur in the previous equations.

The source distribution has been calculated for a semi-infinite body with a so-called "ogival" head, i.e., composed of a cylinder and of a head generated by the revolution of a circular arc. The radius of the circular arc is called the "ogival radius," and is usually expressed in "calibers," i.e., as a multiple of the radius of the cylindrical part. In the present example the body has a "six-caliber ogival head." This ratio is chosen because pressure-distribution measurements for a shell of such a ratio are available.

Fig. 3 shows the source distribution for the ratio $V/c = 1.2$.

It will be noticed that the boundary condition [33] could be replaced by $dr/dx = v/V$, because u is considered small in comparison with V. In this case the pressures obtained for the head of the projectile will be somewhat higher, so that our assumption gives a lower limit for the resistance. A closer approximation requires a more exact solution of the non-linear differential equation.

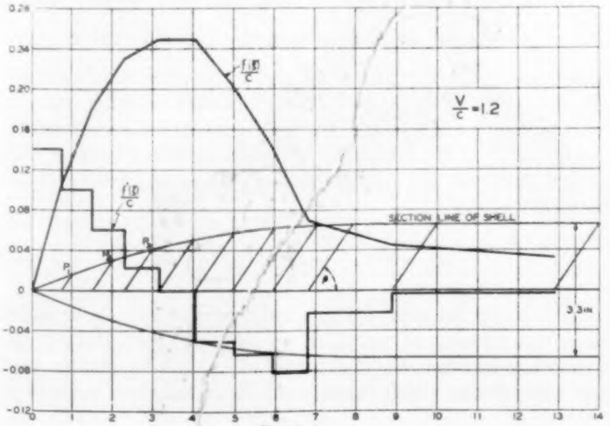

Fig. 3

6—The Expression for the Wave Resistance

If a body moves in a perfect fluid with a velocity less than that of sound, there is no drag so long as the flow follows the surface of the body (i.e., no "wake" is produced). This theorem holds even for a body extended to infinity. The pressure distribution gives no resultant force. Considering the pressure distributions represented in Fig. 4, it is seen that a finite drag results from an integration of the pressures over the surface. We can also deduce this resistance directly by applying the momentum theorem to the system.

A flow of a perfect fluid with velocities below the velocity of sound does not give rise to any resistance for an immersed body, because the velocities induced by the body vanish at infinite distances as $1/R^2$ (R being the distance from the center of the body). This can be shown by applying the momentum law to the portion of the fluid included in a cylinder with the radius R. It is obvious that no finite amount of momentum can be transported through the surface of this cylinder, because the surface increases proportionally with the radius R and the highest term in the expression of transported momentum per unit area is of the order $1/R^2$.

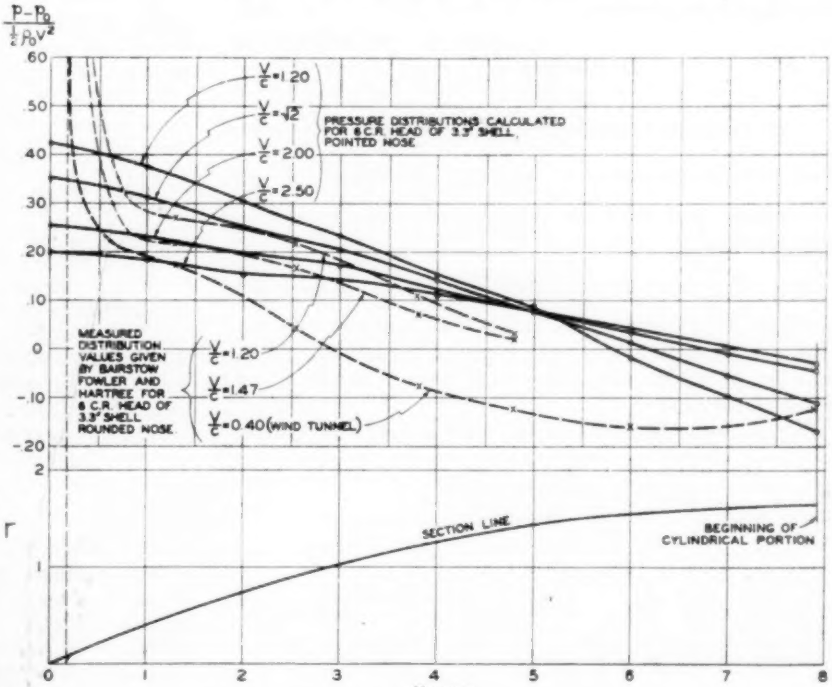

Fig. 4

Considering now the case of flow with velocities higher than the velocity of sound, we find that proceeding to infinity along Mach's lines, the additional velocities vanish as $1/\sqrt{(R)}$, so that the integral which represents the total momentum transported through a cylindrical surface approaches a finite limit different from zero, if the radius of the cylinder increases indefinitely. The drag corresponding to this momentum is called the "wave resistance" of the body in question.

The momentum integral is given by

$$M = \int_{-\infty}^{\infty} 2\pi r \rho v_r v_x dx \ldots\ldots\ldots\ldots\ldots [34]$$

or, introducing $v_x = V + u$, $v_r = v$,

$$M = V\int_{-\infty}^{\infty} 2\pi r\rho v dx + \int_{-\infty}^{\infty} 2\pi r\rho uv dx \quad \ldots\ldots [35]$$

The first term can be written as $V\cdot m$, where m is the mass of fluid passing through the surface of a cylinder with the radius r.

Let us assume that the cylinder includes the body. Obviously the drag on the body is given by the difference between the momentum M and the momentum ρAV^2, where A is the cross-section of the body at infinity. The second term corresponds to the momentum passing through A in unit time and is equal to the term $V\cdot m$ occurring in Equation [35]. Therefore the drag is given by the expression

$$D = -2\pi r\int_{-\infty}^{\infty} \rho uv dx \quad \ldots\ldots\ldots\ldots [36]$$

or, with sufficient accuracy,

$$D = -2\pi r\rho_0\int_{-\infty}^{\infty} uv dx$$

If the body has a finite length (as, for instance, a streamlined body with a sharp point at the rear), the integral $\int \rho v dx$ vanishes, so that we obtain the same expression for the drag as before.

It is easily shown that the expression $2\pi r\int_{-\infty}^{\infty} \rho uv dx$ is independent of r, so that we can consider a cylinder of very small radius close to the x-axis, which carries the sources. In this case we can use the first terms in the development for u and v for small values of r.

We can write the velocity components in the following form:

$$u = -\int_0^{x-\alpha r} f'(\xi)\frac{d\xi}{\sqrt{(x-\xi)^2-\alpha^2 r^2}},$$

$$v = \int_0^{x-\alpha r} f'(\xi)\frac{d\xi\,\frac{x-\xi}{r}}{\sqrt{(x-\xi)^2-\alpha^2 r^2}} \quad \ldots\ldots [37]$$

Proceeding to the limit $r \rightarrow 0$,

$$\left.\begin{aligned} u &\cong -f'(x)\log\frac{x}{\alpha r} + \int_0^x \frac{f'(\xi)-f'(x)}{\xi - x}d\xi \\ v &\cong \int_0^x \frac{f'(\xi)d\xi}{r} = \frac{f(x)}{r} \end{aligned}\right\} \quad \ldots\ldots [38]$$

Hence the drag is equal to

$$D = 2\pi\rho_0\int_0^{\infty} f(x)f'(x)\log\frac{x}{\alpha r}dx - 2\pi\rho_0\int_0^{\infty} f(x)\int_0^x\frac{f'(\xi)-f'(x)}{\xi - x}d\xi dx \quad \ldots\ldots [39]$$

Taking into consideration the fact that $f(x) = 0$ for $x = -\infty$ and $x = \infty$, it is seen immediately that the integral $\int_0^{\infty} f(x)f'(x)dx = 0$, so that we can cancel the term $-\int_0^{\infty} f(x)f'(x)\log(\alpha r)dx$ and obtain

$$D = 2\pi\rho\int_0^{\infty} f(x)f'(x)\log x dx + 2\pi\int_0^{\infty} f(x)\int_0^x \frac{f'(\xi)-f(x)}{\xi - x}d\xi dx \quad \ldots\ldots [40]$$

or by partial integration,

$$D = -2\pi\int_0^{\infty}\frac{[f(x)]^2}{x}dx + 2\pi\int_0^{\infty} f(x)\int_0^x\frac{f'(\xi)-f(x)}{\xi - x}d\xi dx$$

The integral is to be extended over the x-axis, i.e., along the range, in which $f(x)$ and $f'(x)$ differ from zero.

7—THE RESISTANCE OF PROJECTILES

The three components of the resistance of projectiles are:

(*a*) *The head resistance*, i.e., the resultant of the pressure acting on the head of the projectile

(*b*) *The skin friction*, i.e., the resultant of the tangential forces acting along the surface of the body, and

(*c*) *The wake resistance*, which is the contribution of the underpressure (vacuum) at the base.

Let us first try to estimate the contributions (*b*) and (*c*). The skin friction is in the first approximation proportional to the density of the air and to the square of the velocity. Put $D_f = C_f\frac{\rho V^2}{2}S$, where S is the surface area of the projectile. The coefficient C_f is in fact a function of the ratio Vd/ν, called the Reynolds number (d = diameter of the body, ν = kinematic viscosity), and probably of the ratio V/c. For such high values of the Reynolds number as those which correspond to the velocities and sizes of projectiles, the value of C_f can be estimated to be between 0.002 and 0.003. The influence of the ratio V/c is not known, but probably it is not very large. The drag is usually referred to the frontal area A of the projectile. For long projectiles we can assume S/A = 16 to 18, whence, approximately,

$$D_f = (0.03 - 0.05)\frac{\rho V^2}{2}A \quad \ldots\ldots\ldots\ldots [41]$$

a mean value of C_{Df} = 0.04 will be used.

It is somewhat difficult to obtain a fair estimate for the contribution of the underpressure at the base. Fortunately there are some wind-tunnel measurements at low velocities on the resistance of shell models (point A, Fig. 5), and also on the pressure distribution at the head. For a comparatively long shell we can assume that the drag coefficient at low speeds varies between the values 0.2 and 0.24.[6] The resultant of the head pressures has a small negative value, about $-(0.01 \sim 0.015)\frac{\rho V^2}{2}A$. Obviously we shall obtain the probable value of the underpressure at the base if we add to the drag coefficient the absolute value of the negative mean pressure resulting from the head pressures and subtract the coefficient which corresponds to the resultant of the frictions. We shall assume, therefore, that at low velocities the contribution of the underpressure at the base amounts to

$$D_B = C_{DB}\frac{\rho V^2}{2}A \cong 0.2\frac{\rho V^2}{2}A \quad \ldots\ldots\ldots\ldots [42]$$

Considering the case of high velocities, especially those higher than the velocity of sound, it is probable that $D_B/(\rho V^2/A)$ diminishes because the underpressure cannot be greater than one atmosphere, which corresponds to an absolute vacuum at the base Denoting the absolute value of the pressure at the base by p, for low velocities we write

---

[6] Cf. Fowler, Gallop, Lock, and Richmond, *Phil. Trans.*, A591, 1920.

$$p_0 - p \cong \lambda \frac{\rho V^2}{2} \qquad [43]$$

where $\lambda = 0.2$. For very high velocities $p_0 - p$ will be constant and equal to one atmosphere. To establish a transition between these limiting cases it appears plausible to write

$$\int_p^{p_0} \frac{dp}{\rho} = \lambda \frac{\rho V^2}{2} \qquad [44]$$

using the same value of λ as at low velocities. For adiabatic dilatation, we obtain

$$\int_p^{p_0} \frac{dp}{\rho} = \frac{k}{k-1} \frac{p_0}{\rho_0}\left[1 - \left(\frac{p}{p_0}\right)^{\frac{k-1}{k}}\right] \qquad [45]$$

Or, putting $k(p_0/\rho_0) = c^2$,

$$\frac{p}{p_0} = \left[1 - \frac{(k-1)\lambda}{2} \frac{V^2}{c^2}\right]^{\frac{k-1}{k}} \qquad [46]$$

For $V^2 = \frac{2}{(k-1)\lambda} c^2$, $p = 0$; so that the absolute vacuum would be reached at a velocity which is more than four times as great as the velocity of sound.[7] For $V/c < 2.5$ we can use the approximative formula

$$p_0 - p = \lambda \frac{\rho V^2}{2}\left(1 - \frac{V^2}{4c^2}\lambda\right) \qquad [47]$$

Using this formula, the contribution of the underpressure at the base to the total drag will be:

$$D_B = C_{DB} \frac{\rho V^2}{2} A$$
$$= 0.2\left(1 - 0.2 \frac{V^2}{4c^2}\right) \frac{\rho V^2}{2} A \qquad [48]$$

In order to compute the contribution of the head pressures at velocities higher than the velocity of sound, we have to compute the pressure distribution. We assume that for this purpose we can use the pressures corresponding to the flow along the semi-infinite body, which has been considered in section 5. The calculated pressure distribution, using Equation [27], is shown in Fig. 4. With the object of measuring the dynamic pressures acting on the head of an actual shell, very interesting experiments have been carried out in England by Bairstow, Fowler, and Hartree.[8] The method used by these investigators is rather ingenious. They fire shells of the same type under identical conditions, i.e., with same initial velocity and the same elevation, but with holes at different points of the head. Because the time necessary to burn off a fuse with a certain setting depends on the pressure, the shells with different holes will burst at different points of the same trajectory. The relation between the rate of burning and the pressure has been established by laboratory experiments made on shells exposed to different pressures and spinning around a fixed axis, and, assuming this relation is not altered by the translatory movement, the pressure at the different holes can be calculated from observations on the time of burning, or on the distance at which the shells burst. The experimental curve for the pressures obtained in this way (for $V/c = 1.2$ and 1.41) is also shown in Fig. 4. It is to be noticed that the character of the curve is similar, but the experimental values are smaller than the calculated values. However, it seems that the measurements are not extremely reliable; the Messrs. Bairstow, Fowler, and Hartree mention two sources of error which may have considerable influence. First, the zero point of the time of burning was guessed at, and second, the holes on the shells were comparatively large. It is believed that the effective pressures must be superior to the measured values; it will be shown that even the computed higher pressures lead to too small values for the total drag. In addition, the pressure measurements in flight, which have been extended to velocities as low as $0.7c$, can be compared with the pressure distribution obtained by wind-tunnel measurements at a velocity $V = 0.4c$, and given in the same paper. Theoretical and experimental investigations show that the negative values of $(p - p_0)/(\rho V^2/2)$ obtained at $V = 0.7c$ ought to be smaller than the respective values at $V = 0.4c$; however, the measurements in flight give considerably lower values for the higher velocities. It seems, the zero point of the pressure measurements is not exact enough. Of course, the experimental task faced by the British investigators was a very difficult one, but the credit of having done a beautiful piece of experimental research must nevertheless be given, even though the results show a considerable degree of uncertainty.

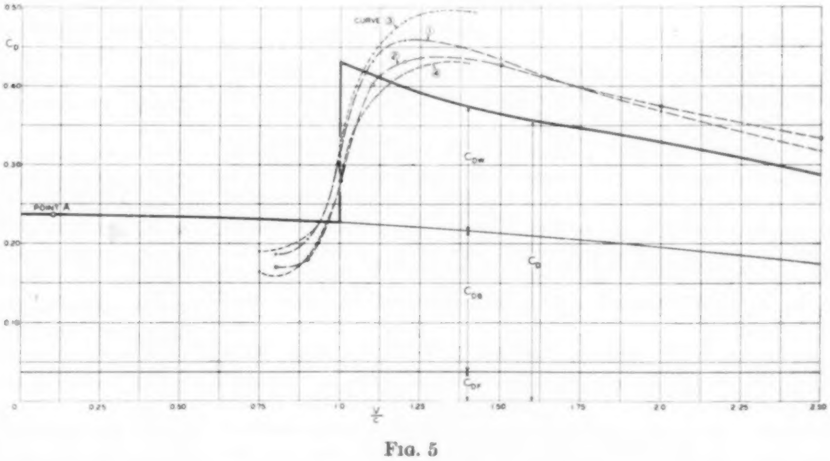

Fig. 5

The pressure of the nose has not been determined by measurement. The British investigators mentioned used Rayleigh's formula for adiabatic compression, assuming a "stagnation point" at the nose. It is believed that this is correct for a shell with a rounded nose; in the case of a shell with sharp point, however, the pressure at the nose is much lower and depends on the vertex angle of the cone.

Fig. 5 shows the total drag as function of the ratio V/c computed as the sum of the friction, the underpressure at the base, and the head resistance resulting from the pressures calculated according to the theory developed in this paper. Unfortunately, no exact data are available for the drag curve of a shell with the shape used in the calculation and in the British experiments. For an approximate comparison, the drag curve for the so-called S-projectile used in the German army is shown in the diagram. This projectile has an "ogival radius" equal to seven calibers; the ogival radius of the shell considered by the authors is equal to six calibers. Curve (1) is deduced from experiments on shells with an ogival radius equal to three calibers.[9] According to an empirical rule given by Heydenreich, a shell with a "six-caliber" ogival radius has about 20 per cent less drag than one with a "three-caliber" ogival radius. Curve (2) shows the values reduced in this way. They are in fairly good accordance with the values obtained for the S-projectile. Finally, Messrs. Bairstow, Fowler, and Hartree give the curves (3) and (4) and state that the total drag of the shell used in their tests lies between the values represented by those two curves.

---

[7] See Appendix.

[8] Proc. Roy. Soc., A97, 1920.

[9] See Cranz, "Lehrbuch der Ballistik," Berlin, 1925, p. 60 et seq.

It is to be noticed that the computed values for the total drag represented by the solid line are fairly near to the actual values, and even the variation of the drag with the ratio V/c is given by the theory in a nearly correct way. As was pointed out in section 5, the computed pressure distribution gives a lower limit for the resistance. In addition the drag is increased in actual flight by yaw and conical oscillations of the shell. As far as the transition at the point $V = c$ is concerned, the present approximate theory fails to give any information. It is to be hoped that a further development of the theory, especially in connection with scientifically directed experiments, will lead to a more exact knowledge of the complex phenomena connected with the aerodynamics of supersonic velocities.

Appendix

The magnitude of the depression developed at the base of the projectile has been discussed by several authors. Depreux[10] and Gabeault[11] assume vortex rings in the wake of the projectile, and arrive at the conclusion that for velocities higher than twice the velocity of sound, full vacuum must reign immediately behind the projectile. Furthermore, they conclude that, like the head resistance, the depression at the base is suddenly increased when the velocity of the projectile passes the velocity of sound. They use the assumption that the "circulation" propagates with the velocity of sound; unfortunately they do not give any proof to justify this statement, and it is very difficult to follow their deductions.

It seems to the authors that M. T. Harris[12] gives a more adequate description of the phenomena, in that he discusses the wave fronts shown in photographs obtained by various optical methods. He points out that, corresponding to the depression at the base, the flow immediately behind the base must be convergent.

Using the equations given by L. Prandtl[13] and Th. Meyer[14] and applied recently by P. S. Epstein[15] to a two-dimensional model of a projectile, it is possible to calculate the deflection around the rim of the projectile if the depression is given, or to estimate the depression if the direction of either the deflection or of the wave fronts is known. The authors carried out this calculation for $V = 880$ m per sec, corresponding to the photograph, Fig. 6, which is reproduced from Cranz's "Ballistik."[16] It is easy to show that if full vacuum were to be reached at the base, then the flow behind the base would have to be deflected nearly 90 deg. However, the actual deflection can be estimated from the direction of the waves starting from the rim, and also from the location of the strong compression shock waves which follow the shock between the convergent streams. The authors believe that their estimate of the depression is in fairly good agreement with the conclusions deduced from the photographical records.

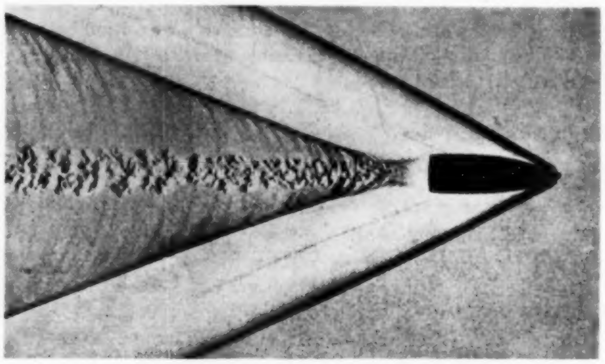

FIG. 6 BULLET MOVING WITH VELOCITY OF ABOUT 880 M PER SEC

Discussion

GEORGE B. PEGRAM.[17] On page 309 and elsewhere in the paper it is stated that behind the projectile an "absolute vacuum" is, according to the mathematical equations, to be reached at a certain velocity. For several obvious reasons the space back of the projectile, even if it is going with several times the velocity of sound, cannot be anything like free of gas molecules. Would it not therefore be better to use a milder term than "absolute vacuum?"

AUTHORS' CLOSURE

The authors agree with Professor Pegram that an absolute vacuum is not possible in one region of a fluid that is in contact with another region of finite pressure. The reason for the discrepancy between the mathematical solution and the reality is due to the fact that deduction of the hydrodynamical equation is based on the assumption that the mean free path of the molecules is small compared with the dimensions of the vessels containing the fluid or of the bodies immersed in it. This is obviously no longer true in the case of the projectile, if the pressure at the base approaches zero. As far as the resistance is concerned, the difference will be quite imperceptible.

Strength of Semicircular Plates and Rings Under Uniform External Pressure

By A. M. Wahl,[1] East Pittsburgh, Pa.

The exact solution of the problem of a semicircular ring subjected to uniform pressure involves the solution of a fourth-order partial-differential equation, in conjunction with certain specific boundary conditions. As an exact solution could not be found, the author has developed approximate methods which tests show are sufficiently accurate for practical use in cases where the inner radius of the ring or plate is over 0.4 that of the outer radius. These methods, it is believed, will be found useful by machine designers in the calculation of thrust-bearing plates, split-ring keys, semicircular split diaphragms, and similar mechanical structures.

In connection with analyses of the strength of machine parts of various shapes, the problem of the strength of a semicircular ring or plate with a hole, subjected to uniform pressure on the surface, and simply supported on its outer circumference, was considered. This is the case of a split diaphragm under external pressure. Since problems of this general kind are of considerable interest to machine designers, the methods of solution of this problem will be given in detail, particularly in view of the fact that similar methods may be applied to a wide variety of problems of the same general nature.

The exact solution of the semicircular-plate problem mentioned above involves the solution of a fourth-order partial-differential equation, in conjunction with certain specified boundary conditions. For the case in question, namely, that of the semicircular ring, this exact solution could not be found, and hence resort was had to an approximate method which is discussed below.

In order to show the order of exactitude of the general method, the case of a narrow rectangular plate having one long edge free and the other edges simply supported, was first considered. Two approximate solutions were applied and compared with the known exact solution for this case. A similar approximate method was then applied to the case of a semicircular ring or plate, mentioned before.

It is the author's hope that the methods developed herein may find application in practical machine design to the calculation of similar mechanical structures, such as, for example, thrust-bearing plates, split-ring keys, and semicircular split diaphragms under external pressure. In any case the general method should be applicable to many cases of the same general nature.

I—THE RECTANGULAR PLATE OF CONSTANT THICKNESS SIMPLY SUPPORTED ON THREE EDGES AND THE FOURTH FREE

Exact Solution

This case is represented in Fig. 1, and was chosen because it is, to some extent, similar to the semicircular plate without a hole, and of constant thickness, the plate being simply supported on its circumference and free along its diametral edge. The exact solution for the case shown in Fig. 1 was first obtained by E. Estanave[2] using the general method developed by Levy.[3]

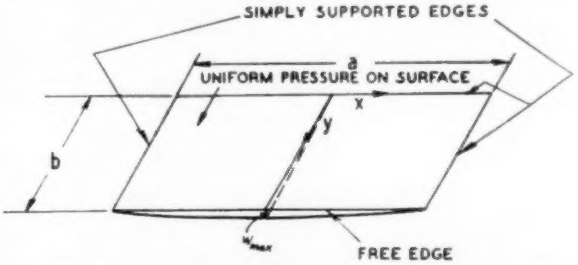

Fig. 1 Rectangular Plate Under Uniform Pressure, Three Edges Simply Supported, the Fourth Free

Essentially this problem[4] consists in obtaining solutions compatible with the given boundary conditions for the biharmonic equation:

$$\nabla^4 w = \frac{\partial^4 w}{\partial x^4} + 2\frac{\partial^4 w}{\partial x^2 \partial y^2} + \frac{\partial^4 w}{\partial y^4} = \frac{p}{N} \qquad [1]$$

where w = deflection of the plate at any point having the coordinates x, y (Fig. 1)

p = pressure on surface of plate (assumed uniform in this case)

N = plate rigidity = $Eh^3/12(1 - \nu^2)$

ν = Poisson's ratio

h = thickness of plate (assumed constant), and

E = modulus of elasticity of the plate material.

The function w for this case must satisfy the following boundary conditions (referring to Fig. 1). At $x = \pm a/2$, $w = 0$, and $\partial^2 w/\partial x^2 = 0$, since these edges are supported along straight

[3] *Comptes Rendus*, Oct. 9, 1899, pp. 535–539.

[4] See A. Nádái, "Die Elastische Platten" (Berlin, Julius Springer, 1925), for a more complete discussion of this problem.

edges and no moments act thereon. At $y = 0$, $w = 0$, and $\partial^2 w/\partial y^2 = 0$ likewise. At $y = b$,

$$\frac{\partial^2 w}{\partial y^2} + \nu \frac{\partial^2 w}{\partial x^2} = 0$$

$$\frac{\partial}{\partial y}\left\{ (2 - \nu)\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right\} = 0$$

The last two equations express the fact that no moments or shearing forces act on the free edge.

It may be shown that the following series will satisfy these conditions:

$$w = \sum_{n=1,3,5}^{\infty} Y_n \cos\frac{n\pi x}{a} \qquad [2]$$

where Y_n is given by Equation [37] in Appendix No. 1.

As a case of particular interest, let us take that where $a = 2b$. The maximum deflection may be shown to occur at $x = 0$, $y = b$, and taking two terms of the series [2] (which is very rapidly convergent), the maximum deflection becomes

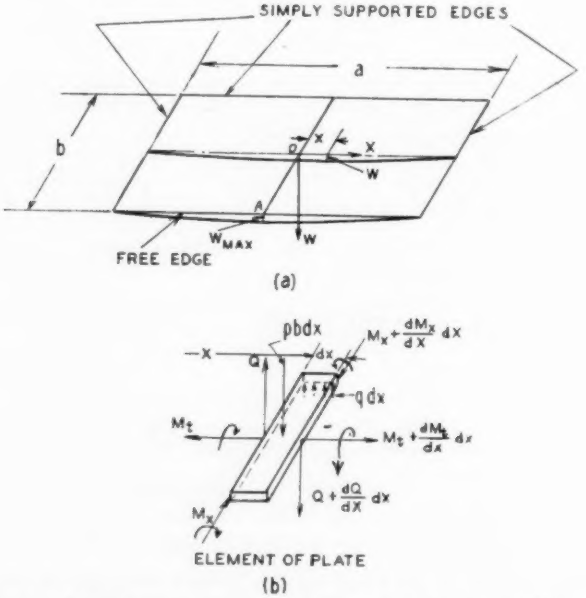

FIG. 2 RECTANGULAR PLATE—APPROXIMATE SOLUTION NO. 1 (BEAM METHOD)

$$w_{\max} = 0.546\,\frac{4pa^4}{\pi^5 N} \qquad [3]$$

(Poisson's ratio being taken as $^1/_4$.)

Using the value $N = Eh^3/12(1 - \nu^2)$, this may be written

$$w_{\max} = 0.0804\,\frac{pa^4}{Eh^3} \qquad [4]$$

APPROXIMATE SOLUTIONS FOR A NARROW RECTANGULAR PLATE

(One long edge free, the other edges simply supported.)

1—Beam Method. This method consists in assuming a narrow rectangular plate with the given conditions of loading and edge support to be a beam, each element of which is acted on by bending moments, twisting moments, loads, and shearing forces, as shown in Fig. 2(*b*). Obviously the solution holds with fair approximation only when b is not over, say, $a/2$, since the assumption that cross-sections of the plate perpendicular to its length deflect without distortion is no longer approximately correct when the width is too great. By applying the conditions of equilibrium of the bending moments, loads, and shearing forces acting on an element of the plate, the following differential equation is obtained:[5]

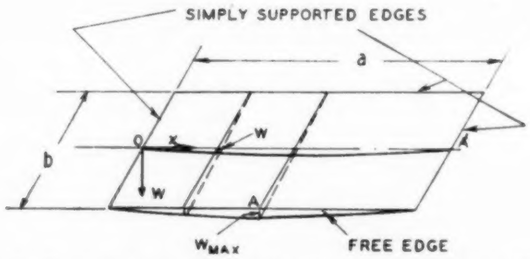

FIG. 3 RECTANGULAR PLATE—APPROXIMATE SOLUTION NO. 2 (ENERGY METHOD)

$$\frac{d^4 w}{dx^4} - \frac{4C}{EIb^2}\frac{d^2 w}{dx^2} = \frac{pb}{EI} \qquad [5]$$

In this w = deflection of center line of the plate at a distance x from the point O, Fig. 2(*a*); C = torsional rigidity of a cross-section perpendicular to the x-axis and may, with sufficient approximation,[6] be taken as

$$C = \frac{bh^3 G}{3}\left(1 - \frac{0.625\,h}{b}\right) \qquad [5a]$$

where h = thickness of plate
b = width of plate perpendicular to free edge
a = length of plate, parallel to free edge
I = moment of inertia of cross-section = $bh^3/12$, and
G = modulus of rigidity of the material.

A solution of [5] which satisfies the boundary conditions $w = 0$ and $d^2w/dx^2 = 0$ for $x = a/2$ and the symmetry conditions at $x = 0$, is:

$$w = \frac{pb^5}{16\,C}\left[\frac{EI}{C}\left(\frac{\cosh\frac{2x}{b}\sqrt{\frac{C}{EI}}}{\cosh\frac{a}{b}\sqrt{\frac{C}{EI}}} - 1\right) + \frac{a^2}{2b^2}\left(1 - \frac{4x^2}{a^2}\right)\right] \qquad [6]$$

The maximum deflection occurs at point A, Fig. 2(*a*), and will be found by putting $x = 0$ in [6]. Thus:

$$w_{\max} = 2(w)_{x=0} = \frac{pb^5}{8C}\left[\frac{EI}{C}\left(\frac{1}{\cosh\frac{a}{b}\sqrt{\frac{C}{EI}}} - 1\right) + \frac{a^2}{2b^2}\right] \qquad [7]$$

Taking $b = 2a$, as before, and $h = b/10$, this becomes[7]

$$(w_{\max})_{a=2b} = 0.0906\,\frac{pa^4}{Eh^3} \qquad [8]$$

Comparing this with the value obtained by the exact solution

---

[5] See Appendix No. 2 for derivation of this differential equation.

[6] Timoshenko, S., "Strength of Materials," New York, D. Van Nostrand Co. Todhunter and Pearson, "A History of the Theory of Elasticity," Cambridge University Press.

[7] It should be noted that a considerable change in the ratio h/b would not affect the final result much, since the thickness is assumed small relative to the width.

(Eq. [4]), it is seen that this value is about 12 per cent in error. This error is probably due to the fact that the beam in this case is taken relatively wide, i.e., b not small relative to a, so that the underlying assumptions do not hold with a high degree of accuracy. Nevertheless the degree of approximation appears sufficient for most practical work in the case of plates where the width perpendicular to the free edge is not over half the length.

2—Energy Method. This method[8] consists in assuming the deflection curve of the center line of the plate (OA' in Fig. 3) in the form of a Fourier series and determining the coefficients of this series so as to make the total energy of the system a minimum. (See Appendix No. 2 for a more complete discussion of this method.) Referring to Fig. 3, the deflection w of the center line at a distance x from O is assumed in the form of a series which satisfies the symmetry conditions and those at the ends $x = 0$ or a. Such a series is:

$$w = a_1 \sin\frac{\pi x}{a} + a_3 \sin\frac{3\pi x}{a} + \dots$$

or

$$w = \sum_{n=1,3,5\dots}^{\infty} a_n \sin\frac{n\pi x}{a} \dots\dots\dots\dots [9]$$

Under this assumption, and the further one that cross-sections of the plate perpendicular to the x-axis deflect without distortion, the total energy U stored in the system may be calculated. Then to obtain any coefficient a_n, the equation

$$\frac{\partial U}{\partial a_n} = 0 \dots\dots\dots\dots [10]$$

is used. Thus it is found that

$$a_n = \frac{2pba^2}{\pi^3 n^3 \left[\frac{2C}{b^2} + \frac{EI\pi^2 n^2}{2a^2}\right]} \dots\dots\dots\dots [11]$$

Again, taking $a = 2b$ and $C/ET = 1.48$, and using the first two terms of [9], the maximum deflection at point A, Fig. 3, becomes

$$w_{\max} = 0.0912\,\frac{pa^4}{Eh^3} \dots\dots\dots\dots [12]$$

This solution is quite close to that obtained using the beam method (see Equation [8]), which is reasonable since the underlying assumptions are essentially the same for both methods, and it is about 12 per cent in error compared with results obtained by using the exact method, Equation [4].

II—THE SEMICIRCULAR PLATE OR RING UNDER UNIFORM EXTERNAL PRESSURE

General. The case of a semicircular ring or plate with a hole having the shape shown in Fig. 4(*c*) will now be considered. It is assumed that the inside diameter is not over 0.4 that of the outside diameter, that the thickness is constant, and that a uniform pressure acts on the surface of the plate. (The analysis may, however, be adapted to cases where the thickness is variable in the radial direction and where the pressure is not constant.) The outer circumference of the plate or ring is assumed to be simply supported, and the inner circumference and diametral edges free. Since, as mentioned before, an exact solution involving the integration of the fundamental equation $\nabla^2\nabla^2 w = p/N$ $\left(\text{where } \nabla^2 \text{ is the Laplacian operator } \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2}\right)$ could not be found by exact methods, it was necessary to use an approximate solution, based on the fundamental theory[9] of the bending of an initially curved bar out of its plane of initial curvature.

Approximate Solution for Deflection. Taking w as the deflection of the mean radius def [Fig. 4(*a*)] of the plate, and assuming as before that radial cross-sections deflect without distortion, it is possible to derive the following differential equation for the deflection w (see Appendix No. 3):

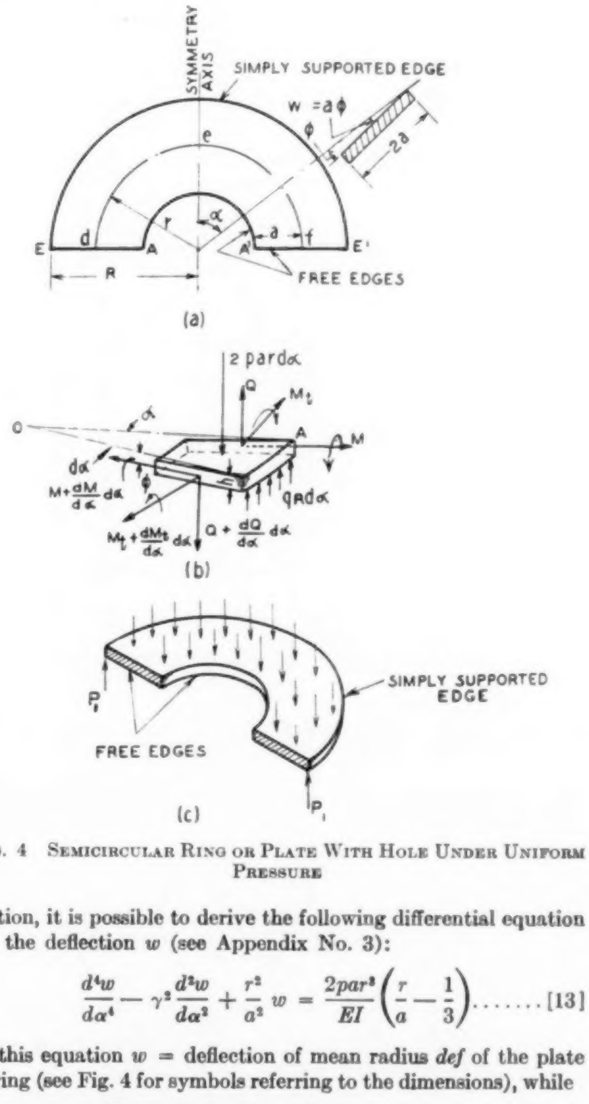

FIG. 4 SEMICIRCULAR RING OR PLATE WITH HOLE UNDER UNIFORM PRESSURE

$$\frac{d^4w}{d\alpha^4} - \gamma^2\frac{d^2w}{d\alpha^2} + \frac{r^2}{a^2}\,w = \frac{2par^3}{EI}\left(\frac{r}{a} - \frac{1}{3}\right) \dots\dots [13]$$

In this equation w = deflection of mean radius def of the plate or ring (see Fig. 4 for symbols referring to the dimensions), while

p = uniform pressure on surface
α = angle from symmetry axis of plate
r = mean radius of plate
a = half-width of plate
I = moment of inertia of a radial cross-section of the plate $= {}^1/_{12} \times 2ah^3$

---

[8] Rayleigh, Lord, "Theory of Sound," London, Macmillan Co., 1926, Sec. Ed. Ritz, W., *Crelles Journal*, vol. 135, p. 1, 1908. See footnotes 4 and 6.

[9] This theory was developed by St. Venant, J. H. Mitchell, and A. E. H. Love. See Love, A. E. H., "The Mathematical Theory of Elasticity," Cambridge University Press, 1927, 4th Ed. Also footnote 6, "Strength of Materials," vol. 2, p. 468.

h = thickness of plate (assumed constant), and
C = torsional rigidity of a radial cross-section.

$$C = 2\beta a h^3 G$$

where E = modulus of elasticity of the material
G = modulus of rigidity of the material
β = a factor[10] depending on the ratio $h/2a$ and which may be taken from the curve of Fig. 5. For practical cases where $h/2a < 0.8$, the formula

$$\beta = \frac{1}{3}\left(1 - \frac{0.625h}{2a}\right) \qquad [14]$$

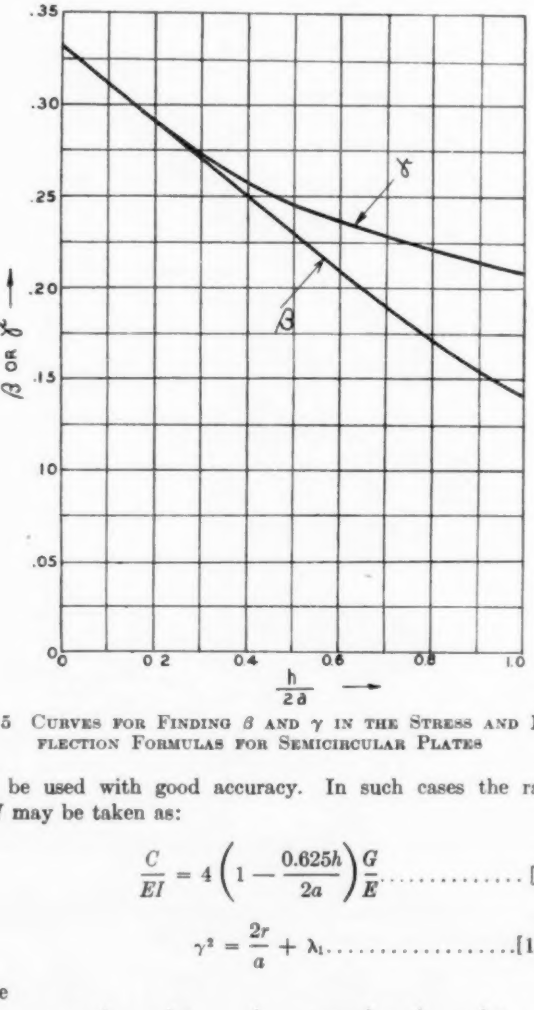

FIG. 5 CURVES FOR FINDING β AND γ IN THE STRESS AND DEFLECTION FORMULAS FOR SEMICIRCULAR PLATES

may be used with good accuracy. In such cases the ratio C/EI may be taken as:

$$\frac{C}{EI} = 4\left(1 - \frac{0.625h}{2a}\right)\frac{G}{E} \qquad [15]$$

$$\gamma^2 = \frac{2r}{a} + \lambda_1 \qquad [15a]$$

where

$$\lambda_1 = \frac{C}{EI}\left(1 + \frac{r}{a}\right)^2 = 4\left(1 - \frac{0.625h}{2a}\right)\frac{G}{E}\left(1 + \frac{r}{a}\right)^2 \qquad [16]$$

A solution of this equation which satisfies the condition of symmetry with respect to the symmetry axis $\alpha = 0$ is:

$$w = C_1' \cosh \gamma_1\alpha + C_2' \cosh \gamma_2\alpha + \frac{2pa^4r}{EI}\left(\frac{r}{a} - \frac{1}{3}\right). \qquad [17]$$

In this equation

$$\gamma_1 = \frac{\gamma}{\sqrt{2}}\sqrt{1 + \sqrt{1 + \frac{4r^2}{a^2\gamma^4}}} \qquad [18]$$

$$\gamma_2 = \frac{\gamma}{\sqrt{2}}\sqrt{1 - \sqrt{1 + \frac{4r^2}{a^2\gamma^4}}} \qquad [19]$$

From the conditions at the end $\alpha = \pi/2$, the two constants C_1' and C_2' may be found, thus giving an expression for w equal to:

$$w = \frac{12\,pa^2r^2}{Eh^3}\left(\frac{r}{a} - \frac{1}{3}\right)\left(C_1 \cosh \gamma_1\alpha + C_2 \cosh \gamma_2\alpha + \frac{a}{r}\right). \qquad [20]$$

where

$$C_1 = \frac{1}{\left(\frac{r}{a} - \gamma_1^2\right)\left(\lambda - 1\right)\cosh \frac{\gamma_1\pi}{2}} \qquad [21]$$

$$C_2 = \frac{1}{\left(\frac{r}{a} - \gamma_2^2\right)\left(\frac{1}{\lambda} - 1\right)\cosh \frac{\gamma_2\pi}{2}} \qquad [22]$$

$$\lambda = \frac{\gamma_1\left(\frac{r}{a} - \gamma_1^2 + \lambda_1\right)\left(\frac{r}{a} - \gamma_2^2\right)\tanh \frac{\gamma_1\pi}{2}}{\gamma_2\left(\frac{r}{a} - \gamma_2^2 + \lambda_1\right)\left(\frac{r}{a} - \gamma_1^2\right)\tanh \frac{\gamma_2\pi}{2}} \qquad [23]$$

In these expressions, γ_1, γ_2, and λ_1 are given by [18], [19], and [16], respectively.

The maximum deflection $w_{\max}$ will occur at points A and A', Fig. 4(a), where $\alpha = \pi/2$ and is found from [20] by substituting $\alpha = \pi/2$ therein.

$$w_{\max} = 2(w)_{\alpha=\pi/2} = \frac{24pa^2r^2}{Eh^3}\left(\frac{r}{a} - \frac{1}{3}\right)\left[C_1 \cosh \frac{\gamma_1\pi}{2} + C_2 \cosh \frac{\gamma_2\pi}{2} + \frac{a}{r}\right] \qquad [24]$$

where C_1 and C_2 are given by [21] and [22].

Calculation of Stresses. In calculating the stresses, the fundamental Equations [63] and [64] of Appendix No. 3 may be used in connection with [20]. The value of bending stress σ' determined in this way will, however, be the *average* bending stress over a radial section, and not the *maximum* bending stress which occurs at the inner circumference of the plate, due to the decreased fiber length. To get an approximation to this maximum stress, the average stress σ' thus obtained must be multiplied by a factor K_1 which may be obtained by taking the ratio of the maximum bending stress in a *full* circular plate having the given ratio of inner to outer diameter as determined from the known circular-plate theory, to the value calculated by considering the circular plate as a beam acted on by external moments which may be calculated from the statical equations of equilibrium. Taking σ' as the average bending stress at any angle α from the axis of symmetry, determined from the beam method, the fundamental Equations [63] and [64] of Appendix No. 3 reduce to:

$$\sigma' = \frac{M}{Z} = \frac{6M}{2ah^2} = \frac{Eh}{2r}\left(\frac{w}{a} - \frac{1}{r}\frac{d^2w}{d\alpha^2}\right) \qquad [25]$$

$Z = 2ah^2/6$ = section modulus of a radial cross-section. The calculated shearing stress τ will likewise be, using [64],

$$\tau = \frac{M_t}{2ah^2\gamma} = \frac{\beta G h}{\gamma r^2}\left(1 + \frac{r}{a}\right)\frac{dw}{d\alpha} \qquad [26]$$

where $2ah^2\gamma$ is the section modulus in torsion of a rectangular section, γ being a function of $h/2a$ and may be taken from the curve of Fig. 5, or calculated with enough accuracy from:[11]

---

[10] "Strength of Materials," part 1, p. 76, footnote 6.

$$\gamma = \frac{1}{3 + 1.8\dfrac{h}{2a}} \quad\ldots\ldots\ldots\ldots\ldots\ldots [27]$$

Using the expression for w given by [20], the stresses σ' and τ as functions of α become:

$$\sigma' = \frac{6par}{h^2}\left(\frac{r}{a} - \frac{1}{3}\right)\left[C_1\left(1 - \gamma_1^2\frac{a}{r}\right)\cosh\gamma_1\alpha + C_2\left(1 - \gamma_2^2\frac{a}{r}\right)\cosh\gamma_2\alpha + \frac{a}{r}\right] \quad\ldots\ldots\ldots [28]$$

$$\tau = \frac{12pa^2}{h^2}\left(\frac{G}{E}\right)\left(1 + \frac{0.3h}{a}\right)\left(1 - \frac{0.312h}{a}\right)\left(1 + \frac{r}{a}\right)\left(\frac{r}{a} - \frac{1}{3}\right)\left(C_1\gamma_1\sinh\gamma_1\alpha + C_2\gamma_2\sinh\gamma_2\alpha\right) \quad\ldots\ldots [28a]$$

in which C_1, C_2, γ_1, and γ_2 are given by [21], [22], [18], and [19], respectively.

An examination of these equations shows that, for practical cases, the shearing stress τ is a maximum at $\alpha = \pi/2$ and the bending stress σ' is a maximum at $\alpha = 0$. These maximum values are:

$$\sigma'_{\max} = \frac{6par}{h^2}\left(\frac{r}{a} - \frac{1}{3}\right)\left[C_1\left(1 - \gamma_1^2\frac{a}{r}\right) + C_2\left(1 - \gamma_2^2\frac{a}{r}\right) + \frac{a}{r}\right] \quad\ldots\ldots\ldots [29]$$

$$\tau_{\max} = \frac{12pa^2}{h^2}\frac{G}{E}\left(1 + \frac{0.3h}{a}\right)\left(1 - \frac{0.312h}{a}\right)\left(1 + \frac{r}{a}\right)\left(\frac{r}{a} - \frac{1}{3}\right)\left(C_1\gamma_1\sinh\frac{\gamma_1\pi}{2} + C_2\gamma_2\sinh\frac{\gamma_2\pi}{2}\right) \quad\ldots\ldots\ldots [30]$$

An examination into the sign of the second derivative of the stress shows that at $\alpha = 0$ the bending stress σ' is a maximum.

It should also be noted that this stress $\tau_{\max}$ at $\alpha = \pi/2$ arises mainly because of the action of the concentrated loads P_1, Fig. 4(*c*). It is also clear that near these concentrated loads, local stresses of considerable magnitude may be set up. Hence the stresses τ as given by [28*a*] must be considered as approximations valid only near the mean radius of the plate, and at some distance from the diametral edges. The stress $\tau_{\max}$ given by [30] must also be considered as a very rough approximation.

As mentioned before, to get the true *maximum* bending stress σ at the inner edge of the plate, the *average* stress σ' figured as above, must be multiplied by a correction factor K_1, greater than unity, to take into account the stress increase at the inner edge due to the shorter length of the inner fibers. An estimate of the factor K_1 may be had by taking the ratio of the maximum stress σ_f in a *full* circular plate, having the same ratio of inner to outer radius as the semicircular plate in question, to the average stress σ_f' in a full circular plate figured by the beam method mentioned previously. The stress σ_f may be easily calculated from known circular-plate formulas and is:[12]

$$\sigma_f = K_f\frac{p(r + a)^2}{h^2} \quad\ldots\ldots\ldots\ldots\ldots\ldots [31]$$

where

$$K_f = \frac{3.9\log_e\beta_1 + \dfrac{2.475}{\beta_1^2} - 3 + 0.525\,\beta_1^2}{1/\beta_1^2 - 1} \quad\ldots\ldots [32]$$

and β_1 = ratio $\dfrac{r - a}{r + a} = \dfrac{\text{inner radius}}{\text{outer radius}}$

The average bending stress σ_f' in a full circular plate may be figured as follows: The moments acting on any diametral cross-section are obtained by taking the moments of the edge reactions and subtracting from these the moment due to the pressure load. This gives a moment acting on a diametral section equal to

$$M_r = \frac{p}{3}\left[(r + a)^3 - 3(r + a)(r - a)^2 + 2(r - a)^3\right]$$

and the *average* stress σ_f' thus becomes (since $\sigma_f' = M_r \div$ Section Modulus):

$$\sigma_f' = \frac{p(r + a)^2}{h^2}\left[\frac{1/\beta_1 - 3\beta_1 + 2\beta_1^2}{1/\beta_1 - 1}\right] \quad\ldots\ldots\ldots [33]$$

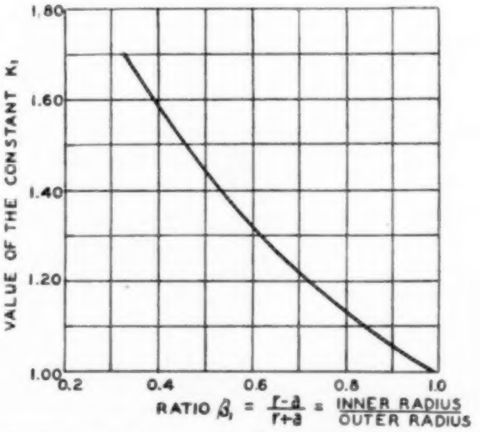

FIG. 6 CURVE FOR FINDING THE CONSTANT K_1 IN THE STRESS FORMULAS FOR SEMICIRCULAR PLATES

The stress multiplication factor then becomes, using [31] and [33]:

$$K_1 = \frac{\sigma_f}{\sigma_f'} = \frac{3.9\log_e\beta_1 + \dfrac{2.475}{\beta_1^2} - 3 + 0.525\beta_1^2}{\left(1 + \dfrac{1}{\beta_1}\right)(1/\beta_1 - 3\beta_1 + 2\beta_1^2)} \quad\ldots\ldots [34]$$

In Fig. 6, for convenience in calculation, values of K_1 are plotted as functions of the ratio $\beta_1 = \dfrac{r - a}{r + a} = \dfrac{\text{inner radius}}{\text{outer radius}}$.

To obtain the true maximum bending stress σ at the *inner* edge of a semicircular plate or ring as a function of the angle α, the value of the average stress σ' given by [28] is multiplied by K_1. Thus the bending stress σ at the inner edge as a function of the angle from the symmetry axis is:

$$\sigma = K_1\sigma' \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots [35]$$

where σ' and K_1 are given by [28] and [34].

The maximum value of bending stress $\sigma_{\max}$ occurs when the angle α is zero. This value is again obtained by multiplying the value of $\sigma_{\max}$ found above by the factor K_1. Thus

$$\sigma_{\max} = K_1 \sigma'_{\max} \ldots\ldots\ldots\ldots\ldots\ldots [35a]$$

where $\sigma'_{\max}$ is given by [29].

Tests. In order to check up the stress and deflection formulas given herein, some tests were made on two semicircular plates designated as plates G and H. A special test apparatus, which will be described in a forthcoming paper, was used to carry out these tests. This apparatus consisted essentially of means for applying hydraulic pressure to the surface of a semicircular plate of the shape shown in Fig. 4(a), the plate being simply supported on the outer circumference and free on the inner circumference and diametral edges. The deflections of the plates were measured at various points by dial gages. Also provision was made for attaching Huggenberger extensometers at the inside edge of the plate where the maximum stress occurs. The method of attachment of the extensometers was similar to that described in a previous paper.[12] The plates tested had dimensions as indicated in Table 1.

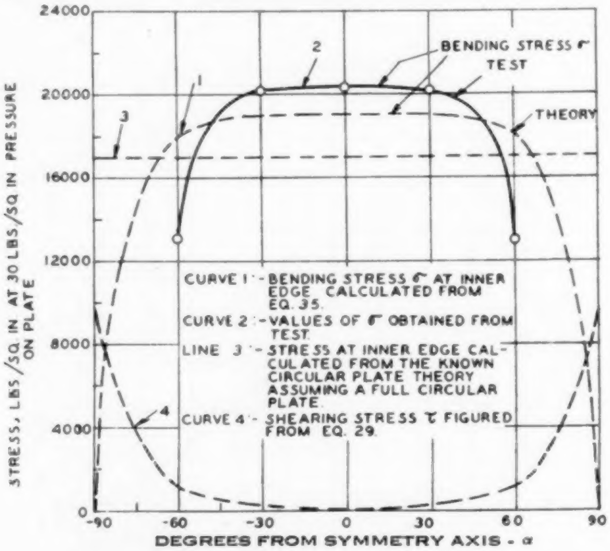

Fig. 7 Stress Distribution, Plate H

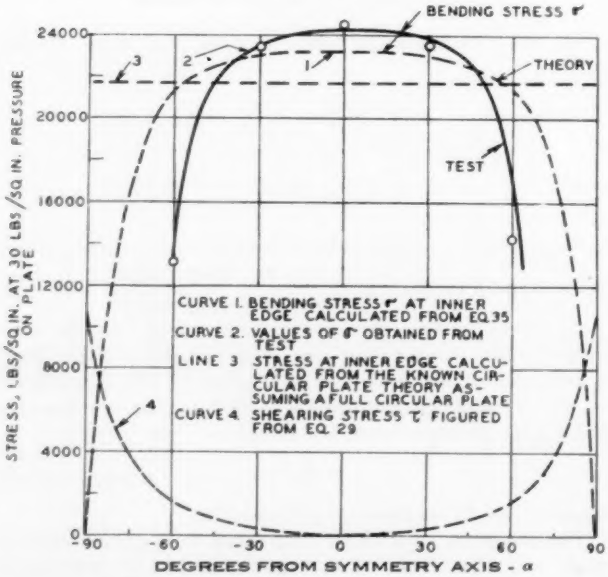

Fig. 8 Stress Distribution, Plate G

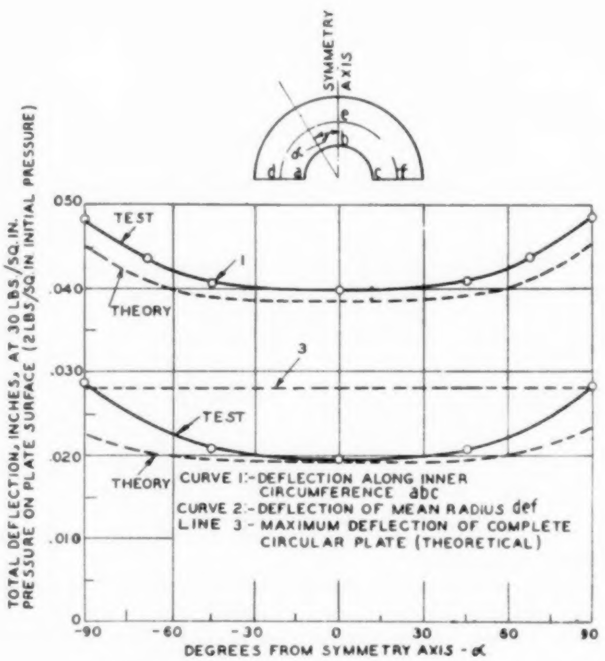

Fig. 9 Deflection Distribution, Plate G

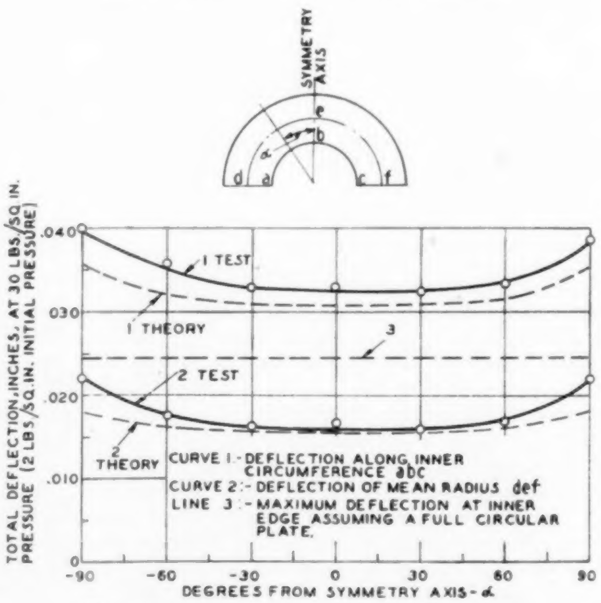

Fig. 10 Deflection Distribution, Plate H

TABLE 1 DIMENSIONS OF SEMICIRCULAR PLATES

(All dimensions refer to Fig. 4)

Plate	R Outer radius, inches	r Mean radius, inches	a Semi-width, inches	h Thickness, inches
G	4.97	3.48	1.48	0.250
H	4.97	3.73	1.23	0.250

In Fig. 7, curve 1 shows the bending stress σ at an external pressure of 30 lb per sq in., calculated from Equation [35], plotted as a function of the angle α from the axis of symmetry for plate H. Curve 2 of this figure shows the test curve representing the bending stresses obtained from the extensometer readings at various angles at the inner edge. It may be seen that as far as the *maximum* stress is concerned the test curve gives results approximating the theoretical curve. At larger angles α, however, the test curve drops off much faster than the theoretical curve. This may be explained by the fact that near the diametral edges $\alpha = \pi/2$, this stress-concentration effect due to the decrease in fiber length is not present to any marked degree, since these portions do not act in a manner similar to those of a complete circular plate. Nevertheless, as far as the maximum stress is concerned, it is seen that the method gives a good approximation. It is also seen that curve 3 of Fig. 7, which represents the stress calculated from the known full-circular-plate theory (Equation [31]) also gives a fair approximation to the maximum bending stress in a semicircular plate having the geometrical shape of plate H.

Curve 4 of Fig. 7 represents the shearing stress τ plotted as a function of the angle α on the basis of Equation [28*a*]. As mentioned above, this shearing stress arises mainly from the presence of the concentrated reactions P_1 at the corners [Fig. 4(*c*)], and hence this curve must be considered as a rough approximation valid only near the center line of the plate and at some distance from the diametral edges.

The curves on Fig. 8 are similar to those on Fig. 7 except that they represent values for plate G which had a ratio of inner to outer radius of about 0.4, as contrasted with a corresponding ratio of 0.5 for plate H. It may be seen that the results obtained for plate H apply in general to plate G. This would indicate that the method given herein applies to the case of rings or plates where the inner radius is as small as 0.4 the outer radius.

In Figs. 9 and 10, the deflections of the mean radius of the plate and those of the inner circumference are plotted as functions of the angle α from the axis of symmetry, assuming the pressure on the plate surface increased from 2 to 30 lb per sq in. The dotted lines represent theoretical curves calculated on the basis of Equation [20], using a modulus of elasticity of 30×10^6 lb per sq in. and a value of G of 11.5×10^6 lb per sq in. This value of E was checked by tension tests on small specimens of the material.[13] The full lines represent test curves. The straight lines marked "3" represent the deflections of the inner edge calculated on the assumption of a complete circular plate having otherwise the same dimensions. It may be seen that the test curves are somewhat higher than those calculated from Equation [20], but this may probably be explained by irregularities in the supporting edges, which tend to flatten out as the load increases, and thus at first make the plate more flexible than calculated. This hypothesis is verified by Fig. 11, which shows pressure plotted against maximum deflection of the plate [at points A, A', Fig. 4(*a*)]. The test curves represented by full lines are slightly concave upward at first, but straighten out later on. The dotted lines show the theoretical curves of maximum deflection of points A and A' calculated from [24]. It is seen that there is good agreement between the slopes of the test and the calculated curves. It should be noted, however, that the maximum deflections of the semicircular plates (or split rings) tested were around 1.6 to 1.7 times the deflections of a complete circular plate or ring having otherwise the same dimensions and loaded with the same external pressure. In contrast with this the maximum bending stresses as measured in these semicircular plates were found to be only about 20 per cent larger than those which would exist in the corresponding complete circular plate under the same external pressure.

III—CONCLUSIONS

The tests thus indicate that the theoretical formulas and approximate methods developed herein for calculating the stress and deflection of semicircular rings or plates with holes, are sufficiently accurate for practical use in cases where the inner radius of the ring or plate is over 0.4 that of the outer radius.

It is hoped that these methods will prove useful in the analysis of mechanical structures similar to the cases herein considered.

ACKNOWLEDGMENT

The author's thanks are due to Dr. A. Nádái and Dr. S. Timoshenko for valuable suggestions and encouragement during the course of this work. Messrs. Fornes and Richmond assisted in the tests and checking of the numerical calculations.

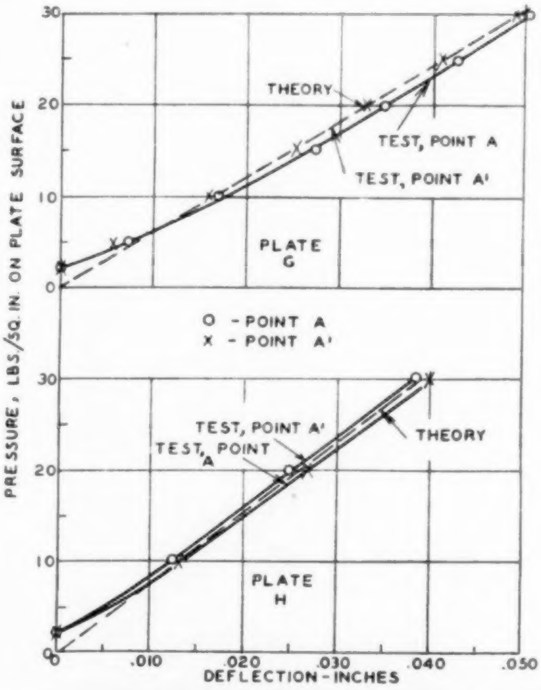

FIG. 11 PRESSURE-DEFLECTION CURVES AT POINTS OF MAXIMUM DEFLECTION OF PLATES G AND H

Appendix No. 1

EXACT SOLUTION FOR RECTANGULAR PLATE HAVING THREE EDGES SIMPLY SUPPORTED AND THE FOURTH FREE

To solve the case of the rectangular plate shown in Fig. 1, the series

$$w = \sum_{n=1,3,5\ldots}^{\infty} Y_n \cos\frac{n\pi x}{a} \ldots\ldots\ldots\ldots\ldots [36]$$

where Y_n is a function of y alone, is assumed. This series obviously satisfies the conditions at $x = \pm a/2$, namely, $w = 0$, $\partial^2 w/\partial x^2 = 0$. In addition for $y = 0$, the conditions $w = 0$, $\partial^2 w/\partial y^2 = 0$ give $Y_n = 0$, $d^2Y_n/dy^2 = 0$ for $y = 0$, while for $y = b$, the conditions

$$\frac{\partial^2 w}{\partial y^2} + \nu\frac{\partial^2 w}{\partial x^2} = 0 \quad \text{and} \quad \frac{\partial}{\partial y}\left[(2-\nu)\frac{\partial^2 w}{\partial x^2} + \frac{\partial^2 w}{\partial y^2}\right] = 0$$

give

$$\left[\frac{d^2Y_n}{dy^2} - \frac{\nu\pi^2}{a^2}Y_n\right]_{y=b} = 0$$

---

[13] These tension tests were made by T. F. Hengstenberg, of the Mechanics Division, Westinghouse Electric & Manufacturing Co.

and

$$\frac{\partial}{\partial y}\left[-(2-\nu)\frac{\pi^2}{a^2}Y_n+\frac{d^2Y_n}{dy^2}\right]_{y=b}=0$$

Furthermore the value of w given by [36] must satisfy the biharmonic Equation [1]. Substituting [36] in [1], it is found that

$$\sum_{n=1,3,5\ldots}^{\infty}\left(\frac{d^4Y_n}{dx^4}-2\mu^2\frac{d^2Y_n}{dx^2}+\mu^4Y_n\right)\cos\frac{n\pi x}{a}=\frac{p}{N}$$

where $\mu = n\pi/a$.

Multiplying both terms of this equation by $\cos\frac{m\pi x}{a}\,dx$, where m is odd, and integrating between 0 and $a/2$, the condition which Y_n must satisfy becomes:

$$\frac{d^4Y_n}{dx^4}-2\mu^2\frac{d^2Y_n}{dx^2}+\mu^4Y_n=(-1)^{\frac{n-1}{2}}\frac{2p}{n\pi N}$$

A value of Y_n which satisfies this equation when p and N are constants, and also satisfies the above boundary conditions, is:

$$Y_n=\frac{(-1)^{\frac{n-1}{2}}}{n^5}\Big[1-\cosh\mu y+\mu y\sinh\mu y-H\sinh\mu y$$
$$-F\mu y\cosh\mu y\Big]\ldots\ldots[37]$$

where

$$H=\frac{-(3-\nu)}{2(1-\nu)}\tanh\mu b+\mu\frac{b}{2}+F\left(\frac{1+\nu}{1-\nu}-\mu b\tanh\mu b\right)$$

and

$$F=\frac{\frac{-(3-\nu)}{2}\sinh^2\mu b+\nu\cosh\mu b\,(1-\cosh\mu b)}{-(3+\nu)\sinh\mu b\cosh\mu b-(1-\nu)\mu b}$$

Appendix No. 2

APPROXIMATE SOLUTIONS FOR RECTANGULAR PLATE UNDER UNIFORM PRESSURE AND HAVING THREE EDGES SIMPLY SUPPORTED AND THE FOURTH FREE

This is the case shown in Fig. 2. Two different approximate solutions will be developed, namely, (1) the Beam Method and (2) the Energy Method.

Approximate Solution No. 1—Beam Method. This method assumes the rectangular plate to be a beam acted on by bending and twisting moments; it is assumed that the equations for bending and twisting of bars hold in this case. Referring to Fig. 2(a), the x- and w-axes are chosen as shown, the deflections w being taken as those of the longitudinal center line of the plate. Assuming an element of length dx cut out from the plate at a distance x from O, by two neighboring cross-sections perpendicular to the x-axis, the forces and moments acting thereon are shown in Fig. 2(b). These consist of a shearing force Q, a twisting moment M_t, a bending moment M_x, a distributed load $q\,dx$ acting at the edge, and a pressure $pb\,dx$ acting on the surface. The following fundamental formulas hold from the equilibrium of these forces (for meaning of symbols see early part of paper):

$$EI\frac{d^2w}{dx^2}=-M_x\ldots\ldots\ldots\ldots\ldots\ldots[38]$$

$$\frac{2C}{b}\frac{dw}{dx}=M_t\ldots\ldots\ldots\ldots\ldots\ldots[39]$$

$$Q=\frac{dM_x}{dx}\ldots\ldots\ldots\ldots\ldots\ldots[40]$$

$$\frac{dQ}{dx}=q-pb\ldots\ldots\ldots\ldots\ldots\ldots[41]$$

$$\frac{dM_t}{dx}=-\frac{qb}{2}\ldots\ldots\ldots\ldots\ldots\ldots[42]$$

Eliminating the unknown quantities M_x, M_t, Q, and q from these equations by differentiation and resubstitution, the following differential equation is obtained:

$$\frac{d^4w}{dx^4}-\frac{4C}{EIb^2}\frac{d^2w}{dx^2}=\frac{pb}{EI}\ldots\ldots\ldots\ldots\ldots[43]$$

A solution of this equation is

$$w=C_1''\cosh\frac{2x}{b}\sqrt{\frac{C}{EI}}+C_2''\sinh\frac{2x}{b}\sqrt{\frac{C}{EI}}-\frac{pb^3x^2}{8C}$$
$$+C_3''x+C_4''\ldots\ldots[44]$$

From symmetry conditions when the origin is at the center of the plate, the constants C_2'' and C_3'' are zero; hence this becomes:

$$w=C_1''\cosh\frac{2x}{b}\sqrt{\frac{C}{EI}}-\frac{pb^3}{8C}x^2+C_4''\ldots\ldots[45]$$

To determine C_1'' and C_4'', the conditions $M_x = -EI\frac{d^2w}{dx^2} = 0$, $w = 0$ at $x = a/2$, are used. The expression for w thus determined is:

$$w=\frac{pb^5}{16C}\left[\frac{EI}{C}\left(\frac{\cosh\frac{2x}{b}\sqrt{\frac{C}{EI}}}{\cosh\frac{a}{b}\sqrt{\frac{C}{EI}}}-1\right)+\frac{a^2}{2b^2}\left(1-\frac{4x^2}{a^2}\right)\right]\ldots[46]$$

The maximum deflection of the plate at A, Fig. 2(a), will be

$$w_{\max}=2(w)_{x=0}=\frac{pb^5}{8C}\left[\frac{EI}{C}\left(\frac{1}{\cosh\frac{a}{b}\sqrt{\frac{C}{EI}}}-1\right)+\frac{a^2}{2b^2}\right]$$
$$\ldots\ldots[47]$$

In the case where $a = 2b$, taking $C = 0.333\left(1-\frac{0.625\,h}{b}\right)bh^3G$ and $\frac{C}{EI} = 4\left(1-\frac{0.625\,h}{b}\right)\frac{G}{E}$ (see Equation [5a] et seq.) the value of the maximum deflection becomes:

$$(w_{\max})_{a=2b}$$
$$=\frac{3pa^4}{128\left(1-\frac{0.625\,h}{b}\right)h^3G}\left[\frac{\frac{1}{\cosh\frac{a}{b}\sqrt{\frac{C}{EI}}}-1}{4\left(1-\frac{0.625\,h}{b}\right)\frac{G}{E}}+2\right]\ldots[48]$$

Taking as a typical case $t = b/10$ and $G/E = 0.4$, this reduces to

$$(w_{\max})_{a=2b}=\frac{0.0906\,pa^4}{Eh^3}\ldots\ldots\ldots\ldots[49]$$

Approximate Solution No. 2—Energy Method. In this method the coordinates of Fig. 3 are used for convenience, x being taken as the distance from the left edge. As before, the deflections of the center line of the plate parallel to the free edge are taken as w. The method consists essentially of assuming the deflection curve w in the form of a Fourier series[8] of a type which satisfies the boundary and symmetry conditions, and determining the coefficients of this series so that the total energy of the system is a minimum. In addition it is assumed as before that cross-sections perpendicular to the x-axis rotate without distortion, which means that the angular twist ϕ at any point x is $\phi = 2w/b$. The total energy consists of the energy due to bending U_1, the energy due to twist U_2, and the energy lost during the displacement of the load $-U_3$.

$$U_1 = \int_0^a \frac{EI}{2}\left(\frac{d^2w}{dx^2}\right)^2 dx$$

$$U_2 = \int^a \frac{C}{2}\left(\frac{d\phi}{dx}\right)^2 dx = \int_0^a \frac{2C}{b^2}\left(\frac{dw}{dx}\right)^2 dx$$

$$-U_3 = -\int_0^a pbwdx$$

The total energy is thus

$$U = U_1 + U_2 - U_3 \qquad [50]$$

The deflection w is assumed in the following form (which is required from symmetry conditions):

$$w = a_1 \sin\frac{\pi x}{a} + a_3 \sin\frac{3\pi x}{a} + \dots$$

$$w = \sum_{n=1,3,5\dots}^{\infty} a_n \sin\frac{n\pi x}{a} \qquad [51]$$

This form also satisfies the conditions at $x = 0$ or a, i.e., $w = 0$, $d^2w/dx^2 = 0$. Differentiating [51] as required, substituting the result in [50], and integrating, the following expression for the total energy is obtained:

$$U = \frac{C\pi^2}{ab^2}\sum_{n=1,3,5\dots}^{\infty} a_n^2n^2 + \frac{EI\pi^4}{4a^3}\sum_{n=1,3,5\dots}^{\infty} a_n^2n^4 - \frac{2pba}{\pi}\sum_{n=1,3,5\dots}^{\infty} a_n \qquad [52]$$

To determine any coefficient, the energy U is differentiated partially with respect to a_n and the result set equal to zero. Thus:

$$\frac{\partial U}{\partial a_n} = \frac{2C\pi^2}{ab^2}a_nn^2 + \frac{EI\pi^4 a_nn^4}{2a^3} - \frac{2pba}{\pi n} = 0$$

from which

$$a_n = \frac{2pba}{\pi^3n^3\left[\dfrac{2C}{ab^2} + \dfrac{EI\pi^2n^2}{2a^3}\right]} \qquad]53[$$

Each coefficient a_1, a_3, ... may be determined from this equation. Thus

$$a_1 = \frac{12pa^4}{\pi^3Eh^3\left[\dfrac{Ca^2}{EIb^2} + \dfrac{\pi^2}{4}\right]} \qquad [54]$$

$$a_3 = \frac{12pa^4}{27\pi^3Eh^3\left[\dfrac{Ca^2}{EIb^2} + \dfrac{9\pi^2}{4}\right]} \qquad [55]$$

Using $a/b = 2$, $C/EI = 1.48$ (which would be true for $h = {}^1/_8b$), the first two coefficients become

$$a_1 = 0.0461\,\frac{pa^4}{Eh^3} \qquad [56]$$

$$a_3 = 0.0005\,\frac{pa^4}{Eh^3} \qquad [57]$$

The deflection curve for the case where $a = 2b$ is thus

$$w = \frac{pa^4}{Eh^3}\left[0.0461\sin\frac{\pi x}{a} + 0.0005\sin\frac{3\pi x}{a} + \dots\right]$$

It is seen that this is a rapidly converging series. Using the first two terms and taking $x = a/2$, the maximum deflection at A, Fig. 3, becomes:

$$w_{\max} = 2\,(w)_{x=a/2} = 0.0912\,\frac{pa^4}{Eh^3} \qquad [58]$$

Appendix No. 3

DEFLECTION OF SEMICIRCULAR RING OR PLATE WITH A HOLE

Referring to Fig. 4(b), the following forces and moments act on an element cut out by two neighboring radial planes perpendicular to the plane of the plate. Bending moments M and $M + \frac{dM}{d\alpha}d\alpha$, twisting moments M_t and $M_t + \frac{dM_t}{d\alpha}d\alpha$, and external pressure load 2 $pard\alpha$, a force $qRd\alpha$ at the outer edge, and shearing forces Q and $Q + \frac{dQ}{d\alpha}d\alpha$. The equations of equilibrium are derived as follows: Taking moments about the axis OA and considering the fact that the moments M_t and $M_t + \frac{dM_t}{d\alpha}d\alpha$ act at an angle and hence have components in the same direction as M, the following equation results (neglecting terms of higher order):

$$\frac{dM}{rd\alpha} + \frac{M_t}{r} = Q \qquad [59]$$

Likewise, taking moments about an axis perpendicular to OA, the condition of equilibrium gives:

$$-\frac{dM_t}{ad\alpha} + \frac{2}{3}pa^2 + \frac{M}{a} = qR \qquad [60]$$

where q is the load per inch along the edge at an angle α.

By summing up the forces in the vertical direction, the equation

$$\frac{dQ}{d\alpha} + 2apr = qR \qquad [61]$$

results. Assuming that radial cross-sections deflect without distortion, it follows that

$$w = a\phi \qquad [62]$$

where ϕ is the angle which a radial element of the surface makes with the plane of the ring [Fig. 4(b)]. The following equations, fundamental in the theory of bars bent out of their planes of initial curvature, also hold:[9]

$$\frac{M}{EI} = \frac{\phi}{r} - \frac{d^2w}{r^2d\alpha^2} = \frac{w}{ar} - \frac{d^2w}{r^2d\alpha^2} \qquad [63]$$

$$\frac{M_t}{C} = \frac{d\phi}{rd\alpha} + \frac{1}{r^2}\frac{dw}{d\alpha} = \frac{dw}{r^2 d\alpha}\left(1 + \frac{r}{a}\right) \ldots\ldots\ldots [64]$$

Eliminating the unknown quantities M_t, M, q, Q, and ϕ from the six equations, [59], [60], [61], [62], [63], and [64], by successive differentiations and resubstitutions, the fundamental differential Equation [13] is obtained. A solution of this equation, compatible with the symmetry conditions, is:

$$w = C_1' \cosh \gamma_1\alpha + C_2' \cosh \gamma_2\alpha + \frac{2pa^4r}{EI}\left(\frac{r}{a} - \frac{1}{3}\right)$$

To determine C_1' and C_2', the conditions at the end $\alpha = \pi/2$ are used. It is necessary to assume the possibility of a concentrated reaction P_1 at the corner [Fig. 4(c)]. Under this assumption, the boundary conditions become: At $\alpha = \pi/2$, the bending moment $M = 0$, and hence from [63]

$$\left(\frac{w}{a} - \frac{d^2w}{rd\alpha^2}\right)_{\alpha = \pi/2} = 0 \ldots\ldots\ldots\ldots\ldots [65]$$

At $\alpha = \pi/2$, the shearing force $Q = -P_1$ and $M_t = P_1a = -Qa$, from which, using [59], [63], and [64], we obtain the condition:

$$\left[\frac{dw}{d\alpha}\left(\frac{r}{a} + \lambda_1\right) - \frac{d^3w}{d\alpha^3}\right]_{\alpha = \pi/2} = 0 \ldots\ldots\ldots [66]$$

Using the value w given by [17], differentiating, substituting in [65] and [66], and taking $\alpha = \pi/2$, the values of C_1' and C_2' are determined; using these, Equation [20] is obtained.

Discussion

William Hovgaard.[14] The writer believes that Professor Wieghardt's method described in "Drang und Zwang" could be applied to this problem with advantage—at any rate, to the rectangular plates. He also would suggest that perhaps polar coordinates might be applied to the semi-circular plate.

Author's Closure

Regarding Professor Hovgaard's discussion, as the author understands it, Professor Wieghardt's method makes use of the similarity of the differential equation for the stress function corresponding to a state of plane stress or strain and the equation corresponding to the deflection of a flat plate, in order to determine the stress distribution in complicated cases of plane stress or strain by experimental observations on a bent plate, loaded so as to satisfy the required boundary conditions. Thus for a plate loaded only along the boundary, the pressure p is zero, and the plate equation becomes $\nabla^4w = 0$, which is also that satisfied by a plane stress function F. In the present instance, however, we are interested in the stresses and deflections in a plate loaded transversely, and not in the stress distribution in cases where states of plane stress or strain exist. Since the stresses and deflections in plates loaded transversely may usually be measured directly, using apparatus of the kind mentioned in the paper, such tests from experimental solutions of the plate problem, much as Professor Wieghardt's method, form an experimental solution to the problem of plane stress or strain.

Professor Wieghardt's method might be applied to the solution of certain problems involving semi-circular plates where no pressure acts on the surface and all external loads or moments act at the edges. (Such cases were not considered in the paper.) This method would then involve the determination of the stress distribution in the corresponding case of plane stress or strain (by photoelastic or other experimental methods); knowing this distribution, by a process of integration the stress function could be found, and this would enable the determination of the stresses and deflections in the plate to be made. Such a procedure, in the author's opinion, would in general be considerably more complicated than the simple experimental measurement of stresses and deflections on the plate in question. It might, however, be of advantage in a few particular cases where the direct experimental determination of stress and deflection is very difficult.

Regarding the use of polar coordinates, an exact solution of the semi-circular plate problem using these requires that a function for the deflection w be found that will satisfy both the fundamental equation $\nabla^4w = 0$ and the boundary conditions at the edges, these being expressed in polar coordinates. Since the differential expressions for boundary conditions at free edges are rather complicated, no function, to the author's knowledge, has been found that will satisfy the conditions of the case considered in the paper, although solutions have been found for semi-circular plates having all edges either clamped or simply supported (but not free). It is the author's opinion, however, that, where the inside diameter is not too small, the approximate method developed in the paper is sufficiently accurate for most practical needs.

Slag Tap Furnaces

By A. L. BAKER,[1] CHICAGO, ILL.

The molten-slag tap furnace is followed from its original application to a power-plant boiler and brought up to date. The troubles which have developed in operating large furnaces with this type of ash removal are discussed, with the remedies applied. A comparison is made between similar boilers equipped with a hopper bottom and a slag bottom, and some experimental data are given.

THE extremely rapid development of pulverized fuel in all its applications during the last five years has caused attention to center upon its successful production and combustion under varied conditions. The fact that its use is so widespread testifies to the degree of success attained in these two fundamentals. As is usually the case in any mechanical or chemical development, this success has carried with it a number of unsolved problems of such a minor nature that they have been deliberately set aside pending the practical solution of the major problem. With the major problem solved, however, its large-scale application has transformed the former minor problems into major problems of almost first magnitude. Among these supplementary problems are:

1 Fire hazard
2 Explosions
3 Erosion of all parts of boiler and auxiliary equipment
4 Fouling of boiler, economizer, and air heater
5 Handling of ash in boiler, economizer, superheater, air heater, fans, ducts, breechings, and stacks
6 Handling of ash after removal from boiler
7 Prevention of nuisance caused by ash in stack gases.

Needless to say, most of these difficulties have been solved to a greater or less degree in the various applications according to their local importance. A problem which is always present in any pulverized-fuel installation is the removal of ash from the furnace, and one of the solutions proposed for this is discussed herein.

First Slag Tap Furnace

As often happens, the first application of the principle of removing the ash from a pulverized-fuel furnace in molten form was more or less accidental. The idea is not original, however, as the steel industry has used it with great success for a number of years. They first removed molten slag from blast furnaces into ladles and later broke up the hot slag stream with a water jet located at the slag hole, to form granulated slag. This product was more easily handled and disposed of than the chilled slag or "skull" in the ladle, and occasionally had a commercial value. Other industries also have utilized the same principle prior to its application to the pulverized-fuel furnace.

In the 1926 extension to the Charles R. Huntley Station of the Buffalo General Electric Company at Buffalo, four direct-fired pulverized-fuel boilers were authorized. The first of these, No. 13, was installed and operated at high ratings to determine the practical limitations of capacity of this type of equipment and furnace design. This boiler had an 8-ft.-square well, sunk in the flat furnace floor, into which the pulverized-fuel burners discharged. During the operation of this boiler it was noted that pools of slag accumulated in a molten condition at the bottom of the well. This happened in spite of an attempt to keep the well walls as cool as possible and to prevent slagging of the ash by the installation of bare cast-iron and steel blocks on the well tubes.

With that curious twist of the mind which often distinguishes an engineer, a distinct liability was quickly converted into a real asset. The remaining three furnaces were deliberately and courageously designed for collection of molten slag on their flat bottoms, after experiments with handling the slag and disintegrating it with water had convinced every one that it could be done in a practical way. It was thought that the furnaces could be operated at very high rates of combustion per unit volume because of not having to limit the furnace temperature when burning a low-fusion-ash coal. The only limit was felt to be the effect of temperature and erosion on the walls.

Modern Removal Methods

The most successful method of handling the molten ash is today almost exactly that used on the original experiments at Buffalo. The tap hole leads into a cast-iron spout outside the water walls. This spout is usually equipped with bottom liners to regulate the slag level in the furnace and to permit easy replacement when eroded by the movement of hot slag. The slag runs over the liners when the plug is removed, and in falling into the disintegrating chamber passes through a high velocity jet of water. The jet carries the small particles of hot slag against a break-up plate, and this impact, combined with the sudden cooling action of the water, shatters the red-hot slag stream into very small particles. These are then carried off as desired by a low-velocity jet to a storage pit or sludge pump for final disposition. The slag from Kincaid coal from central Illinois when granulated looks like a mass of very coarse black sand. The individual pieces viewed under a magnifying glass are cellular and show a dull iridescence. The particles have all corners rounded and handle easily as a mass without excessive use of jet water. Erosion of sluice plates seems somewhat less rapid with the granulated slag than with the normal hopper-bottom furnace ash.

Use of Low Fusion Ash Coals

Until this first experiment it was thought that low-fusion-

[1] Assistant Mechanical Engineer, Sargent & Lundy, Inc. Assoc-Mem. A.S.M.E. Mr. Baker was born in Englewood, N. J., on Dec. 27, 1897. He was educated in the Williamsport, Pa., and Yakima, Wash., high schools; U. S. Naval Academy, Annapolis, graduating in 1918; University of Washington, Seattle, graduating with B.S. in E.E., in 1922. He enlisted as electrician first-class radio, U.S.N.R.F., at Seattle, April 13, 1917. He was commissioned Ensign, U.S.N.R.F., Oct. 16, 1917; commissioned Ensign, U.S.N., June 1, 1918; commissioned Lieutenant (j.g.), U.S.N., Oct. 16, 1918, serving on destroyer *Jouett* until Aug. 1, 1919; now holds commission as Lieutenant (DV-G) U.S.N.R. Mr. Baker has held these positions: Test engineer, General Electric Company, Schenectady, N. Y., 1922–1923; assistant superintendent mechanical construction, Commonwealth Edison Company, Chicago, 1923–1926; assistant mechanical engineer, Sargent & Lundy, Inc., 1926 to date. He assisted in the design or construction of Calumet and Crawford Avenue Stations, Commonwealth Edison Company; State Line Station, Chicago District Electric Generating Corporation; and Michigan City Generating Station, Northern Indiana Public Service Company.

Presented at the Fourth National Fuels Meeting, Chicago, Ill., Feb. 10 to 14, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

ash coals should be avoided by prudent operators of pulverized-fuel equipment who aspired to relatively high combustion rates and correspondingly high temperatures in the furnaces. The coal burned at Buffalo has about 12 to 14 per cent ash with a fusing point of 1900 to 2000 deg. fahr., and it was successfully burned at rates in excess of 40,000 B.t.u. per cu. ft. per hour with about 18 per cent excess air. Thus the accidental adoption of the molten-slag bottom furnace opened the way for the use of those coals formerly not considered for pulverized fuel, and which were in danger of becoming quite a drug on the market. With all concerned—i.e., the mine owner, mine operator, coal dealer, engineer, and power executive—seeking to lower their fuel cost, and all welcoming this new factor in the burning of the abundant poorer coals, it is to be expected that the adoption of this new bottom should be widespread.

Construction of Early Slag Bottoms

Early liquid or "wet" bottoms were constructed with a flat

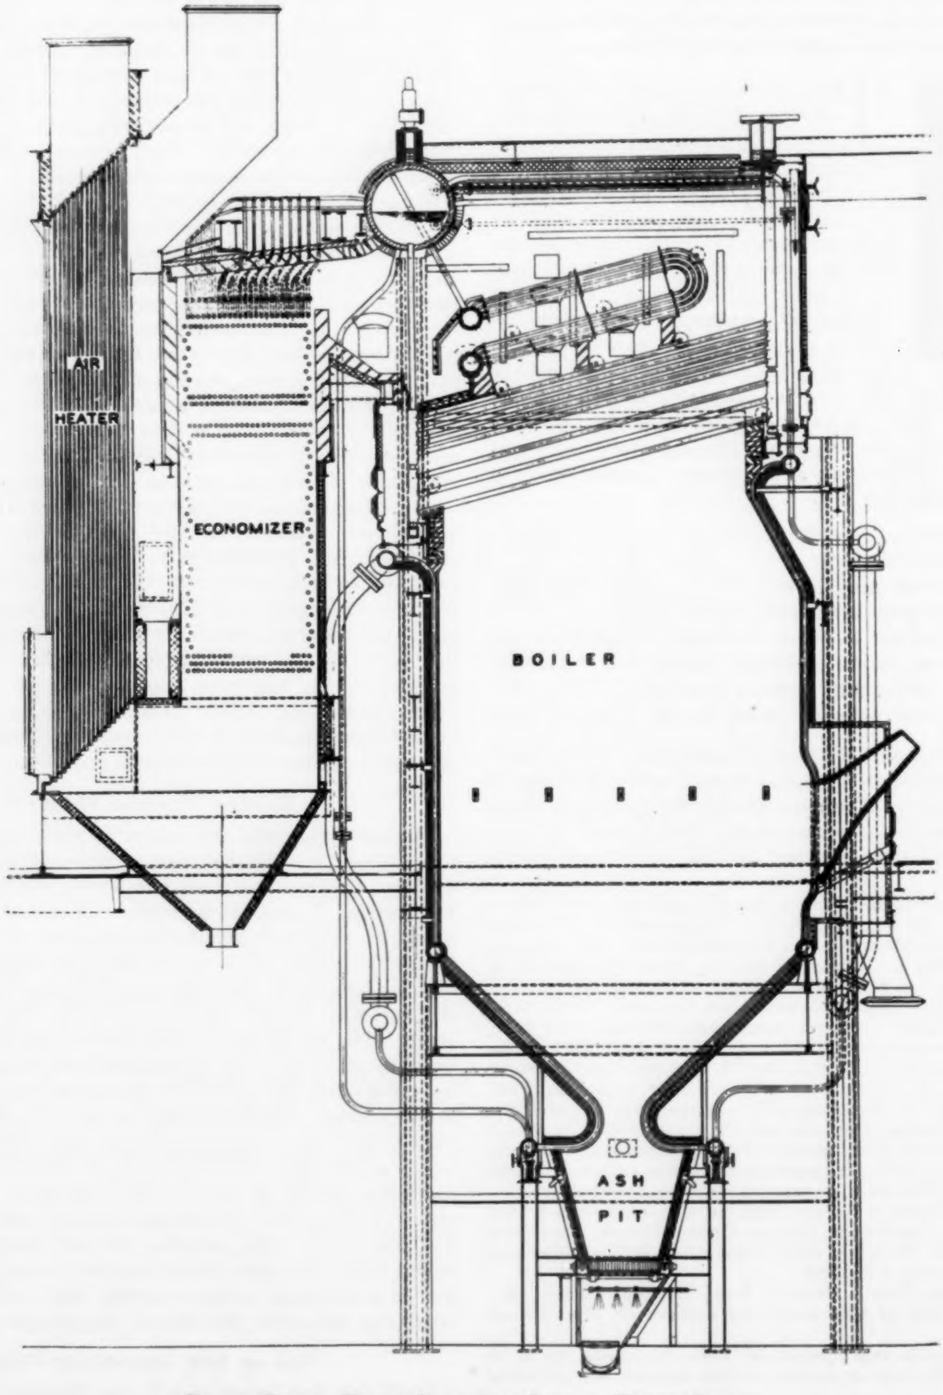

Fig. 1 Boiler, Unit 1, State Line Station, Hopper Bottom

steel bottom plate properly supported on structural-steel members, as illustrated in Fig. 2. This plate was covered with one or more layers of firebrick laid flat and dry. Then 6 in. or more of burned dolomite was added and ramped up to a foot or more in thickness at the corners and along the sides. This use of dolomite, by the way, came to us from the steel industry, which uses it for making open-hearth bottoms and for necessary repairs during a melt. The initial dolomite went into solution or was carried off with the slag soon after melting temperature was reached, but for further shutting down and starting operations of the boiler, the slag itself formed the protective bottom. The slag level was carried according to the convenience of the operators in tapping operations and sometimes attained a depth of $1^1/_2$ ft.

It was soon discovered that slag, when in the molten state, has some of the properties that fuel oil displays on board ship. It can go through cracks apparently invisible to the eye with remarkable facility and volume. Leaks in bottoms were a frequent occurrence, and a shower of molten slag occasionally came through open joints. A firehose quickly applied at the base of the floor was the immediate solution and this point seemed solved.

As the applications grew in size, the problems involved in supporting the slag weights added complications to the steel supporting structures. That old nemesis of many a designer, expansion, began to trouble the operator. As a furnace went into service the dolomite and brick bottom supported the slag. After a period of operation, the dolomite usually went into solution or was eroded by liquid-slag action, and as the temperature and thickness of the slag bed increased, the dolomite and crevices between the bricks were permeated with molten slag. The slag also filled the space between side walls and brick bed, and eventually the bottom became a practically solid mass of molten slag from wall to wall and from bottom plate to top of bed. While the slag remained liquid, no temperature changes in the furnace or bed caused trouble from resulting expansion, but when the boiler was shut down, the liquid slag remaining in the bottom below the slag tap hole quickly froze into a solid black mass. As it cooled, it contracted, and large cracks appeared throughout the bottom. When the furnace was started up, these deep cracks filled with molten slag which froze, and then the whole bottom expanded horizontally. As the mass could not displace within itself, being still a solid, it forced the side walls of the boiler out. This process continued, and the outward pressure on the wall was exerted until the bed was melted down in a continuous line across the furnace. Then the expansion could force slag upward, and the walls were relieved somewhat. However, the pressure was so great during the first part of the starting period that the walls were strained beyond the elastic limit and took a permanent set. This operation proved to be cumulative, and the walls continued to move out slowly but definitely, a movement of an inch taking about six weeks or two months. This condition increased the number of leaks between side walls and bottom of economizer, and added an extra hazard to operation. The speed of outward-wall movement was a function of the frequency of boiler outages.

A further difficulty appeared, in that the movement of hot slag due to flame or air-blast impingement on the bottom in a constant direction caused whirlpools of hot slag. These in turn eroded the bottom material, and eventually caused hot spots in the supporting plate. Apparently the bottom conditions were ideal as a reducing agent for the production of iron from the ash in the coal, and thick chunks of metallic iron were often found in embarrassingly large pieces in front of burner positions. Sulphur compounds were also determined to be present as separate pools within the molten bed. These were of a lower fusion point and less viscous than the slag proper and were very dense. These compounds melted first, therefore, and filled the cracks. On freezing, the typical needle crystals were formed.

Trend of Slag Bottoms in 1928

To summarize the conditions as they existed about 1928, it was thought that the molten bottom furnace would have the following advantages:

1 The first cost of a boiler should be somewhat less.

2 It permitted the burning of low-fusion-ash coals at very high rates of combustion per cubic foot of furnace volume.

3 With the accompanying high temperatures in the vicinity of the liquid bottom, combustion was completed in a minimum of furnace volume—a distinct economy.

4 Satisfactory turbulence could be obtained in a minimum of space with a direct flame impingement on the bottom without damage being caused by erosion to furnace parts.

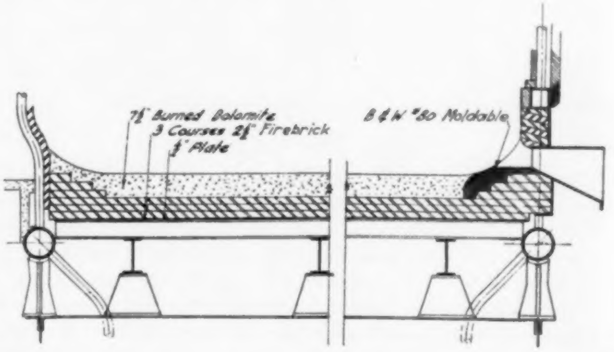

Fig. 2 Boiler 6, Unit 1, State Line Station, Dolomite Bottom

5 Losses due to combustible in the ash could be reduced by burning on the slag surface.

6 A reduction could be made in the height of the boiler-room roof, due to shape of bottom and the reduced furnace volume.

7 Due to completion of combustion in the lower part of the furnace, the gases could be cooled below the fusing point in passing to the generating tubes, and thus prevent slagging of the boiler proper. This assumes that there is provided sufficient cooling surface in the form of tubes or water-cooled walls to absorb the heat.

8 A far simpler system of ash handling could be used and some man power dispensed with.

9 An increase in boiler capacity might be available due to the increased radiation surface of the molten bottom. Absorption of heat by water walls and tubes in the boiler which could "see the fire" should be increased.

10 Reduction of boiler outages due to accumulations of slag not possible to get rid of during normal operation. This of course reduces the spare boiler plant required.

11 Ash from other parts of the boiler setting, such as economizer hoppers and dust-collector hoppers, could be returned to the furnace, melted, and handled with the furnace slag with a minimum of trouble.

12 The production of a "revenue" ash which could be used for fill or railroad grading or in the manufacture of various products requiring a cheap, strong aggregate.

13 The removal of ash is a clean operation, allowing a far cleaner boiler room.

14 It was claimed that a greater percentage of ash recovery was possible due to adhesion of ash particles striking the liquid bottom.

Arrayed against this imposing list of advantages (if true) were the following disadvantages, which were more or less appreciated at the time or which soon developed:

1 It was realized that there were available no materials known to be satisfactory for the make-up of the slag bottom in a permanent form.

2 Expansion of the slag bed when being melted caused wall troubles and leaky tubes.

3 It was difficult to allow for wall expansions parallel to their faces, and at the same time maintain an effective hot-slag seal at the sides and corners.

4 There was a sensible heat loss in the molten slag.

5 High heat radiation from slag bed caused a higher temperature in the furnace below the bottom generating tubes. This caused a somewhat greater slagging up of the boiler tubes.

6 Maintenance of soot-blower units on the lowest generating tubes was high, as these elements were not properly protected against increased temperatures.

The difficulties with slag bottoms in plants of the Chicago district were much greater than in most plants on account of the high percentage of iron and sulphur in the coal, but even so, the troubles encountered were not insurmountable, and there were distinct advantages in continuing the development.

CHICAGO AREA DEVELOPMENT

The first large boiler installation in the Chicago District was made on boiler 6, unit 1, at the State Line Station of the Chicago District Electric Generating Corporation. This boiler was ordered in the summer of 1928 and placed in service in the spring of 1929. The other five boilers of this unit had furnaces as shown in Fig. 1. Except for its flat-brick and dolomite bottom, it was similar in all respects to the other five hopper-bottom boilers of the unit. The boiler was designed to steam at 450,000 lb. of steam per hour normal maximum rating at a working pressure of 700 lb. pressure in the drum and 730 deg. total temperature. The boiler was designed to burn central Illinois "Kincaid" coal[2] at a rating of 1375 per cent and a heat liberation of approximately 34,300 B.t.u. per cu. ft. This boiler was operated as a normal station boiler for the period from July to December, 1929, with the original dolomite bottom constructed as shown in Fig. 2. During this period the following characteristics were noted:

1 Expansion of bed caused a constant outward movement of walls.

2 Slag leaks occurred along walls and at corner seals due to this expansion.

3 Maintenance of brickwork and soot blowers at top of Bailey downtake wall was very high due to high temperatures caused by radiation from slag bed and erosion from molten slag dripping off the generating tubes.

4 Lower generating tubes slagged over more quickly than with the hopper-bottom boilers at the same ratings.

5 Furnace steaming capacity was slightly greater than with the hopper-bottom boilers when boiler was clean, and was reduced after a few hours of steaming, due to difficulty in keeping slag off of the generating tubes.

6 Tapping of slag was simple, though a rather long operation. The time required to tap slag through one spout was about $1^1/_2$ hours for a 24-hour normal day. During this period 425 tons of coal was burned, which contained 64 tons of ash as fired. With an estimated percentage of ash collected in the slag bed of 35 per cent, a total tap per day of 22.4 tons was made. The slag flowed, therefore, at a rate of about 15 tons per hour.

The major trouble experienced in operation was the outward movement of the walls and the subsequent slag leaks. These leaks were dangerous and destructive to the concrete slab beneath the boiler and might have weakened the structural-steel supports of the boiler if not properly protected. It was considered necessary to protect this steelwork by guniting.

After repeated experiments to determine actual wall movements with variation in rating on the boiler, it was finally determined that the walls would be continually moved out unless the boiler were operated at a constant rating without allowing the slag bed to freeze. For temporary protection the bed was trenched all around the walls after eight months of operation, and the walls were jacked back to position. Tie rods and anchors were then installed below the bottom plate, tying the wall headers together with turnbuckles and springs to provide the necessary take-up and expansion. These provisions, though helpful, were not a solution, and it was determined to substitute a new bottom material.

It was demonstrated in this test, however, that the dolomite bottom might be considered a thoroughly practical and economical type for certain applications with less severe conditions and better coal. The trenching operation, which might be required at intervals, is a simple and normal form of maintenance.

SAND BOTTOM

A new bottom was made up, which was placed in service Dec. 17, 1929. Over the bottom plates was laid $2^1/_2$ in. of firebrick. On top of the brick was placed a $2^1/_2$-in. layer of dry sand. This in turn was completely covered with a No. 20 gage plate of special alloy steel containing chromium as a heat-resisting element. On top of this plate was a 10-in. layer of granulated slag for an initial filler. The theory of operation of the bottom was as follows:

After the first slag layer had formed on or in the 10-in. layer of granulated slag, the No. 20 gage plate would form the bottom limit of the molten slag. It was known that the temperature of the molten bed decreased considerably a few inches away from the top and that the fusing temperature of the plate would be a safe amount above the actual temperature at the bottom of bed. The plate would thus prevent penetration of the sand and afford a relatively thin slag bed in which the depth could be controlled. The tap spout was located so as to permit draining the bed to the thin plate level.

This bottom in practice, however, did not corroborate the theory due to the presence of pools of sulphur compounds which attacked the thin plate by erosion and corrosion and permitted penetration of the sand below. The chromium-bearing steel was readily attacked and soon worn through. The presence of the separate sulphur compounds in a molten state was first determined here. They would be in evidence during tapping operations as separate dense streams of very active nature, which would course down the main slag stream like mercury, giving off strong sulphurous fumes which would grow in volume and strength as the bed was tapped nearer the bottom.

This bottom was the first attempt to reduce the side-wall thrust by decreasing the thickness of the bed. It was very simple and relatively inexpensive, and, except for the presence of the sulphur compounds in the Kincaid ash slag, would have been successful.

FIRST COKE-CAN BOTTOM

Experiments were then made on numerous materials,[3] and it was decided to install a bottom made up of round corrugated-steel cans about 8 in. in diameter, filled with compressed coke. The interstices between the round cans were filled with loose coke, iron punchings, coking coal, and other experimental materials. In order to prevent flotation the cans were fastened to the bottom plate with lugs and bolts.

[3] By the Fuller Lehigh Company at Fullerton, Pa.

A 2-in. layer of sand was spread on top of the coke cans to protect the bottom while the initial slag was being formed, and was expected to aid in coking part of the ingredients of the bottom.

It was hoped that the slag would not permeate the coke in the cans, either by absorption or erosion, and that consequently the bottom would remain in a more or less permanent state with its adequate provision to take care of expansion movements. The actual construction is shown in section in Fig. 3.

This new bottom was placed in service on April 20, 1930. It was noted that, as soon as the furnace was heated, gas began to generate from the coke and to seep out along all the walls. The heat of the furnace ignited this gas, and the entire exterior furnace bottom was surrounded for many days with a gas flame of fairly constant volume. It was found that the protective sand layer was blown off the bottom in front of the burners, almost before the boiler was lighted, by the air from the burners, thus exposing the coke to flame impingement from the Calumet burners before the slag could form.

Inspection of the bottom during initial operation showed a number of cans floating in the hot slag. It was at first assumed that these had been insecurely anchored. The wall movement was normal during the first few weeks of operation; that is, the walls returned approximately to cold position each time the boiler was shut down. After this period, however, it was apparent that the slag had begun to permeate the bottom. More cans were observed floating in the bed, the walls started moving out, some major slag leaks developed, and all the old troubles appeared that had occurred on the dolomite bottom. Subsequent examinations of the bed and excavations proved this. Iron was found in metallic form in large chunks weighing as much as 10 tons. No trace of the coke cans could be found in those sections of the bottom most subject to flame impingement and consequently subject to most active slag movement. The photograph of the bottom in section (Fig. 4) is typical of the conditions found in areas subject to slag movement. While theoretically and actually coke is known to resist slag erosion and penetration to a very marked degree, the failure of this bottom is laid to the presence of the sulphurous compounds existing in the molten bed as separate bodies. These compounds are very dense and actively attacked the coke by erosion and chemical combination, aided of course by the high temperature and ideal oxidizing conditions. This bottom is still in service at this writing, however, though it has been necessary to trench the bottom around the walls and to jack the walls in place. The area of coke cans removed in this operation and other excavations has been filled with the original brick, with magnesite and chrome ore (KN) added.

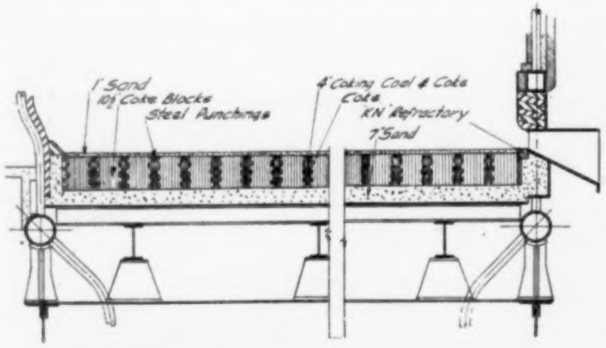

Fig. 3 Boiler 6, Unit 1, State Line Station, Coke-Can Bottom Diagram

First Water-Cooled Bottom

With the rather disappointing performance of this bottom in mind, it was decided to attack the problem of securing a permanent bottom from a new angle. One of the old hopper-bottom boilers at Toronto Station had been converted to a slag tap type by adding a bottom on top of the water tubes of the hopper. It was felt that the successful operation of this bottom was due to the tubes underneath, which carried off heat from the bottom materials and tended to preserve the bottom in its original condition. Probably the wedge action accidentally secured on two sides by placing the bottom on sloping hopper tubes aided considerably. A new water-cooled bottom was designed, therefore, to replace the hopper bottom on the adjacent boiler 5 at State Line Station. This new bottom had a V-shape, though with less slope than the hopper bottom, and was designed to carry a very thin slag bed.

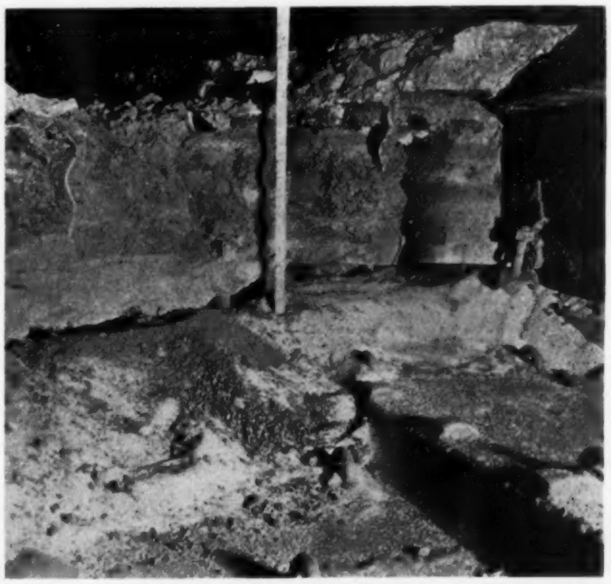

Fig. 4 Boiler 6, Unit 1, State Line Station, Coke-Can Bottom Section of Floor

It was determined to limit the height of the molten bed by tapping more often. With this design, therefore, the slag left in the bottom to freeze would be a very small quantity, and would not present the expansion difficulties of the previous bottoms. The success of the block-faced water side walls in resisting erosion and trouble on the slag line on previous wet bottoms led to the belief that the water-tube cooled bottom, properly faced, would supply the answer to the problem.

Boiler 5 Converted

The bottom installed on boiler 5 (see Fig. 5) consists of $3^1/_4$-in. tubes on 6-in. centers, insulated on the outside. The tubes are completely faced on the furnace side with Bailey bare cast-iron blocks. Over the blocks was placed a layer of dead burned magnesite varying from 3 to 14 in. in thickness. This was in turn surfaced with a 1-in. layer of pyrites. Granulated slag 3 in. deep was then added to control the temperature on the bottom during the first start. This bottom had a total area of about 700 sq. ft., practically the same as boiler 6. Some 1-in. air pipes were installed through the bottom near the throat and connected to the station compressed-air lines. It was thought that oxidation

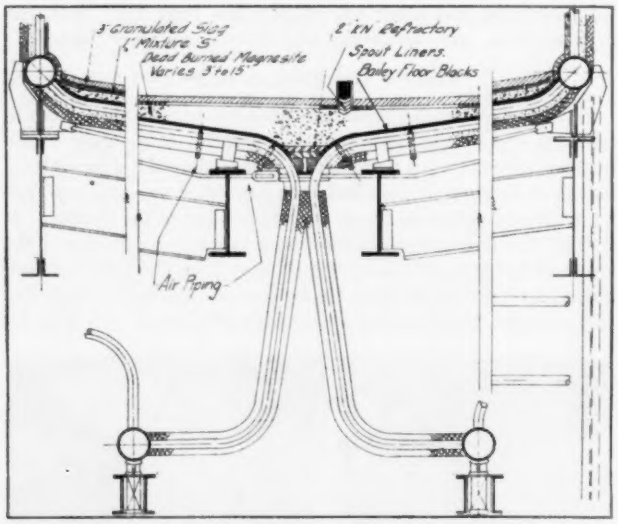

FIG. 5 BOILER 5, UNIT 1, STATE LINE STATION, CONVERTED WATER-COOLED BOTTOM DIAGRAM

of the sulphur compounds could be accelerated in this manner, but in subsequent tests it was found that insufficient penetration of the bed by the air defeated the scheme.

The boiler was first brought up so as to give a rate of increase in temperature at the surface of about 50 to 100 deg. per hour for a period of 36 hours. The pyrites then combined with the magnesite to form a hard crust about 1 in. thick. This crust is an iron-magnesite compound which seems to be solid at 3000 deg. fahr. at surface, and from which the slag can be tapped down to the surface without appreciably affecting the crust by erosion or exposure to furnace-heat conditions.

Figs. 6, 7, and 8 are photographs of the furnace interiors taken at intervals after a considerable period of operation at high ratings. All are taken with furnace down and bottom frozen. Fig. 6 shows a portion of the floor. The pool in the foreground is slag, while along the borders of the bottom can be seen the original magnesite. Fig. 7 shows the floor adjacent to the slag tap hole, and illustrates the cooling cracks which form upon the freezing of the bed. The rough material adjacent to the side wall is the original magnesite. Fig. 8 shows the shrinkage crack between floor and side wall. This crack is continuous along the entire wall, and probably fills first with molten material when the furnace is brought up.

Except for two minor leaks caused by holes being left in the side-wall seals accidentally during construction, this bottom has given no trouble. The wall movement has been practically normal. The lack of a sustained outward movement is caused by the inability of the relatively thin slag bed and bottom to exert a heavy thrust on the walls. That this thin bed can be successfully maintained is undoubtedly due to the cooling effect of the water tubes immediately below.

Cracks occur in this bottom material on shutting down as in the other bottoms, but a system of introducing compressed air into the bottom during the starting period to prevent molten slag getting in them has been tried out with success. This boiler has been in operation and under test for the period from Aug. 28, 1930, to Dec. 11, 1930, and has shown no major troubles or defects. It has been subjected to abnormally hard service conditions during this period. Its obvious disadvantage is in invest-

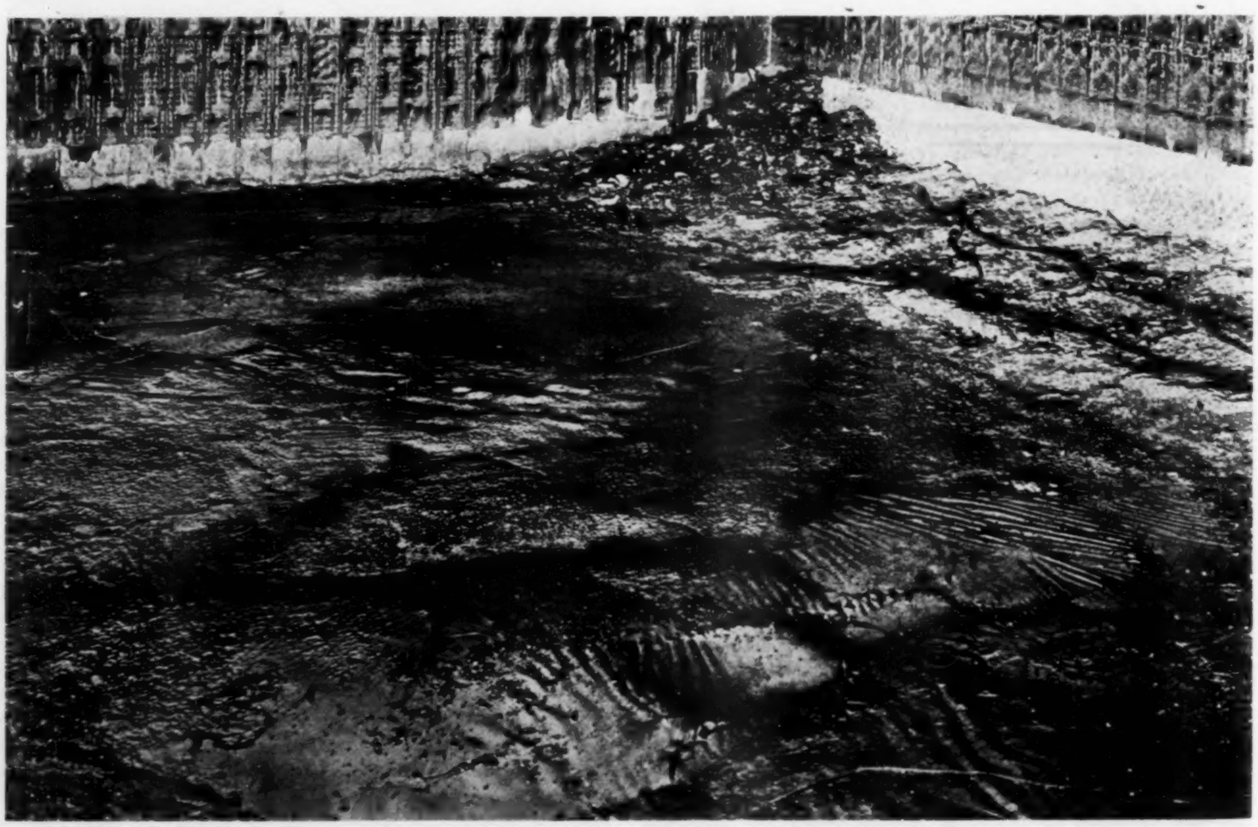

FIG. 6 BOILER 5, UNIT 1, STATE LINE STATION, VIEW OF CORNER

ment cost. It is a much more expensive type than the dolomite bottom, and thus offsets one of the advantages which should be available in this type of bottom.

The boiler was again placed in service on Jan. 1, 1931, after some alterations in the upper furnace for experimental purposes, and additional tests were made during January.

Late Installations

In an effort to design a bottom for handling molten slag which combined the virtues of low first cost, low maintenance, and no wall trouble, the air-cooled bottom was introduced late in the fall of 1930. A typical example of this type of construction, illustrated in Fig. 9, is now installed on boiler 1, at the Michigan City Generating Station of the Northern Indiana Public Service Company.

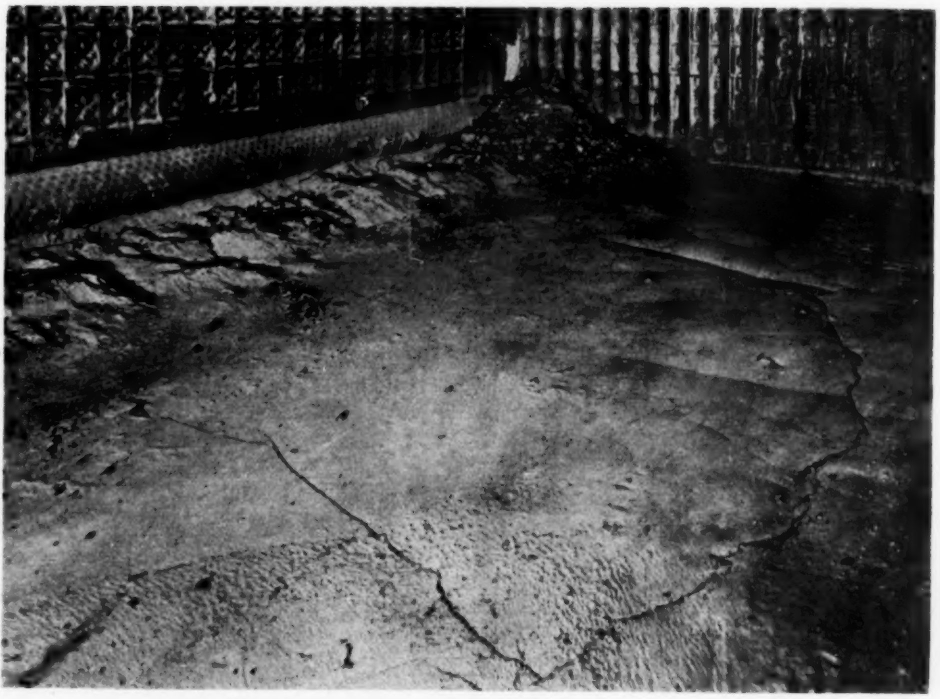

Fig. 7 Boiler 5, Unit 1, State Line Station, View of Floor Cracks

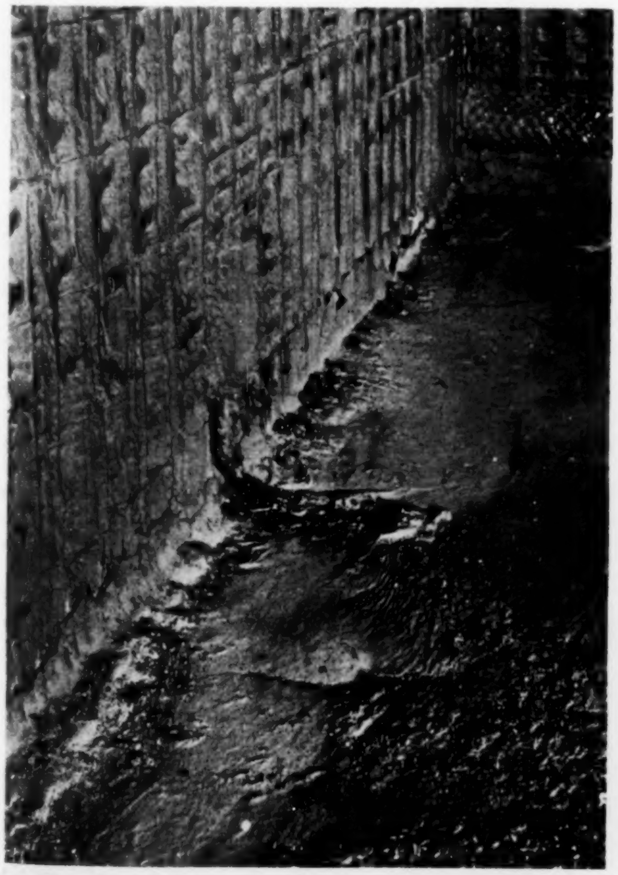

Fig. 8 Boiler 5, Unit 1, State Line Station, View of Slag Tap Hole

A $^1/_4$-in. flat bottom plate is provided, supported by the usual structural members, but unique in that the sides are turned up in a generous curve like a frying pan. This feature was intended to provide a means of taking up expansion within the bottom itself, without carrying thrust into the side walls. Firebrick was laid $12^1/_2$ in. thick on top of the plate, and the brick in turn was covered with 3 in. of magnesite mixed with a special liquid known as "liquid U." A layer of $1^1/_4$-in. split brick covered this mixture, laid with a slope toward the slag tap hole. A mesh screen was placed on the split brick, and 3 in. of granular slag was added for original firing.

At frequent intervals throughout the bottom vertical perforated pipe nipples were installed extending about 6 in. above the bottom plate. These were packed with The Babcock & Wilcox Co.'s No. 80 moldable mix, and dry magnesite was added around the nozzles. These pipes were connected with headers to a motor-driven compressor, which developed about 29 in. of air pressure to insure an even distribution of air to all nozzles. The air is intended to circulate from the nozzles to the split-brick "roof," and then flow to the side walls and through orifices into the furnace. The air thus acted as a cooling medium under the roof, similar to a water-cooled bottom. Metering equipment was also provided to meter all air fed into the furnace through the bottom. This type of bottom is more expensive in first cost than the dolomite type, due mostly to the compressor and piping. It has also the disadvantage of requiring continuous auxiliary power for proper operation. An attempt has been made on this bottom to deflect the heavy side thrust of the expanding slag bed upward by providing special ledge blocks on the wall tubes at the slag line. These blocks extend below the slag bed at a fair angle, the theory being that side expansion of the slag crust will be turned upward and the bed cracked or broken up by the turn.

This boiler is now ready for service (January, 1931), but has not yet carried any appreciable load, pending start of turbine operation.

Flat Water-Tube Bottoms

A development of the water-tube cooled bottom as successfully tried out on boiler 5, at State Line Station, but with a decided saving in first cost, is exemplified in the two other boilers installed at Michigan City. The first of these (boiler 2) is equipped with what may be called a transverse, straight-tube, water-cooled bottom (see Fig. 10). It has the usual flat bottom plate without the frying-pan feature because of the relatively low temperatures expected on it. Above the plate is a layer of loose-laid firebrick which varies from 5 to $7^1/_2$ in. in thickness. Then the $2^1/_2$-in. cooling tubes are laid in, extending from an outside header at the front of the boiler to another header at the tap or downtake wall. These headers are connected to the boiler circulating system with special tubes. The bottom tubes have a slope toward the downtake wall of about $^1/_4$ in. per ft. Above the tubes are laid $^1/_{16}$-in. steel plates overlapped to provide for expansion. On the plate are 4 in. of dry magnesite and then 3 in. of granulated slag, all sloped toward the tap hole. This boiler is also ready for service at this writing, but has not yet carried load.

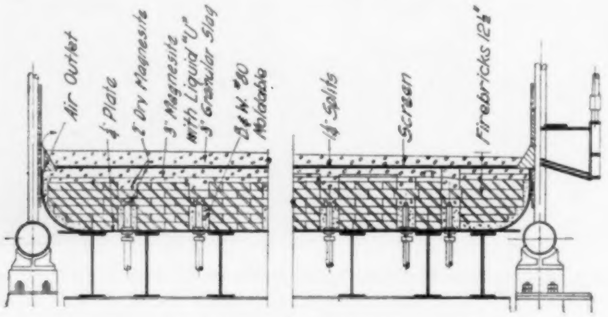

Fig 9 Boiler 1, Michigan City Generating Station, Air-Cooled Bottom

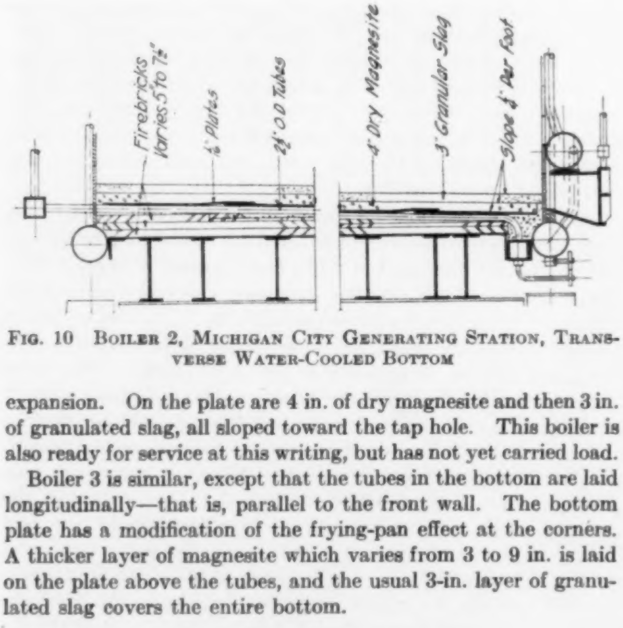

Fig. 10 Boiler 2, Michigan City Generating Station, Transverse Water-Cooled Bottom

Boiler 3 is similar, except that the tubes in the bottom are laid longitudinally—that is, parallel to the front wall. The bottom plate has a modification of the frying-pan effect at the corners. A thicker layer of magnesite which varies from 3 to 9 in. is laid on the plate above the tubes, and the usual 3-in. layer of granulated slag covers the entire bottom.

Other Applications

Other applications in the Chicago district include the following slagging boilers on major power plants ordered or in service:

Waukegan Power Station No. 6 of Public Service Company of Northern Illinois: Unit 4, one water-cooled boiler and two coke-can bottom boilers. Unit 5, three water-cooled boilers.

Powerton Power Station of Super-Power Company of Illinois: Unit 2, boiler 2-1, dolomite bottom; boiler 2-2, hexagonal coke-can bottom; boiler 2-3, corrugated coke-can bottom. Unit 3, boiler 3-1, sloping water-cooled bottom; boilers 3-2 and 3-3, air-cooled bottoms.

Test Data

Some miscellaneous data and curves are given in Tables 1 to 3 to illustrate the physical nature of the molten slag from Kincaid coal.

TABLE 1 TYPICAL ANALYSIS OF SLAG ASH

	Buffalo[a]	State Line	Comparative analysis Slag and flue dust	Flue dust
Carbon	0	0	0	0.98
Silica (SiO_2)	44.52	37.42	43.43	46.36

Through 200 mesh	97.3
Through 325 mesh	91.5

Test data on distribution of ash throughout the boiler setting have been rather unreliable to date. Although many ash balances have been made and reported, there are some factors that are extremely hard to determine accurately, and the unaccounted-for losses are sometimes charged against other partially determined parts of the balance. For instance, it is common practice to assume that all ash fired should be accounted for in slag or ash to the flue. This is incorrect, as the "ash in the coal" determination is commonly made at low temperatures of about 900 deg. fahr., while the burning of the coal occurs in temperatures around 2800 deg. fahr. At these high temperatures it is known that a portion of the ash will be volatilized, and so may not be measured as dust at the stack. This may represent a percentage of the ash as high as 15 per cent.

The distribution of ash, as given in Table 4, varies with boiler rating, the collection in the furnace increasing with rating, as is also the case with a hopper bottom.

TABLE 4 TYPICAL DISTRIBUTION OF ASH

Ash content by analysis (dry basis) of average Kincaid sample, per cent	13.97
Total ash per lb. dry coal, lb.	0.1397
Ash to flue per lb. dry coal, lb.	0.05
Ash collected as slag per lb. dry coal, lb.	0.06
Ash collected on boiler tubes, economizer hoppers, etc., and removed by soot blowing operations, lb.	0.03

TABLE 5 ASH COLLECTION IN FURNACE PLOTTED AGAINST RATING

Boiler rating, lb. per hour	220,000	300,000	375,000
Collection in slag bottom, per cent	25	24	36
Collection in hopper bottom, per cent	23	26	36

A typical curve of collection in the furnace plotted against rating is given in Table 5. These readings must be considered as an approximation only, as there are insufficient test data available for more exact figures.

CONCLUSIONS

1 The slag-bottom boiler is undoubtedly in the process of major development at this writing. It will require considerable time and further experimentation with designs and materials before all the facts required for a final analysis may be established. The problems involved when using many coals other than Kincaid are undoubtedly easier of solution.

2 Sufficient progress has been made, however, with the present installations to establish the following summary of advantages and disadvantages as they may be considered to exist today:

Advantages:

(*a*) A practical molten-slag bottom can be installed at less first cost than a water-cooled hopper bottom.

(*b*) Any low-fusion-ash coal may be burned in pulverized form in an economical furnace using the molten-slag bottom.

(*c*) Any type burner may be used and turbulence of flame assisted by impingement on the molten bottom, if required, without damage to furnace or bottom.

(*d*) A saving in building height and cost may be obtained by using a lower setting. Very little headroom is required for handling the granulated slag.

(*e*) A simple and cleanly system of ash handling can be used.

(*f*) Dry dust collected from other parts of the boiler may be conveniently and automatically melted in the furnace bottom, thus eliminating duplication of ash handling in dry and molten form.

(*g*) Increased radiation absorption from the slag bed develops higher efficiencies from the exposed surfaces.

(*h*) Recent tests in one of the Chicago area stations seem to indicate that fairly coarse coal may be burned readily with an appreciable saving in mill maintenance.

Disadvantages:

(*a*) Expansion movements of the furnace-bottom materials cause wall troubles and slag leaks.

(*b*) A satisfactory and permanent seal between walls and bottom has not yet been developed.

(*c*) The high temperature existing in the vicinity of the lower generating tubes due to radiation from the slag bed causes fouling of these tubes, and consequently the boiler must be blown or hand-lanced more often.

(*d*) Low soot-blower elements near the furnace must be protected from high temperatures.

3 A balancing of the preceding items from the designing engineer's viewpoint would indicate that the slag tap furnace has certainly justified the efforts expended to date. Its development will proceed more rapidly with the present confidence existing in the correctness of its basic principles.

Discussion

P. B. RICE.[4] The Special Research Committee on the Removal of Ash as Molten Slag From Powdered-Coal Furnaces would submit a statement of the work being done under the supervision of the committee by the Pittsburgh Experiment Station of the U. S. Bureau of Mines.

The program which is being followed is a sequence of the limited studies made by the bureau at the Toronto Station of the Pennsylvania-Ohio Power & Light Company, the results of which were presented to the Society[5] in 1929. These studies showed that a coal having an ash with a high fusion temperature did not form a molten bed, so that the ash could not be removed by tapping. It followed that it was necessary to know the possibility of adding materials to flux the ash deposited in the furnace. The bureau undertook to make such a study, the committee supplying funds for all special equipment required and the extra money required for field work, should this be necessary.

The work was started in September, 1929, and it is expected that a full report can be submitted later this year. The program called for the following method of attack:

(1) *Small scale laboratory tests*, by which the fluxing effects of admixtures were to be determined under the ideal conditions of intimate mixture and uniform temperature. It was not proposed to undertake an extended fundamental investigation of the relationship of viscosity to the composition of slags, because years would be required for the complex systems involved; rather it was hoped that a spotting of the field would be sufficient.

(2) *Large scale laboratory tests* in a gas-fired furnace having a slag hearth of $2^1/_2$ by 3 ft. This area would be large enough to check conclusions arrived at from the small-scale tests. It was proposed also to use this furnace to study mass effects, influence of size, and other factors simulating the application of fluxing to a full-size furnace.

(3) *Plant Tests*. The objects of work conducted at plants would be to confirm the laboratory results and to develop the mechanical details for the addition of the flux.

Instead of working with synthetic mixtures, as would be done in a truly scientific investigation, large samples of ashes or slags were obtained from eight power stations using coals which fairly well cover the range of variations in composition of the ash. These ashes had fluid temperatures, determined by the A.S.T.M. method, of from 2470 to 2940 deg. fahr.

Most of the work to date has been on the small-scale laboratory tests, the apparatus consisting of a platinum-wound furnace and platinum crucibles in which to heat the mixtures. The technique consists, in brief, in determining the temperature at which the molten mixture has a standard viscosity as measured by the feel of a platinum stirring rod; the viscosity used as standard corresponds to that of a slag which gave free flow at Toronto. Determinations are not made if the fluid temperature is above 2650 deg. fahr., which was taken as the maximum possible of a slag bed; the lower limit was fixed at 2300 deg. fahr., which is low enough for any application of the slagging method likely to be used.

Materials studied as possible fluxes have included iron oxides, limestone, dolomite, magnesite, fluorspar, saltcake, silica, open-hearth waste slags, low-grade clays, as well as mixtures of some of these. This laboratory work has been, in effect, a study of various component systems, but the complete field has been covered only for a few of the infinite number of combinations possible.

Only a few large-scale laboratory tests have been made, but further work is now under way to study the mass effect and the time required for the flux to penetrate into the bed; also to study the relative action of fluxes which themselves melt at a low temperature, such as saltcake and those which are refractory by themselves, such as limestone.

---

[4] General Engineer, Allied Engineers, Inc., New York, N. Y.; Chairman, Special Research Committee on the Removal of Ash as Molten Slag From Powdered-Coal Furnaces. Assoc-Mem. A.S.M.E. (Mr. Rice not being present, the report was read by Mr. P. Nicholls, of that committee.)

[5] Sherman, Nicholls, and Taylor, "Study of Some Factors in Removal of Ash as Molten Slag From Powdered-Coal Furnaces," A.S.M.E. Trans., paper FSP-51-51, pp. 399–413.

The occasion has not arisen as yet to do field work because of a plant being in difficulties due to inability of the slag to run, and the assumption is that coals with refractory ashes have not been used. Studies are, however, being made for one plant which burns oil and in which the deposited slag is not fluid, and recommendations for fluxes have been made.

One of the objects of the committee in presenting this report is to acquaint those using or considering the use of slagging furnaces with the availability of help from the committee or the bureau; also to invite the cooperation of individuals interested in the subject. The benefits possible by the use of fluxes are not limited to continuous slagging of the whole bed. The following conditions are occasions where the use of a flux might be necessary; they are stated in the order of their probability of occurrence:

(*a*) That a flux would be useful, and perhaps sometimes necessary, to make more fluid the portion of the bed around the tap hole; thus the flux would be used only occasionally and in relatively small quantities.

(*b*) That a flux might be used occasionally over the whole bed to make it possible to more thoroughly drain the bed before the boiler was shut down for repairs; the use of a flux would permit of this being done without maintaining an abnormal overload over a long period. The reason for desiring to drain the bed might be one of several, of which one might be the avoidance of strains because of the shrinkage of a large mass of slag.

(*c*) That a flux over the whole bed might be required occasionally because a shipment of coal contained ash with a higher than normal fusibility.

(*d*) That in a large furnace the use of a flux was required continually because the deposited ash was never fluid enough to run.

(*e*) That the slagging-bottom design was applied to smaller furnaces and boilers in which the furnace temperature was materially lower than is customary in larger furnaces; consequently, the range of coals that could be used would be narrower and the need of a flux more probable.

The original reason for starting the investigation was to protect against (*c*) and (*d*), which assume that the deposited ash is not fluid at 2550 to 2600 deg. fahr., or, in other words, a fluxing effect is required to reduce a high-fusion ash to one fluid at 2550 deg. fahr., which is assumed to be the temperature at which the bed can be maintained in large furnaces. The other three conceived possibilities involve the assumption that the deposited ash is fluid at or below 2550 deg. fahr. and that the flux must reduce its fluid temperature still further.

The latter conceptions will explain why the attempt was made in the tests to bring the fluid temperature down to 2300 deg. fahr. or lower, and why studies were made on ashes which had normal fluid temperatures lower than 2550 deg. fahr.

The advisability of extending the investigation to plant application and experimentation will depend on the experience of those operating furnaces equipped with slagging bottoms. Their reactions and recommendations are required as guides.

P. Nicholls.[6] As stated in the report presented by Mr. P. B. Rice, we have been studying some of the factors associated with the slagging-bottom type of furnace as applied to the burning of pulverized coal. Although we have had samples of ash and slag and have obtained data from several operating companies, yet previous to the presentation of Mr. Baker's paper we had not been in touch with the State Line Station. Since then, they have supplied us with small samples, and also with some further records of their own analyses.

The form of construction of the bottom or hearth is outside our investigations except as far as it affects the deposition of ash, the depth of the bed of slag, and the temperature gradient through it, or as the bottom reacts with the slag.

The author attributes the peculiar trouble they have had and the fluidity of the slag to the high percentage of iron. The writer suggests that as far as the ash in the coal is responsible, it is because of its high percentage of calcite, which is much smaller in Eastern coals. Our study of the fluxing phase has developed a fairly complete set of data on the relation between the "flow temperature," or the temperature at which the slag is fluid enough to flow, and the composition of mixtures of coal ash and fluxes; the most interesting set are those including iron and lime. Iron oxides by themselves will not produce a slag fluid at a very low temperature. The "flow temperature" decreases as the percentage of iron oxide increases up to about 22 per cent, when it is about 2640 deg. fahr., with 1 per cent lime; further increase leaves the flow temperature stationary, but somewhat decreases the fluid range. Slag having the equivalent of 42 per cent ferric oxide and 1.4 lime has a flow temperature of 2590 deg. fahr.

The sample of slag from State Line which we received analyzed: SiO_2, 38.6; Al_2O_3, 15.4; Fe_2O_3, 11.7; FeO, 19.3; Fe, 3.1; CaO, 7.6; MgO, 0.8; SO_3, 0.2.

The flow-temperature determination gave 2545 deg. fahr. for the as-received sample, and 2495 deg. fahr. after the iron was oxidized, which values are about 80 deg. lower than they would have been if the lime were around 1 per cent. In addition, the lime increases the fluid range between the plastic and flow state, changing it from a value of 80 deg. to one of 250 deg. The State Line slag differs from the Deepwater in having a 2.5 silica-alumina ratio as against 1.72, which also influences the effectiveness of the 7.6 per cent of lime, which amount has little fluxing effect on the Deepwater.

The author does not emphasize the influence of the flame impinging directly on the bed and the comparatively small travel before it strikes the slag. The suggestion is made, however, that this is the real distinctive feature of the State Line installation and the primary reason for the peculiar properties of the slag as compared, for example, with Deepwater or Toronto. The direct impingement will occur before combustion is complete, and one would expect that it will maintain a highly reducing atmosphere over that part of the bed; it will also produce a high temperature there and, as the author states, will tend to cause a motion at the surface and probably considerable convection in the slag.

Does not this offer a simple explanation for the peculiarities? The particles of iron pyrite will take longer to burn than the coal, and many of them will strike the bed unburnt and, because of their density, with considerable force. There will be a greater probability of their being held by the surface, and, because of the reducing conditions, will have no opportunity to burn. If they are not at once buried in the slag, and even if they melt, their greater density will tend to make them sink and ultimately reach the lowest level permitted by the temperature gradient in the bed.

Speculation on the reason for the large masses of molten iron is questionable, but it is quite possible that the metallic iron is formed in the reducing area at the surface, and that an explanation based on action at the bottom may not be required. The metallic iron would sink lower than the sulphide, and there would be more chance of it remaining there during the tapping. Even so, some of the burning snake appearing on the surface during tapping may be iron burning, though its presence would be hidden by the burning sulphur.

---

[6] Supervising Fuel Engineer, U. S. Bureau of Mines, Pittsburgh Experiment Station, Pittsburgh, Pa. This discussion published by permission of the Director, U. S. Bureau of Mines. Not subject to copyright.

Although the author does not so state, it may be assumed that one of the objectives of impinging the flame on the bed was the expectation that it would result in the deposition of an increased quantity of ash. If this be so, how far was it successful? The fact that the percentage of the ash collected in the wet bottom was no greater than that in the dry, does not indicate much success.

A determination of the "flow temperature" of the average ash of the Kincaid coal was made and gave 2580 deg. fahr. in an oxidizing atmosphere, showing that if the whole of the ash of this coal could be deposited on the bed, then it could be tapped successfully.

One would think that the direct impingement of the flame would have tended to cause the retention of a large percentage of the fluxes in the bed, that is, to cause a large selective action. Actually the selective action is less than at Deepwater with its horizontal flame.

	Fe_2O_3 in the coal	Fe_2O_3 (equivalent) in the slag

This selective action in the furnace as fixing the quality and the quantity of ash deposited and of fly ash is fundamental in the slagging operation, and an understanding of it is necessary if maximum slag deposition is desired. The Special Research Committee has approved the suggestion that a study of the selective action shall be the next phase of the investigations the bureau is making on factors connected with the use of fuels in slag tap furnaces.

Design Features and Operating Results of Fairfield Blast-Furnace Power Plant

By F. G. CUTLER,[1] ENSLEY, ALA.

This paper discusses one of the latest blast-furnace power plants, built at the Fairfield Steel Plant of the Tennessee Coal, Iron & Railroad Company, and shows that by the improvement in efficiency in general it was possible to increase the electric power generated from surplus blast-furnace gas per ton of product about 50 per cent over what was average practice nine years ago, this result being due to increased efficiency of boiler plant, as well as to the increased amount of blast-furnace gas available. The operating results for a week's period are given, as well as descriptions of the automatic combustion control employed, the system of utilizing surplus steam from an adjacent plant, the method of handling water systems, and other unusual features.

ONE of the most modern power plants in the steel industry is located at the Fairfield Works of the Tennessee Coal, Iron & R.R. Company, and the operation has been so satisfactory that it is believed that a presentation of some of the unusual features and operating results will be of interest to those engineers who are concerned with blast-furnace power plants.

Descriptions of the plant have been published so that it is not necessary to list the several units composing the station, but reproductions of drawings are included in order to show the principal features.

Fig. 1 is a view showing blast furnaces Nos. 5 and 6 and the power house; Fig. 2 is a general cross-section of the power plant showing the relation of the boilers to the turbo-blowers and power units; Fig. 3 is a cross-section of the boiler setting, showing the relation of the boiler to its auxiliaries, and Fig. 4 a view of the coal-pulverizing and water-treating plants and cooling towers.

No complete test has been made of the entire plant, but as it is equipped with recording meters, gages, and pyrometers, it is possible to check the operating efficiencies continually, and in the following discussion some of the operating results will be presented.

Since it would not be possible within the scope of the paper to furnish complete data, especial attention will be given to answering the questions most frequently asked by those who have visited the plant.

The power plant consists of five boiler units; two 20,000-kw. turbo-generators and three 75,000-c.f.m. turbo-blowers, with auxiliary equipment.

Each boiler is equipped with economizers, air heaters, and superheaters, and the combustion chamber is equipped with air-cooled hollow side walls, a bare-tube front-wall section above the burners, and tubes faced with refractory and cast-iron protection for the back of the combustion-chamber hopper. Four of the five boilers are equipped with powdered-coal burners supplied with coal from storage bins. These bins are filled through a 5-in. pipe line from an adjacent coal-pulverizing plant which has steam-heated rotary-type coal driers, the coal burned being a middle product of the coal washers.

Automatic control of air and gas supply is provided, but there is no automatic control of the powdered-coal feeders as the amount of coal burned at present would not justify its installation.

The turbo-generators and turbo-blowers have surface condensers, and, owing to the shortage of plant cooling water, the condensing water is cooled by natural-draft cooling towers.

There are two steam pressures used at this plant, the higher, of 325 lb. gage and 200 deg. fahr. superheat, supplying the main units and main boiler auxiliaries (fans and two feed pumps driven by geared non-condensing turbines), and the lower, of 200 lb. and about 100 deg. superheat, supplying the condenser auxiliaries, boiler soot blowers, and the blast-furnace plant for operation of bells, mud guns, etc. The line supplying this 200-lb. steam is connected to a battery of waste-heat boilers (located in the adjacent open-hearth plant), this boiler plant supplying steam to a pump and compressor station, and several mills in the Fairfield steel works.

Steam is supplied from the high-pressure system to the low-pressure system through two reducing valves controlled from the 200-lb. system.

The condenser circulating-water pumps of the five main units are each driven by both motor and geared turbine, each of sufficient capacity to drive the pump, and the steam drive is utilized to the extent of the supply when available and to maintain sufficient exhaust-steam supply to the deaerating type of open feedwater heaters.

It is therefore possible to supply steam from the blast-furnace system to the open-hearth system and also to absorb surplus steam from the open-hearth system into the blast-furnace system for operation of auxiliaries when it is available, and maintain a uniform pressure on the mill steam system, which has a variable demand and which is supplied from waste-heat boilers. This connection does away with the necessity of auxiliary gas fuel for the waste-heat boiler.

The condensate is returned to a storage tank above the heaters, and make-up is supplied to an underground sweet well from the water-treating plant which furnishes the open-hearth boilers

[1] Chief of Bureau of Steam Engineering, Tennessee Coal, Iron & R.R. Co. Mem. A.S.M.E. Mr. Cutler was educated at the University of Kentucky, receiving the degree B.M.E. in 1901 and M.E. in 1904. He was assistant in the steam engineering department of the South Works of the Illinois Steel Company from 1901 to 1906. He then became steam engineer of the Tennessee Coal, Iron & R.R. Co. at its Ensley plant, and later was appointed to the position he now holds. He was a member of the Executive Committee of the Birmingham Section during the organization period in 1915, served as its chairman in 1920–1921, and has presented papers before the Society dealing with steel works problems. He is also a member of the American Iron & Steel Institute, the Birmingham Engineers Society, and the Iron & Steel Electrical Engineers.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Birmingham, Ala., April 20 to 23, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

with feedwater. Water from the sweet well is admitted to one or more of the blower condensers and pumped to the feedwater tank over the heaters.

When the plant was designed it was expected that there would be a surplus of steam from the open-hearth plant at all times, but due largely to increased demands of steam by the mills there is usually considerable steam delivered from the blast-furnace system to the open-hearth system. As a consequence of this loss of high-pressure steam it is necessary to add about 10 per cent of treated water to the system.

The cooling water required by the power house to make up the loss at the cooling towers and for water supplied to the blast-furnace high-pressure water system, ash-sluicing system, etc., is first treated with lime and iron sulphate and filtered in a separate plant (shown in Fig. 4), and then delivered through the generator air and transformer oil coolers to a sump in the power-house basement. Motor-driven pumps deliver this water to the cooling-tower system and to the turbo-blower jackets so that the total fresh water used by the plant is usually less than 3 per cent of that circulated, and the various cooling surfaces are therefore found to be relatively free from contamination.

The blast-furnace plant is equipped with eleven Cottrell-type electric precipitators, eight of which clean all the gas from the two furnaces going to the boilers and stoves. The stove gas is sent by a separate main from the boiler house through the three remaining precipitators, thus receiving a double cleaning.

The average amount of flue dirt in the blast-furnace gas, as shown by the Brady method and by the continuous dust-recording equipment described by Dr. A. W. Simon of the company in a paper presented at the October, 1930, meeting of the Ameri-

After the plant was started the connection from the power company was maintained for protection and regulation, and an arrangement was made with the power company by which surplus power generated from blast-furnace gas was delivered to the power company's lines whenever the supply of water at their hydroelectric plants was not sufficient for all demands without operation of steam stations.

Owing to the ample supply of water available at the power company's hydroelectric plants there has been a surplus of blast-furnace gas wasted at the bleeders of the blast furnaces

most of the time, but there have been periods during which the power company took surplus power when practically all of the surplus gas was consumed by the boilers.

One such period, when only No. 6 blast furnace was in service, occurred during September, 1930, and the principal data for a week of this period during which three boilers operated are given in Table 1.

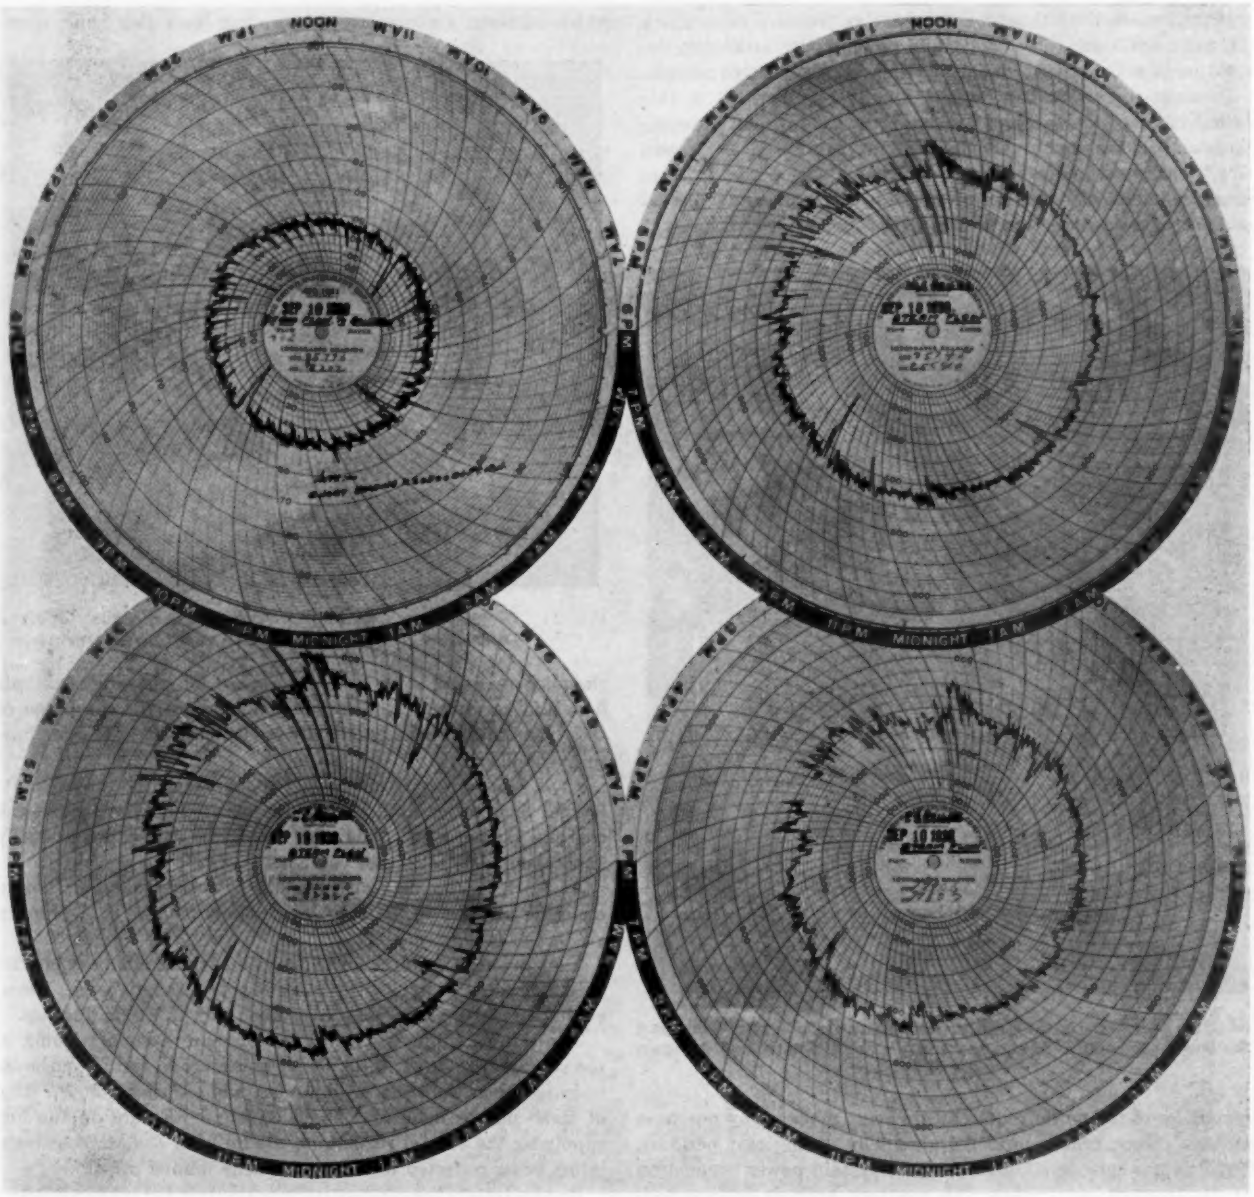

Fig. 9 Charts Showing Gas Flow to Boiler Plant and Steam Flow From Boilers

The B.t.u. in blast-furnace gas from coke as shown in this table are calculated by the method given in a paper presented at the Spring Meeting of the A.S.M.E. in Atlanta, May, 1922, the furnace coke averaging 92 per cent carbon.

The fuel value of the coal charged into the furnace (in order to add tar vapors for better cleaning by the Cottrell precipitators) was included separately at 12,000 B.t.u. per lb. The data for the period from September 9 to 13 (Tuesday to Saturday, inclusive), when there was a market for practically all surplus power, indicate that less than 5 per cent of the top gas was lost at the bleeders, and an average of 22,632 kw. per hour was generated with 5.5 per cent of the boiler fuel being powdered coal. The steam sent to the open-hearth system in this period, if it had been used for power, would have increased the total power generation to about 24,000 kw.

In the paper referred to previously it was shown that the steam available from surplus gas after the blast had been heated was a function of the coke rate, hot-blast temperature, and stove and boiler efficiency, and a formula was given showing the relation of steam from surplus top gas after the blast had been heated for an assumed standard efficiency of 66.6 per cent for boilers and 60 per cent for stoves, these efficiencies being considered good average practice at the time the paper in question was prepared (about nine years ago).

In order to show how boiler and stove efficiencies have been improved in a relatively short time, a comparison is given in Table 2 of the assumed efficiencies of that paper with the actual results at Fairfield for the period of five consecutive days shown in Table 1 during which the power company took surplus power, based on the coke rate of 3219 lb. per ton of product.

A symbolic chart showing total hourly power production at Fairfield and Ensley, and purchase and sale of power, is shown in Fig. 7, the full lines showing conditions for the entire week, and the broken lines those for the five-day period during which the mills operated, this chart being prepared by arranging the total loads in the order of magnitude over the respective periods.

Recording charts taken for one day (September 10) in this period indicate the extent of variation in electric power conditions and in the steam and gas pressure, feedwater, and steam flow from the three boilers in service for this period. From these the effect of reduction of gas production at a cast period is reflected in a reduction of steam and power production, the remainder of the power requirements being made up by purchase or sale. Some coal is burned (principally during cast periods), but it is not considered advisable to maintain power production at the normal rate unless the contract limit is approached. Power is purchased on a kva. contract, and the generators in service are automatically regulated to maintain a uniformly high power factor on the purchased power.

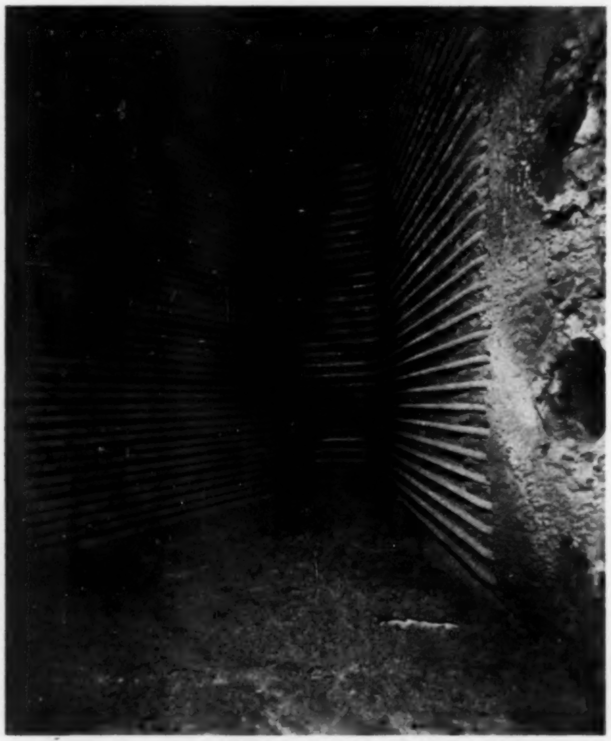

Fig. 10 View Looking Upward in Boiler Combustion Chamber Showing Flue-Dirt Accumulation on Side Walls and Around Front Tubes

The automatic control system is shown diagrammatically in Fig. 8. This system consists of several regulators, each of which has a particular function briefly discussed in the following paragraphs.

At *A* a master regulator operating primarily from steam pressure controls through an oil-pressure system the position of a plunger at the basement level near the gas burners *C*, which plunger operates the gas and interconnected air dampers, admitting gas and preheated air to the combustion chamber, opening these when there is a drop in steam pressure and closing them when the steam pressure on the main rises. An auxiliary regulator also at *A* operating from the blast-furnace-gas main closes the valves at the boilers whenever the gas pressure drops below a set pressure of about 6 in. water column in order to protect the supply to the stoves.

At *D* on the main operating floor of the boiler plant near the water columns are regulators operating from the combustion-chamber pressure to control the speed of the induced-draft fans and position of the louver dampers on the discharge of these fans to maintain practically balanced draft in the combustion chamber.

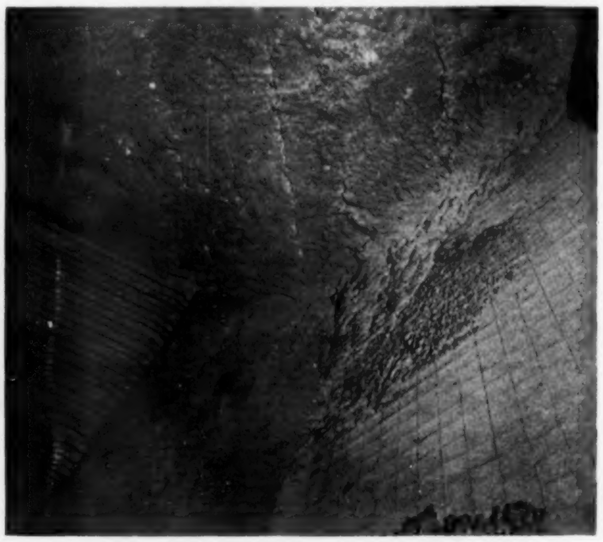

Fig. 11 Interior of Boiler Showing Accumulation of Flue Dirt on Water-Cooled Floor and Side Walls

At *E*, similar regulators control the speed of the forced-draft-fan turbines to maintain constant preheated-air pressure at the coal and gas burners. This pressure may be varied, but is usually kept about $1^{1}/_{2}$ in. water column.

At *F*, regulators control the speed of the primary-air fans to maintain about 6 in. on the blast main supplying cold primary air to the coal burners.

Each of the blast-furnace dust catchers has an auxiliary bleeder with the valve controlled by a regulator *G* to relieve gas whenever the main pressure goes over about 20 in. at the furnace.

The pumps supplying oil to the pressure system running to the several regulators in the boiler house are in the power-house basement near the boiler-feed pumps, and are shown at *B*. One of these pumps maintains about 60 lb. oil pressure on the line supplying the several regulators, the oil after use at these regulators being collected in a tank over the pumps.

By this system the combustion conditions in the boiler are maintained uniformly good, as evidenced by the low stack heats and CO_2 content of the stack gases, the latter usually above 20 per cent. The preheated-air temperatures leaving the side walls are usually within 50 deg. of the stack temperatures and these are recorded by pyrometers on the same chart, and as only about 12 deg. is added to the air temperature in the side walls, the counter-current arrangement of the tubular air heater is effective.

Particular attention is called to the power and boiler charts (Fig. 9) about 1:30 and 2:00 p.m. of September 10, when due to trouble on the power company's system there were two complete interruptions, causing the turbo-generator in service to drop about 22,000 kw. and pick it up again almost immediately.

When the power load was dropped, the automatic regulation system shut off the gas and combustion air supply to the boilers and reduced the steam production to less than one-third of that carried previously very quickly, and when the load was resumed the boiler output was increased almost as quickly, with no serious loss in steam pressure.

It is the opinion of the operators that it would not be possible to successfully operate the plant without the automatic control and boiler instruments provided, and the results, as indicated by the power production, indicate the maintenance of good combustion efficiency.

In order to show the effect of the water-cooling surface in the combustion chamber of the boiler, thermocouples were installed in a number of the blocks fastened on the floor tubes, and tests made indicated that there was a very high rate of steam production in these tubes—as high as 60,000 B.t.u. per sq. ft. per hour, or from 15 to 20 per cent of the total steam production of the boiler; and as a result of employing this heat-absorbing surface and the front-wall bare tubes and air-cooled side walls, practically all the brickwork repairs required to date have been the partial rebuilding of the bridge walls; and the total repair cost, in spite of the relatively high rating as compared with the usual blast-furnace-gas-fired plant, has been very nominal. Photographs taken inside the boiler setting (Figs. 10 and 11) show the condition of the furnace after a usual period of service and the relatively slight deposit of flue dirt on floor wall, side walls, and tubes.

All of the operators were taken from other plants of the Tennessee Company and had had very little, if any, experience with steam pressures over 150 lb., superheaters, turbines, condensers, pulverized coal, or automatic combustion control; however, the operating difficulties encountered have been but nominal.

Discussion

E. J. Billings.[2] The author has described a modern plant in which blast-furnace gas, a by-product, is used as boiler fuel supplemented by pulverized coal. Either fuel, or a combination of the two fuels, may be burned at will in the same furnace with high efficiency in quantities required to meet the steam demands as they may exist. Thus is met one of the first principles in modern steam generation for industry, namely, the efficient and economic use of the cheapest available fuel or fuels.

Modern industry provides many different kinds of by-product boiler fuels besides blast-furnace gas. Only a few need be mentioned to illustrate the range. From the processing of coal there are coke-oven gas, coke breeze, coal tar, and anthracite culm. From the refining of petroleum there are fuel oil, acid sludge, and petroleum coke. From the wood industries there are hogged fuel, tan bark, and dried wood refuse. Natural gas during the season of light domestic demand is sometimes considered a by-product fuel available for boiler use. These are only a few of a long list of by-product fuels, but they illustrate the varying nature of those available.

In almost every case the value of these special fuels for steam-boiler use is compared to that of the cheapest available steaming coal. This is because coal is generally available and therefore less subject to fluctuations in price. Coal is suitable for cheap transportation and storage, whereas the special or by-product fuels must generally be used as and close to where they are produced.

In this connection it is interesting to note that pulverized-coal-fired boiler furnaces may be readily adapted to almost the entire range of by-product fuels and used in the same manner as described by the author. This is a distinct advantage in favor of pulverized-fuel firing because in this age one scarcely knows from one day to the next what by-product fuel may become available at his plant, or conversely, what by-product fuel now available and in use may be suddenly withdrawn because of greater value for other uses.

Another feature evident from the author's paper, which is typical of the modern trend where by-product fuel or process steam is involved, is the reciprocal arrangement whereby power is exchanged with the central-station system. If the author's company owned the central-station system, or vice versa, there would be one design of plant which would most nearly comply with the condition of best overall economics of the situation. In the absence of such condition of ownership it would seem that it would only be necessary to divide the benefits obtained from this efficient overall set-up in some equitable manner between the two companies. Obviously, in this case it requires an equitable contract between the two companies for the exchange of power. It would appear to the writer that the management of both the author's company and the central-station system are to be congratulated on having worked out their mutual problems on the basis of sound overall engineering and economics.

D. S. Jacobus.[3] The author has presented a paper which describes a plant designed for his particular conditions that is a real contribution to the art.

Boiler efficiencies of 66 per cent, as given in his Table 2 for the year 1922, were at one time assumed as typical of boilers serving blast furnaces, and no doubt there are still many boiler plants in operation in which the efficiencies are no higher than this. It is very gratifying to see steel plants such as this one installing boiler units in which the efficiency is 83 per cent and in which the boilers are operated at a higher capacity.

Each of these five units has 14,607 sq. ft. of heating surface in the boiler, 10,601 sq. ft. in the economizer, and 11,781 sq. ft. in the air heater, which compares very favorably with central-station practice.

The daily load curve as represented by the charts is quite uniform and is the type of load that justifies economical units. Table No. 1 indicates that less than 5 per cent of the gas is wasted to the bleeders during five days of the week, and a less efficient plant would have required the burning of more coal.

The results secured through use of automatic control are very interesting and show that load conditions which are uniform on the average, but which are subjected to short sudden swings such as are experienced here, need automatic control as much as, or in some cases more than, loads which vary widely at different times of the day.

The methods of water treatment and cleaning the dust are worked out very completely and reflect credit to the designer.

The use of pulverized coal to make up for any deficiency fits in very nicely where the main supply is a by-product fuel, such as in blast-furnace gas. The furnace design has worked out satisfactorily and is no more complicated than it would be for the use of either fuel alone.

Sanford A. Moss.[4] The author is to be congratulated on the presentation he gives of a blast-furnace plant following power-station practice. For many years power-station practice has steadily improved, and higher and higher pressures and temperatures and various other devices for increasing output for a given amount of fuel have been continuously adopted. Even if a blast-furnace plant makes more than enough gas to operate itself, there is in most cases enough use for surplus power or other uses for the blast-furnace gas to give as much financial gain from improvement in fuel consumption in blast-furnace plants as in power stations. Therefore blast-furnace operators realize that thermodynamic efficiency is just as important for them as for the power stations.

[4] Mechanical Engineer, Thomson Research Laboratory, General Electric Company, Lynn, Mass. Mem. A.S.M.E.

Of course, the time will come when even the pressures and temperatures cited by the author will have to be exceeded by blast-furnace plants. Power stations have already begun to use very much higher pressures and temperatures. There are, of course, other plants in the United States which have conditions similar to those cited by the author. One of these is an installation in the Youngstown Sheet and Tube Company, where blast-furnace blowers have been operated since the latter part of 1928 on 400 lb. gage pressure and 690 deg. total temperature and 240 deg. superheat, with the same success as is indicated in the paper. These machines also follow modern power-station practice by extracting steam from the main turbine in three places to heat feedwater.

FSP-54-3

Conversion of Coal-Fired Boilers and Furnaces to Gas Firing

By WILLIAM D. EDWARDS,[1] MEMPHIS, TENN.

This paper deals with the use of natural gas in the City of Memphis, the methods and data used in making estimates of gas consumption, the application of the degree-day to this end, and the actual operating data for various types of plants converted to gas fuel.

WHEN, after months of preparation and expectancy, the pipe line finally delivers natural gas to a community, the necessity of building up a load becomes of paramount importance, to which end the installation of gas-burning equipment under existing boilers is a most important factor.

With due regard to all of the advantages obtained by the substitution of gas for other fuels, the prospective user is chiefly interested in its effect upon the operating cost which will result by the combination of fuel expense on one hand and savings to be effected on the other.

The estimate as to the cost of the gas itself can be made with a fair degree of accuracy, remembering, however, that it is a forecast of probable conditions, and as such is subject to modifications.

The other savings in the line of attendance, space, cleanliness, smoke elimination, etc., are questions of the individual plant, upon the conditions of which they may be estimated in the terms of dollars and cents.

To the engineer the question of interest is mainly that of the use of the gas for a given result, embodying its application, volume used, and cost of the same, and it is to this end that the experience covering the last two years of the City of Memphis in the adoption of natural gas for fuel purposes is outlined as a possible guide to other engineers taking up this work.

The natural gas is supplied to Memphis by a 220-mile pipe line, 18 in. in diameter, from the Monroe, La., fields; it is over 90 per cent methane CH_4 and has a heating value of 960 B.t.u.

In selecting the standard by means of which the gas requirements, in relation to the heating load of a given section, can be based, the degree-day is used as the most convenient yardstick upon which are based most of the calculations.

The degree-day as developed by the American Gas Association is a measure of the average daily temperature in its variation from the standard of an average daily temperature of 65 deg.; a day showing an average daily temperature of 35 deg., would be noted as having 30 degree-days. The reports of the U. S. Weather Bureau are recorded each day during the heating season.

In the use of gas, a more direct relation exists between the amount used and the outdoor temperature than is the case with the other classes of fuels. Expressed in terms of degree-days and volume of gas used, it will be found that practically a constant relation exists between the two quantities, which is of great assistance in making estimates of fuel requirements.

The most convenient method of recording the degree-days is to show them in the cumulative form, adding the degree-days of each day to the sum of those of the previous days, from the start of the heating season, showing both the record of the season in question, as well as that for the normal season.

The Memphis section has about 3000 degree-days, starts about October 1, and ends the heating season on the last of April, although some gas is used for heating before and after these dates. While the record is shown for each day, an abstract as given in Table 1 will show the general set-up.

TABLE 1 DEGREE-DAYS FOR SEASON OF 1929–30 AND FOR NORMAL DATE

Date	Degree-days to date	Degree-days, normal	Date	Degree-days to date	Degree-days, normal
Oct. 1..	6	0	Jan. 1..	1238	1162
Oct. 10..	32	0	Jan. 15..	1513	1498
Oct. 20..	32	14	Feb. 1..	2147	1902
Oct. 30..	115	68	Feb. 15..	2379	2210
Nov. 10..	211	173	Mar. 1..	2494	2475
Nov. 20..	358	309	Mar. 15..	2702	2685
Dec. 1..	662	494	Apr. 1..	2922	2858
Dec. 10..	853	668	Apr. 15..	2943	2933

				for season	for season

TABLE 2 DEGREE-DAYS PER MONTH FOR SEASON OF 1929–30 AND FOR NORMAL SEASON

Date	Degree-days, 1929–30	Per cent of total	Degree-days, normal	Per cent of season
Oct., inc. Sept.....	115	4.0	76	2.5
Nov..............	514	17.0	400	13.5
Dec..............	607	20.0	662	22.5
Jan..............	891	30.0	741	25.0
Feb..............	350	12.0	579	19.5
Mar..............	437	14.5	392	13.0
Apr..............	71	2.5	99	4.0
Total...........	2985	100	2949	100

The data in the form of Table 1 have proved to be of value in checking up on the operation of installed equipment, and particularly when a question arises over current gas bills.

To the average person the memory of even recently past weather conditions is very vague, and only the Weather Bureau records for the period in question offer a basis for an intelligent analysis of the seemingly high bill.

---

[1] Mechanical Engineer, Memphis Power and Light Company. Mem. A.S.M.E. The author is a graduate of Worcester Polytechnic Institute, Worcester, Mass., 1897. About twenty years' connection with the various phases of heating and ventilating and air-conditioning consulting, designing, and contracting. Experience in power stoker work and development of a small stoker for heating service. Last two years sales engineer, gas and gas-burning equipment, in the commercial gas department of the Memphis Power & Light Company, embracing in addition the development of gas-burning equipment for special conditions and service.

Presented at the Fourth National Fuels Meeting, Chicago, Ill., February 11 to 13, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

In the form given in Table 1, the volume of gas used in an elapsed period, together with the degree-days covered by this same time and the proportion of the latter to the total seasonal degree-days, forms a workable basis to check the cost of gas for the heating season and its relation to the cost estimate given.

As an illustration it will be noted that during the 1929–30 season the degree-days on December 20 had reached a total of 977, this being about one-third of the season's total of 2985, and the amount of gas used up to December 20 would represent one-third of the anticipated season's requirements. Repeated checks show that this works out very closely in actual practice, and if the estimate of probable gas used, as made at the beginning of the season, falls much below the amount indicated as required by the foregoing degree-day proportion, it is time to give this installation an inspection.

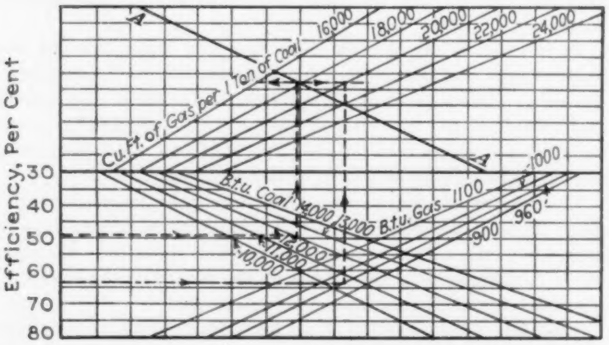

Fig. 1 Gas and Coal Relation, in Terms of Cu. Ft. of Gas and 1 Ton of Coal

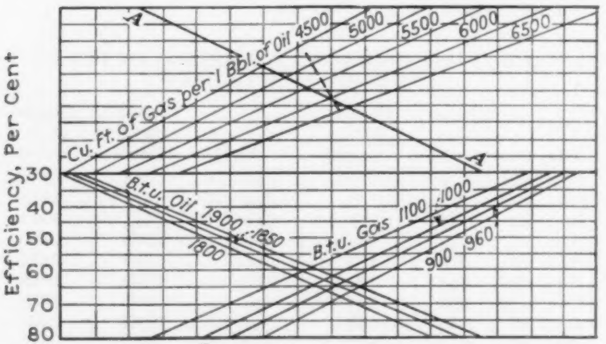

Fig. 2 Gas and Oil Relation, in Terms of Cu. Ft. of Gas and 1 Bbl. of Oil

The question of maintained temperature is of vital importance. The foregoing calculations are based upon an indoor temperature of 70 deg., while in practice the users like to keep a temperature of from 5 to 10 deg. higher. The average outdoor temperature during the heating season, locally, is 50 deg., which makes an average difference, when heating to 70 deg., of 20 deg. rise, a greater difference caused by a higher indoor temperature making a proportional increase in the gas requirements.

The degree-day data tabulated in the monthly form with the percentage of the season's total are of material assistance in determining from the total season volume of gas the amount of gas used per month, this being essential due to the fact that about all rates are based upon a monthly gas consumption. This form is shown in Table 2.

In practically all gas rates an increase in volume used results in a lower unit cost, in accord with which the smaller gas consumption during the fall and spring months costs more, per 1000 cu. ft., than does that of the heavy-loaded winter months; hence the necessity of breaking down the total gas of the season to a monthly basis, and applying the rate for each month, the total of which gives the season's cost, which in connection with the total gas gives the average rate per season.

The degree-day data of Table 2, the estimated volume of gas for the season, and the established rates are the three factors involved in making a forecast of operating cost for a heating season. Two of these can be determined with a fair degree of accuracy, but the third, the volume of gas used per season, is the variable quantity the correct estimate of which depends very much on the good judgment of the engineer in his application of basic data to the plant in question.

The determination of the amount of gas required per season may be based on the total of installed radiation in the building under consideration, or, where it is available, the amount of coal or oil used during prior seasons.

In the former, the data are expressed in terms of cubic feet of gas per season required by 1 sq. ft. of installed radiation. In the latter this is given in the form of the number of thousand feet of gas equivalent to one ton of coal or to one barrel of oil, and here it may be noted that this coal-gas ratio is the football of the game between the coal and gas interests.

On a strictly B.t.u. basis and assuming equal efficiency for both coal and gas firing, one ton of 12,000 B.t.u. coal will be equal to 25,000 cu. ft. of 960 B.t.u. gas, but this does not work out in practice, as 20,000 seems to be the average firing ratio, in the comparison of a good hand-fired coal plant with a good gas-fired one. A poorly operated coal plant may bring this ratio down to 15,000 and an efficient stoker-fired plant will bring this up to the 25,000 of theory. With the efficiency playing the important part that it does, the only basis of comparison is that of effective B.t.u. A ton of 12,000 B.t.u. coal at 45 per cent efficiency gives a little less than 11,000,000 heat units, while a cubic foot of 960 gas at $57^1/_2$ per cent efficiency has an effective value of 550, which compared with the 11,000,000 heat units of coal gives a ratio of 1 to 20,000. The ratio of fuel oil to gas ranges from 5000 to 6000 cu. ft. of gas to one barrel of oil.

Fig. 1 shows a graphic method of determining the coal-to-gas relation, based upon available heat units at the different efficiencies, as assumed for each kind of fuel. In this diagram a horizontal line from the coal efficiency selected is extended to intersect the coal diagonal, from which point a vertical is drawn up to intersect the diagonal line *A-A*, a horizontal line is again drawn through this intersection. Starting back at the efficiency line this process is repeated at the efficiency selected for the gas, the horizontal line intersecting the diagonal shown for gas, and then being carried upward to meet the horizontal line previously drawn through the point on *A-A*, this intersection giving the cubic feet of gas in accordance with its location in reference with the diagonals thus designated.

Fig. 2 shows the oil-and-gas relation in the same manner of operation.

The entire question of determining the relation between coal and gas resolves itself into the efficiencies to be secured by each. In the absence of test data, it is simply a matter of the good judgment of the engineer in his survey. However, it might be remarked that the average coal-fired heating plant probably operates at a very low point of efficiency, and in average conditions the gas job will show from 10 to 20 points higher than will the coal, or 40 per cent for coal may be equal to 50 per cent to 60 per cent for gas.

Gas per Square Foot of Radiation

This second method of estimating gas requirements is subject to variations, and depends upon the character of the burner installation, the care in operation, and the temperatures maintained in the building. It is expressed in terms of cubic feet of gas per season, per square foot of radiation, per degree-day. Locally, with 3000 degree-days a gas consumption of 400 cu. ft. per season would be based on the factor of 0.133 cu. ft. per square foot per degree-day.

The consumption of 400 cu. ft. is about the low limit for steam radiation, and it may range up to nearly twice this amount, 550 to 600 cu. ft. being considered a good average, or a factor of from 0.18 to 0.20 cu. ft. per square foot per degree-day.

In the application of these data to the plants in a colder climate it should be borne in mind that the Memphis conditions cover an unfavorable type of heating service, so far as efficient operation is concerned, with the temperature dropping to the vicinity of zero for short periods; yet the average temperature of the heating season is 50 deg., which means that for normal operation the heating systems are of excess capacity. This may be one of the reasons for the prevalent belief on the part of the majority of home owners that if 70 deg. is good 75 is better, and 80 is best of all. In any event, the combinations of these adverse conditions, which cause extravagant operation, would indicate that in sections having a steady heating load, at a point nearer the plant capacity, the proportionate gas consumption per, degree-day could be reduced from the values given.

This is borne out by a comparison made on coal consumption. A survey of a group of buildings in Memphis as to the relation between coal used per season and steam radiation installed showed an average of 3.3 tons of coal per 100 sq. ft., this for 3000 degree-days, while data from Pittsburgh, with 5000 degree-days showed a use of 3.7 tons per 100 sq. ft. of radiation.

It might be added that a survey of a large group of buildings of various types as to coal used per season in relation to installed radiation forms invaluable data to the engineer interested in gas-conversion work.

Gas Rates

With the determination of the season's gas consumption, so divided as to show the amount of gas approximately used during each month of the heating season, the final factor in calculating the season's cost is that of the gas rates for given volumes used per month.

The convenience in operation, saving in space and labor, cleanliness, and freedom from the smoke nuisance as afforded by the use of gas all have a definite value, but in the end cannot be relied upon too strongly to build up a gas-heating load.

The gas rates must be such that the cost of gas fuel is competitive with that of coal or oil within reasonable limits, with all due credits given its use along the line of economies in attendance and space saved, and which must be so tangible as to be expressed in dollars and cents.

Beyond this, the gas rates must not be such as will exact a too-heavy premium for its use. However, this matter of rates is generally out of the province of the engineer, and is a subject which in the end adjusts itself in accordance to whether or not the gas load of the pipe line meets the expectations.

The gas rates, as published, all seem to be in a more or less complicated form. The figuring of a rate for each individual job involves much time and labor. This was very much simplified in Memphis by the figuring out of the average rate for various gas consumptions per season.

The Memphis rate involves a demand charge based upon the maximum daily demand, which in the absence of a test is assumed to be one-twentieth of the monthly consumption.

In addition there is a charge of 30 cents per 1000 ft. for the first 100,000 cu. ft. and 15 cents per 1000 ft. per thousand for all gas used per month in excess of this figure.

Table 3 illustrates the working out of this rate for a building assumed to have 5000 sq. ft. of radiation and operating on 600 cu. ft. of gas per square foot, requiring 3,000,000 cu. ft. per season.

TABLE 3 OPERATING RESULTS FOR ONE BUILDING

Month	Monthly per cent of seasons	Load, cu. ft. of gas	Demand	Gas at 30 cents	Gas at 15 cents	Total	Rate per 1000 cu. ft., cents
Oct...	4.0	120,000	$ 10.00	$ 30.00	$ 3.00	$ 43.00	36.0
Nov..	13.5	405,000	20.25	30.00	45.75	96.00	23.7
Dec..	22.0	660,000	33.00	30.00	84.00	147.00	22.1
Jan...	23.0	690,000	34.50	30.00	88.50	153.00	22.0
Feb..	19.0	570,000	28.50	30.00	70.00	129.00	22.7
Mar..	13.5	405,000	20.25	30.00	45.75	96.00	23.7
Apr..	5.0	150,000	10.00	30.00	7.50	47.50	31.6
Total...	100	3,000,000	$156.50	$210.00	$345.00	$711.50	

Average rate for the season, 23.72 cents per 1000 cu. ft.

From a seasonal consumption of 500,000 cu. ft., in which practically no 15-cent gas is used, the rate drops from 43 cents per 1000 cu. ft. to 20 cents and lower when a season's consumption reaches 10,000,000 cu. ft. or more. This rate is termed the commercial heating rate.

The industrial rate, with a fairly steady month-to-month load, and with gas consumption figured on a monthly basis instead of a seasonal basis, will range from 27 cents to 17 cents as the monthly gas use increases from 500,000 to 10,000,000 cu. ft.

As a check upon the foregoing data, a table of actual operating results covering one or more season's operation is submitted (Table 4). This is for buildings in the commercial heating classification. The gas used is for heating purposes only. Those buildings in the readings of which water heating was involved have their gas consumption corrected to a heating basis only.

TABLE 4 OPERATING RESULTS OF A GROUP OF BUILDINGS USING NATURAL GAS

(Conversion from coal or oil fuel to gas)

Type	Radiation, sq. ft.	Gas per season, cu. ft.	Gas per sq. ft. of radiation, cu. ft.	Cost per season of radiation	Cost per sq. ft. of radiation, in cents
Steam heating:					
1 Office building..	15,100	6,651,000	445	$1395	9.2
2 Office building..	15,000	8,000,000	530	$1720	11.5
3 Office building..	16,000	9,500,000	600	$1925	12.0
4 Office building..	15,000	10,800,000	700	$2150	14.5
5 Office building..	13,000	9,250,000	710	$1909	14.7
6 Office building..	2,000	1,150,000	575	$ 350	17.5

14 Residence hotel	1,100	433,500	395	$174	15.9
15 Medical clinic..	2,000	900,000	450	$275	13.7
Total..........	7,300	2,941,500			
Average.........			400		

When natural gas was available, the large volume of business secured imposed certain adverse conditions in burner installation work, as far as securing maximum efficiency was concerned. The installation crews had to make a large number of conversions in a short space of time, and in addition many were installed in the summer months when it was not possible to secure satisfactory tests of operation. With such defects as may exist being remedied and with increased experience for the operator in the use of gas, it is probable that the operating costs of the first year will be materially lowered.

Condition of Heating Plants

In the survey of a proposed gas installation job, the engineer will come across heating plants of all sorts and conditions, and his investigations should cover not only the boiler alone, but should embrace the plant in its entirety, with a note of its defects of operation in prior seasons.

He will find boilers of all types and methods of installation, and many of them too small for the work required. Piping systems will have many variations and sizes, with many having no relation to the radiation served, and will probably lack covering in many cases. Radiation will be deficient and poorly vented, and control valves be out of order.

The net result of a series of defects will be unsatisfactory service, and while the troubles may have existed during all previous years, yet with the advent of gas firing they will be blamed to the gas. Overheating three-quarters of a building in order to get heat to the balance is a fruitful source of gas waste.

The defects of a plant should be remedied by calling in the heating contractor; otherwise, a plant with many pronounced shortcomings is a good one for the gas engineer to leave alone.

Conversion Versus Gas-Fired Units

This is another subject which will generally start an argument. In a new installation the lower operating costs of the gas-fired equipment will probably justify its use, the bone of contention being the pros and cons of discarding present boilers for new equipment designed especially for gas firing. The saving in operating of the latter over a conversion job has to be weighed in connection with the additional cost of the new installation, the depreciation of the same, and the interest on the investment.

The records in Memphis show a fuel saving of from 15 to 19 per cent of a gas-fired installation over a conversion type for residential use. On the basis of initial cost alone it would require from 13 to 15 years to cover the difference in cost, to say nothing of depreciation or interest, and this will probably be longer than the life of the boiler.

In view of the foregoing it is probable that when the boiler equipment is found to be in good shape, or readily made so, it is more logical to use it by converting it from an oil or coal burner to gas fuel.

Conversion to Gas Firing

Two major classifications may be made of the installation of gas burners to replace oil or coal in the furnace of a boiler and may be designated as follows:

1 For commercial heating, which embraces the boilers of a heating system of 1000 sq. ft. (or less) of radiation on up to that of the largest buildings, and which includes office buildings, hotels, store buildings, apartment houses, etc.

2 Residential heating, which is, as its name implies, that of installing the smaller class of burners in the steam, hot-water, and hot-air furnaces of the various classes of residences.

Another classification of conversion work may be made, which includes the installation of gas burners, replacing coal, in small boilers for domestic water heating, the smaller type of hot-water heating systems of the Arcola nature, and the conversion of coal-fired stoves or circulating heaters to gas.

In the commercial heating field the atmospheric burner is used in the majority of cases. This burner is of the multiport, rectangular-face type, the mixture of air and gas entering through the several ports, and combustion taking place on the face of the burner; the air supply being under control of the gas valve and so arranged that the air supply is cut off by its dampers when the gas valve closes.

This burner is installed in the ashpit or over the grates as the nature of the furnace would indicate to be the more desirable. When installed in the ashpit, a combustion chamber with its baffle walls is built up with firebrick, and the bottom of this chamber is also insulated. With the burner located over the grates, the latter are left in place, and a firebrick bed is constructed on top of them, together with the necessary baffle walls.

The control of the burner is in accord with such water temperature or steam pressure as it is desired to maintain, using a temperature or pressure regulator of the counterweighted lever type, this lever being connected to the lever of the gas-firing valve, the gas being on or off as the temperature or pressure requirements demand.

The foregoing arrangement is sometimes varied by the use of thermostats, limit control, and motor-actuated gas valves.

The use of automatic gas control, however, is limited to the small and medium-size boilers. With burners having a large gas capacity an element of danger arises in the sudden admission of a large volume of gas to a furnace.

In addition to the atmospheric type of burner, the forced-air burner using a blower, motor, and air-gas mixer is being used to a limited extent, and for certain forms of furnaces it is probably better adapted than the atmospheric. Each type has its place.

Burners and Furnaces

The luminous, semi-luminous, and non-luminous flame burner all have their advocates. The latter burns a blue flame at the burner and produces a sort of light haze in the furnace. The semi-luminous starts with a blue flame, changing to an orange-color tip, while the former runs an orange and red flame, which can be carried to such an extent as to produce a bad soot deposit and a smoky stack. The non-luminous burner has a more intense heat at the burner face and furnace space near it, while the others carry this heat further along into the furnace and are supposed to give off more heat by radiation. Here again it is that the type of furnace and boiler setting may be the deciding factor in the burner selection.

As a general thing too much weight is given to the burner itself and too little to the subject of the location of the burner in respect to the heating surface of the boiler. In addition the question of proper arrangement of baffles directing the flame and heat travel over the heating surfaces of the boiler is one that is of utmost importance. The two foregoing subjects, burner location and baffling, offer a most fruitful field for tests and investigation on the part of combustion engineers.

Illustrating this may be cited a recent installation made in a hot-water heating boiler, of the round vertical type, and handling about 750 sq. ft. of radiation. A gas burner was installed in the usual manner, in the ashpit, which was firebrick lined, insulated, and baffled in the regular manner. Later this burner was removed, was placed in the firedoor, and the flame was deflected direct over the heating surface of the boiler. Under identical conditions as to load and gas consumption the time of raising the water through 100 deg. was reduced from four hours to two hours.

Residential Heating

The burners used for this work are the "on and off" thermostat-controlled type, with limit control of water temperature or pressure. Here the grates are removed, the burner ring being placed in the furnace, around the inner face of which vertical radiants are placed. Two of the standard makes of this type are represented in about all of the installations of the residence heating, and are used for steam, vapor, hot-water, and hot-air furnace work.

Secondary Conversion Installations

The most important factor in this line was the domestic water heating in reference to the conversion of the main heating boiler from coal to gas.

In many buildings, particularly apartment houses, the source of domestic hot water is a cast-iron, coal-fired boiler installed in conjunction with a storage tank, these boilers having a grate varying from 10 to 16 in. in diameter. They presented a problem as to conversion to gas in such a manner as to secure an economy of operation.

At the beginning, there was no satisfactory burner available for this work, and when the recommendation was made to discard this boiler and buy a new gas water heater, the cost of this in combination with the cost of gas burners for the main boiler made a total which generally resulted in "no trade." Blocking the installation of gas for heating, as this frequently did, it was necessary to develop an efficient lower-priced burner for this work. This was done, and the burners were placed in service, and their operation was gradually improved as the results of observation of their work.

The burners are controlled by a water-temperature regulator on the discharge line from heater to tank; this is of the balanced lever "Sylphon" type and cuts the burner on or off in accord with the water-temperature requirements.

In some cases this control has been placed on the return line to the heater, with good results. Burners of this class are shown in Fig. 3.

The development of the efficient and low-priced burner for the small hot-water heating systems and coal-fired hot-air circulators is in progress, the successful completion of which is of considerable importance from the viewpoint of adding to the gas load.

LOOKING AHEAD

The development of equipment for the use of gas fuel is in its infancy. Considering the rapidly increasing number of natural-gas pipe lines and the consequent large amount of this gas distributed one may look for many changes and improvements in the line of both the apparatus for the using of gas and in the methods of control of this use.

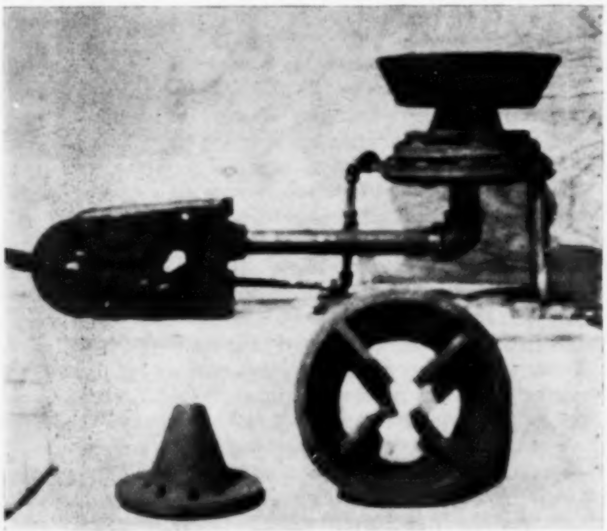

FIG. 3 BURNER FOR DOMESTIC WATER HEATING

With the present practice in mind, one might try to look ahead and forecast some of the places in which this improvement will occur. The following is offered as an individual view, suggesting a line of thought to the combustion engineer interested in this use of gas.

USE AND WASTE OF GAS

The importance of burner location and proper flame direction has been mentioned, and to this may be added the necessity of avoiding the undue consumption of gas which is not required by the heating load or conditions, such as maintaining excessive temperatures, high temperatures during night periods, and when the outdoor temperature is high.

There is a distinct relation between the required temperature of the heating medium (steam, water, or hot air) and the outside temperature, so that it is probable that one may expect decided improvements in the line of control equipment to maintain this relation.

The method of burner operation might be another point of observation; this refers to the "on and off" method of firing, in which the thermostat in the room cuts off the burner with the rise in room temperature, the burner remaining entirely cut off until the cooling of the room starts it again.

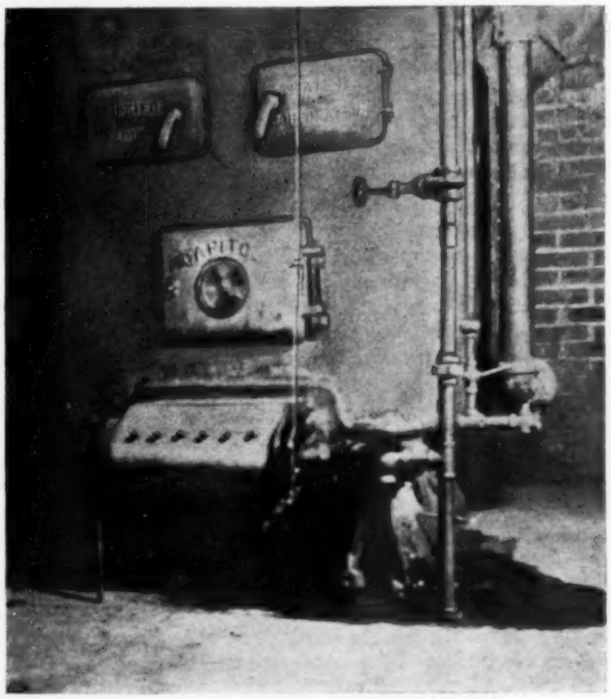

FIG. 4 BURNERS INSTALLED IN THE SLICE DOOR

This intermittent operation imposes a heavy tax upon the burner, as it is always operating against a peak load, calls for a high rate of operation for short periods, and tends to an all-around lowering of efficiency. With a fixed hourly gas consumption it is better to burn it over a long period at a lower rate than over a short period at a high rate. To this end one may look to the "high and low" type of burner, in which the intensity of the flame is under thermostatic or manual control.

Carrying out this theory, a number of burners of this order have been developed and given a season of operation, with excellent results. These burners operate at full, two-thirds, and one-third capacity, with not only the gas being cut off on the burner outlets that are out of commission, but the air to these outlets is also cut off. An installation of this type, with the burner installed in the slice door of the boiler is shown in Fig. 4.

THERMOSTATS

The complete thermostatic-controlled gas-burning installation is near the ideal so far as maintaining an even room temperature is concerned, but even at that, its limitations furnish food for thought.

In spite of many claims as to operating economy on the part of the thermostat enthusiast, it is possible that this maintaining of a constant temperature, sometimes rather high, is at the cost of a higher gas consumption.

Again it is a long step from the day of the coal scoop to the easy chair and the pretty thermostat on the wall, all as shown by the pictures; but perhaps there are many prospective gas users who are desirous of the convenience afforded by gas, but who are willing to regulate the same by hand, if they can thus get the burner installation at a cost within their means. This brings up the question as to whether the use of the thermostat has not been stressed too much and development of an effective manual or semi-automatic control is not desirable.

The advent of natural gas in a community is a more or less disturbing event to the old-established coal industry, and the engineers and would be engineers all start to figure to the end that the use of gas for a fuel is out of the question, the cost being prohibitive, and some remarkable data are evolved by them.

With the passing of time something seems to be the matter with their figures, so they have to revise them. This also happens to the super-enthusiast for gas on the other hand; the high efficiencies he starts out with do not hold up in continuous operation.

This brings up the question as what is the net result in Memphis of about two years of gas operation. The answer is that it has proved to be very successful.

In the commercial heating line practically all of the larger office buildings, stores, hotels, etc., are using gas, and the greater number of the smaller buildings are so equipped.

The successful result of one season's operation of gas in one building justifies other buildings to adopt it.

The costs of operation have proved it to be comparable with coal and materially lower than the average fuel-oil use. In many cases the gas costs have also proved to be lower than the previous season's operation with coal.

In view of the foregoing, the engineer can carry on the work of utilizing natural gas with full confidence that he is contributing to the comfort, convenience, and benefit of the people in general.

FSP-54-4

Recent Developments in By-Products From Bituminous Coal[1]

By A. C. FIELDNER,[2] WASHINGTON, D. C.

After pointing out that the by-product oven has displaced the beehive oven as a producer of metallurgical coke, the author discusses the increasing value of by-products as compared to that of the coke itself. He then takes up successively the subjects of competitive sources of gas for industrial and domestic use; utilization of the hydrogen in coke-oven gas for the production of synthetic ammonia; competition between synthetic and by-product ammonia; utilization of sulphur in coke-oven gas in the production of ammonium sulphate; processes for the recovery of sulphur in connection with gas purification; recovery of phenols from ammonia still wastes; benzol and light oils; production of resins from coal by-products; tar and tar products; and the hydrogenation of coal tar.

TWENTY years ago a favorite theme of the crusader for fuel conservation was the enormous waste of valuable by-products incurred in the manufacture of blast-furnace coke in beehive ovens. Indeed, there was good reason for arousing the national conscience to this needless loss of an irreplaceable mineral resource. In 1910, 83 per cent of the coke production was made in beehive ovens from which surplus gas, tar, light oil, and ammonia, aggregating in value (at 1910 prices) 40 million dollars annually, were discharged into the atmosphere.

In 1929, proportions were reversed and 90 per cent of the production was made in by-product ovens. The average value of by-products obtained in the production of 1 ton of coke in 1929 was $3.60, as compared with $1.16 in 1910, although the value of a ton of coke had increased only from $3.47 to $4.80. As shown in Fig. 1,[3] the production of by-product coke progressed rather slowly until 1915. War needs suddenly expanded the demand for coke and for the by-products benzol and toluol for the manufacture of explosives. Except during the depression of 1921, this accelerating rate of production was maintained up to 1929, largely at the expense of beehive plants. The 1929 production of 60 million tons of coke will probably remain a record-breaking figure for several years. The developments which are now in progress in long-distance transmission of natural gas and in the utilization of volatile petroleum products and refinery gases for augmenting city gas supplies may retard an otherwise accelerating demand for coke and coke-oven gas for domestic and industrial heating.

Trends in Value of By-Products

The increasing value of by-products in comparison to the value of coke is shown in Fig. 2.[3] In 1913 the average value of by-product coke was $3.38, the value of the by-products per ton of coke was $1.41, and the cost of coal per ton of coke was $3.27. In 1929 (not shown in figure), the value of the coke had risen to $4.80 per ton, the value of the by-products to $3.60, and the cost of coal per ton of coke to $5.07. The by-product values in 1929 were 155 per cent higher than in 1913, although the coke value had increased only 25 per cent and the cost of the coal 55 per cent. Actually the increase of the total value of coke plus by-products in this period was very little more than the increase in the cost of the coal, being 55 per cent for coal and 60 per cent for coke plus by-products.

The distribution among the several by-products, of the average gross returns from by-products per ton of coke produced, is shown in Fig. 3.[3] This chart shows important shifts in the trend of income from the different by-products. In 1913 ammonia supplied the greatest income; in 1916 and 1917 war demands for explosives gave benzol and toluol a temporary leadership over ammonia, which, however, was regained by the latter in 1918; and in 1921 gas forged ahead of the other by-products, and ammonia began to decline—a trend which has continued up to the present time. In evaluating the significance of these changes it must be remembered that Fig. 3 represents a composite of all by-product coke plants, most of which are associated with the iron and steel industry. Before 1920 most of the by-product gas was used as a metallurgical fuel and was credited to the oven at very low prices. About 1920 and 1921 the trend toward the use of by-product coke ovens for supplying base-load city gas began to make itself felt in the larger average price returns for this by-product. The decline in returns on ammonia since 1920 is due to the remarkable expansion of synthetic plants which can produce ammonia very cheaply from hydrogen and atmospheric nitrogen. The growing importance of the by-product coke oven as a source of smokeless fuel is shown in Fig. 4[4] by the increasing percentage of total coke sold for domestic use.

The trend in gross value of by-products per ton of coke as shown in Fig. 3 is due to changes in unit prices and in yields of by-products per ton of coke produced. Fig. 5[5] shows the extraordinary rise in price of toluol due to war demands. Between 1919 and 1928 the prize of benzol has been fairly constant, and that of solvent naphtha and toluol has increased slightly. Sulphate of ammonia has declined from 4 cents to less than 2 cents a pound, while tar has risen from 3.2 to 5.3 cents per gallon.

Beginning with the same date, 1919, which may well be regarded as the beginning of the by-product coke-oven era in the coal-carbonization industry, Fig. 6[6] shows a marked upward

trend in the yields of by-products per ton of coke produced. Part of these increases are due to better selection of coals for by-product yields, and others to improvements in oven design and by-product recovery equipment. The marked increase in tar yield is due probably to the use of 100 per cent high-volatile coal at certain large installations of the iron and steel industry. Better oven design has reduced the gas needed for underfiring, and the increased use of producer and blast-furnace gas for heating ovens has released more surplus gas for distribution.

The average yield and value of by-products from a ton of coal for 1929, computed from Bureau of Mines statistics, is given in Table 1. It will be noted that the returns from surplus gas comprise 47 per cent or nearly half of the returns from total by-products. The returns from tar, although higher than 10 years ago, are dominated by the price of fuel oil since approximately half of the total tar production is not sold or refined but is burned as fuel in open-hearth and other metallurgical furnaces.

Present Economic Status of By-Products From Coal

Having briefly reviewed the trends in by-products of the coke-oven industry, let us consider now the present status and future prospects in relation to other sources of these products. Coal as a source of energy must compete with petroleum, natural gas, and water power. The tremendous increase in present and potential production of oil and gas has exceeded all expectations. Natural gas, petroleum, and their products compete with the products of the coal-carbonization plant. Coke for use in blast furnaces and foundries is practically the only major coal product that has no present-day competitor.

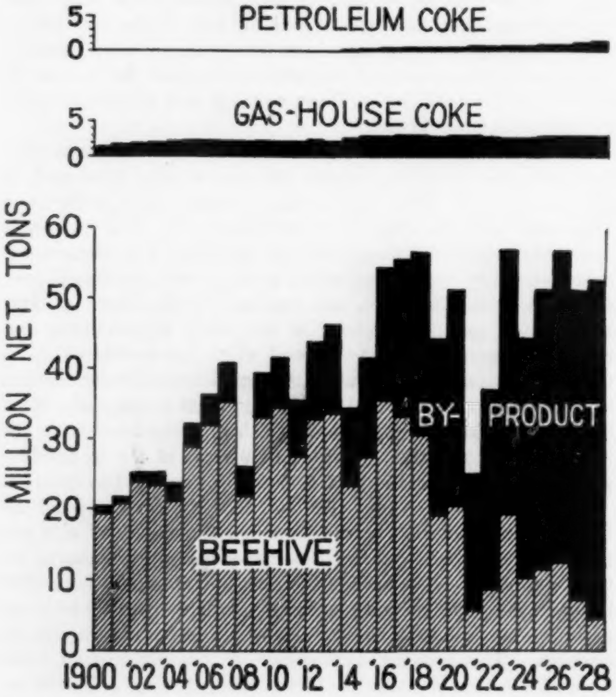

Fig. 1 Production of Coke in the United States, 1900–1928

Competitive Sources of Gas for Industrial and Domestic Use

City gas companies are becoming, to a considerable degree, distributers of purchased and blended gas. They are buying not only the surplus gas of near-by coke-oven plants, but also from oil refineries and natural-gas pipe-line companies. The oil refiners are beginning to appreciate the possibilities of selling their surplus gas, which is increasing greatly in amount due to modern developments[7] in gasoline production. In view of these additional sources of gas, and especially the construction of long-distance (1000 miles and more) pipe lines for transporting natural gas, the economic picture for the immediate future is not so favorable for by-product coke-oven gas as in the past; it will have serious competition.

TABLE 1 AVERAGE YIELD AND VALUE OF BY-PRODUCTS FROM A TON OF COAL IN 1929

	Yield	Value
Ammonium sulphate	22.3 lb.	$0.38
Light oil	2.9 gal.	0.40
Surplus gas	6,600 cu. ft.	1.10
Tar, sold	8.9 gal.	0.22
Tar, used, not sold		0.23
Total of by-products	—	$2.33
Breeze produced	—	$0.14
Coke produced	—	3.34
Total coke	70%	$3.48
Total value coke and by-products	—	$5.84

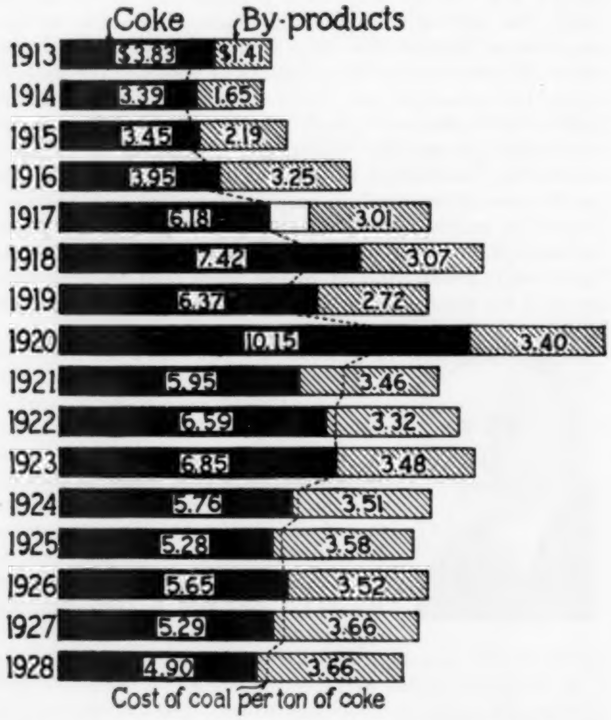

Fig. 2 Average Value of By-Product Coke and Gross Value of By-Products and Cost of Coal per Ton of Coke Produced

(It should be noted that these figures represent the gross values of the products and that there are many other expenses besides the cost of coking coal, including other materials, wages, salaries, purchased electric power, insurance, taxes, and fixed chargs on a large investment. No data on total costs or profits have been collected.)

In the United States most of the by-product coke ovens supplying metallurgical coke are operated in conjunction with steel plants, and the major portion of the gas and the tar is used in the steel plant for heating purposes. However, a few steel-plant ovens make more gas than they can use. Some of these plants sell their surplus to city gas companies, and in recent years they have added to their income by heating the coke ovens with low-B.t.u. blast-furnace gas (100 B.t.u. per cu. ft.), thus releasing all of the much higher-heating-value coke-oven gas (550 B.t.u. per cu. ft.) for sale to the city distributing company.

---

[7] Cracking processes produced more than 250 billion cubic feet of cracked gas of approximately 1250 B.t.u. per cu. ft. during the year 1929, according to Egloff, Gustav, and Morrell, J. C., "The Cracking Process in the Gas-Making Industry," *Ind. & Eng. Chem.*, vol. 22 (1920), pp. 1080–1083.

In Europe by-product coke ovens are usually located at the mines, where surplus gas is not so readily used. This condition in the Ruhr district of Germany led to the formation of the Ruhr-Gas A.G., which collects gas from the Ruhr coke ovens and distributes it through a pipe-line system aggregating 590 miles in length and serving an area of 425 square miles, with a population of 10 million people.[8] The present pipe-line capacity of this system is approximately 50 billion cubic feet per annum, and the most distant town served is Hanover. It is proposed to pipe Ruhr coke-oven gas to Berlin and to construct four major long-distance lines. However, the inevitable accumulation of excess coke in order to fulfil contracts for gas during the present industrial depression may put a damper on extending this project. To meet this difficulty some of the companies are heating the ovens with blast-furnace gas, thus providing greater flexibility in the ratio of salable gas to coke produced.

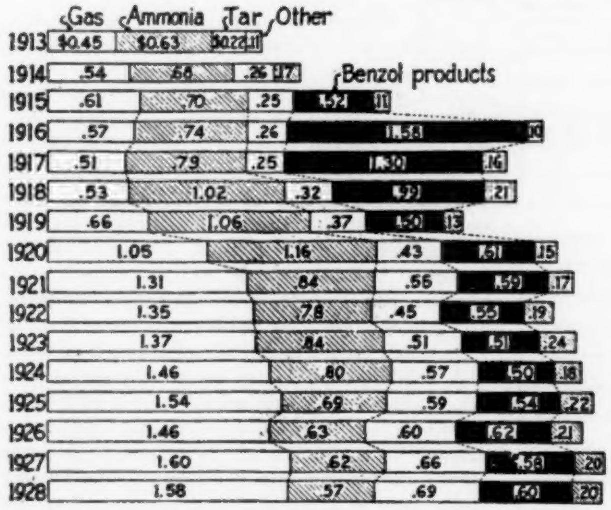

Fig. 3 Gross Value of the Several By-Products per Ton of By-Product Coke Produced, 1913–1928

Chemical Utilization of Coke-Oven Gas

The utilization of the hydrogen in coke-oven gas for the production of synthetic ammonia is another project for utilizing excess gas. The Ruhr-Chemie A.G., a combination of 20 coke-oven operators of the Ruhr district, have under construction and partly completed seven different plants with a total proposed annual capacity of approximately 200,000 metric tons of fixed nitrogen. Some 30,000 tons was produced in 1929, and it was expected that the 1930 production would reach 80,000 tons.[9] However, the present world-wide overproduction of fixed nitrogen may discourage completion of the original plan.

To those who are not familiar with this subject it should be explained that the manufacture of synthetic ammonia from coke-oven gas is quite different from the recovery of the small amounts of by-product ammonia always present in coke-oven gas. The process developed in the Ruhr involves the installation of liquefaction and fractional-distillation plants similar to those used for the production of oxygen from air. Coke-oven gas contains about 50 per cent of hydrogen. This hydrogen is extracted from the gas and chemically combined with nitrogen from the air to form ammonia. The residual gas, after removing the hydrogen, is a valuable fuel gas with a higher heating value per cubic foot than that of the original gas.

Similar plants for producing synthetic ammonia from the hydrogen in coke-oven gas have been installed in Belgium[10] and France.[11] The hydrogen from carbonizing 1 ton of coal yields approximately 110 lb. of fixed nitrogen as ammonia, compared to 5.3 lb. recovered from the gas in the usual by-product plant.

Probably the most complete chemical utilization of coke-oven gas has been made at Bethune, France. Ammonia, methanol, ethyl alcohol, and ethyl ether have been produced from the hydrogen, carbon monoxide, and ethylene in the gas after separating them in a Claude liquefaction and fractional-distillation plant. It is reported that a fourth unit, capable of making 20 tons of ammonia and $1^1/_2$ tons of methanol daily, has been completed recently.

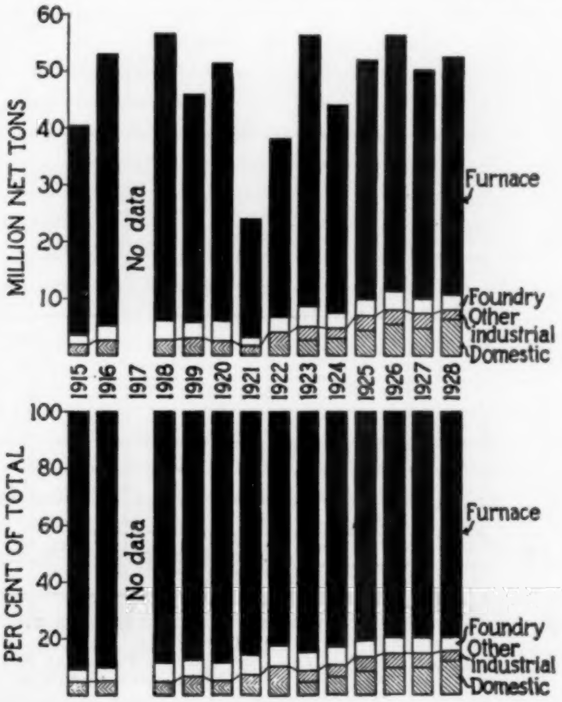

Fig. 4 By-Product and Beehive Coke Sold for Furnace, Foundry, Other Industrial, and Domestic Use

(Figures for furnace coke include all coke used by producer and not sold. The data represent the disposition made of the total production, including exports, except that in 1915 and 1916 the exports are not included.)

Competition Between Synthetic and By-Product Ammonia

As shown in Fig. 5, the decline of ammonium sulphate prices began in 1921, and has continued since that date due to the marked increase in synthetic-ammonia plants. Prior to the World War most of the commercial ammonia was obtained as a by-product from coal distillation. The World War accelerated the commercial development of synthetic processes for the catalytic combination of atmospheric nitrogen and hydrogen. The very rapid increase in world production of synthetic ammonia as compared to by-product ammonia is shown in Table 2.

TABLE 2 WORLD PRODUCTION OF SYNTHETIC AND BY-PRODUCT AMMONIA, IN METRIC TONS OF NITROGEN[12]

Kind of Ammonia	1917	1920	1923	1926	1929
By-product..........	340,000	290,000	325,000	360,000	440,000
Synthetic............	80,000	100,000	220,000	500,000	1,000,000

Tyler[12] estimates the current output (Sept., 1930) of synthetic ammonia for the United States at the rate of 180,000 short tons of ammonia per year, and the total capacity of plants now built, building, and immediately projected as equivalent to 360,000 tons of synthetic ammonia per year. This amount is more than $1^1/_2$ times the 1929 production of by-product ammonia.

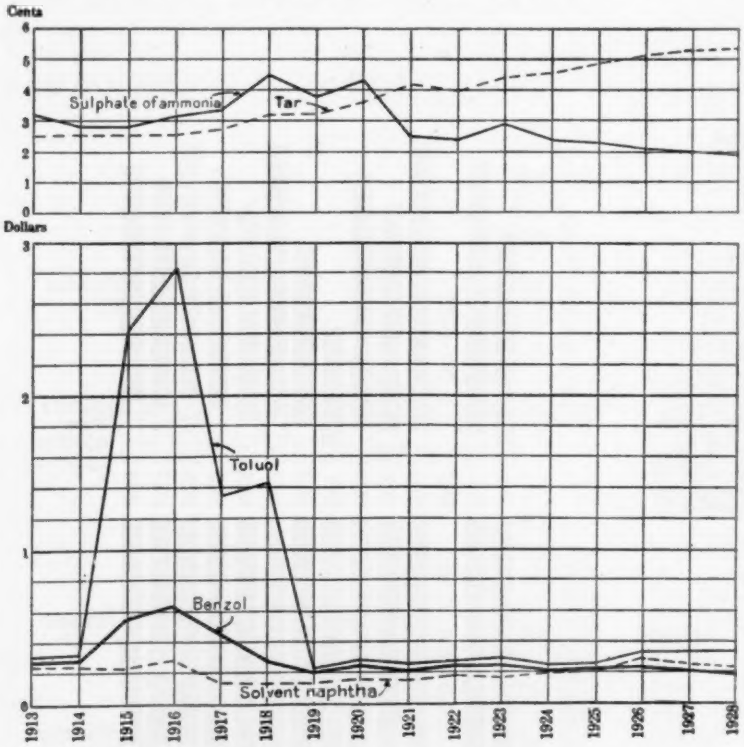

Fig. 5 Average Receipts per Unit for the Principal Refined Light Oils and Other Products, at By-Product Coke Plants, 1913–1928

(The figures for tar and sulphate of ammonia represent cents per gallon and per pound, respectively; the figures for light oils represent dollars per gallon.)

At a recent meeting (Oct. 23, 1930) of the Coke Oven Managers Association in England, J. B. Deakin, the president, stated that:

> This year for the first time we had the depressing sight of ammonia being scrubbed out of coke-oven gas and the resultant ammonia liquor used for coke quenching, and this in a modern up-to-date plant which was particularly well situated for obtaining cheap sulphuric acid."[13]

It is evident that the market price of ammonia is rapidly reaching the point where the returns will scarcely cover the cost of recovery, unless the process is cheapened. For this reason, some consideration is being given to wasting the fixed ammonia by leaving it in the liquor, thus saving steam and lime. Other economies are being introduced in new plants by installing larger saturator units, as, for example, the large new plant at the Prosper Colliery in the Ruhr. All the gas from ovens carbonizing 3750 tons of coal per day is passed through one single saturator producing 45 tons of ammonium sulphate per day.[14]

Utilization of Sulphur in Gas in Production of Ammonium Sulphate

Since sulphuric acid is one of the important elements of cost in the recovery of ammonia by the present sulphate method, investigators have made renewed efforts to utilize the sulphur in coke-oven gas for the production of ammonium sulphate. Two such processes have been developed recently in Germany. These are the Heinrich Koppers "C.A.S." process[15] and the "Tern" process.[16]

C.A.S. Process. In the C.A.S. (Cyanogen-Ammonia-Sulphur) process, cyanogen compounds, ammonia, and hydrogen sulphide are removed from the gas and recovered as ammonium sulphate and free sulphur. It is an improvement on the old Feld process. The essential principle of the C.A.S. process consists of scrubbing the gas with the concentrated ammonia liquor (10–12 per cent NH_3) and a solution of iron thiosulphate and polythionate containing iron hydroxide in suspension. The spent washing liquors containing ammonium thiosulphate, ammonium polythionate, ammonium sulphocyanate, iron sulphide, and free sulphur are then treated in appropriate circuits returning to the scrubbing cycle, with sulphur dioxide and air to regenerate iron thiosulphate, iron polythionate, and iron hydroxide, while free sulphur and ammonium sulphate are recovered in another circuit as end-products, after further treatment with sulphur dioxide and heating under pressure to 180 deg. cent. A part of the free sulphur is burned to generate the sulphur dioxide required in the process. The C.A.S. process has been installed at the Georgeschacht coke plant at Obernkirchen, Germany.

Tern Process. The Tern process, which also eliminates the purchase of sulphuric acid, has been installed by the Thüringer Gas-Gesellschaft at Leipzig, Germany. In this process the tar and ammonia liquor are separated by cooling and condensation in the usual manner. The ammonia is expelled from the liquor by distillation and stored in gaseous form in a suitable container.

The gas is desulphurized in iron oxide boxes by the ordinary dry purification method. The spent oxide is then roasted in a suitable furnace, from which gaseous sulphur dioxide is led off to a storage chamber where it is oxidized to sulphur trioxide (SO_3) in the presence of an electric arc. Gaseous ammonia and sulphur trioxide, in the proper proportions to form ammonium sulphate, are then led from the storage chambers to a reaction chamber which contains sufficient moisture to permit the formation of dry ammonium sulphate crystals. The sulphate is recovered with the aid of Cottrell precipitators.

More industrial experience is required before any opinion can be given on the economics of these new processes. It is largely a question of whether the gas works or the sulphuric acid manufacturer can make the cheapest SO_4 radical.

Sulphur-Recovery Processes

The recovery of sulphur in marketable quantities in connection with gas purification is one of the notable achievements of recent years. Several plants in the United States have installed such processes. In 1929, the average recovery was 2.6 lb. of sulphur per ton of coal carbonized, and the sales value as ordinary brimstone was approximately $18 a ton. Flotation sulphur, which will be discussed later, has a higher value.

Charcoal Process. Activated charcoal, similar to that used in gas works, is one of the newer solid absorbents used for purifying gases from sulphur compounds. It has the advantage of absorbing organic sulphur compounds as well as hydrogen sulphide, and permits the recovery of free sulphur.[17] The gas, to which has been added sufficient air to oxidize the hydrogen sulphide to free sulphur and a very small amount of ammonia, is passed through cylindrical tanks containing activated charcoal. After a tank becomes saturated with sulphur, it is cut out from the gas circuit and the free sulphur is extracted with ammonium sulphide. After the sulphur is extracted the tank is steamed to remove the last traces of solution and regenerate the charcoal for the next cycle of absorption. The ammonia is then distilled out of the polysulphide solution for another extraction of charcoal, leaving behind the free sulphur.

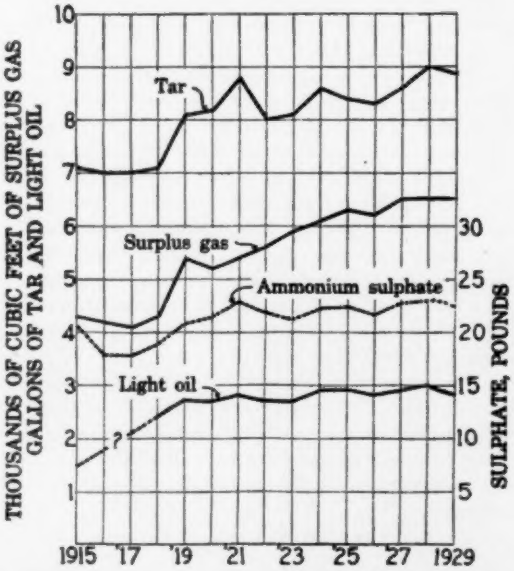

Fig. 6 Average Yield of the Principal By-Products per Net Ton of Coal Carbonized in By-Product Coke Ovens, 1915–1929

(Figures for light oil represent the average at plants recovering light oil.)

This process is used by the German I.G. at the Leuna synthetic-ammonia plant for purifying gases, and was given serious consideration among other processes for purifying the large volumes of coke-oven gases collected by the Ruhr-Gas A.G. for their gas distribution system. However, they finally adopted a similar sulphur-recovery system, using iron oxide in place of charcoal.

Ruhr Iron Oxide Process.[18] The gas is passed through large ferroconcrete boxes, from which the oxide when saturated can be removed through a bottom discharge or from the top with grab buckets. The sulphur is extracted from the oxide with ammonium sulphide in the same manner as in the activated-carbon process. After removing the sulphur the spent oxide is treated in the usual manner for the recovery of cyanogen compounds. It is reported that about 20,000 tons per annum of almost pure sulphur is being recovered by the Ruhr-Gas A.G.

Flotation Sulphur. Ordinary sulphur or brimstone is one of our cheapest commodities, present quotations at the mines being $18 a ton. Consequently the returns from this by-product, while significant, do not pay the expense of purification. However, modern chemical research can aid the by-product coke industry as well as its competitors. The research organizations of American coke-oven builders have tackled the various problems of the industry with courage and intelligent vision. One of their outstanding accomplishments has been the mechanical and chemical improvement of gas purification processes, and especially the development of new by-products from the impurities which have been removed. "Flotation" sulphur, as distinguished from ordinary sulphur, is one of these new products. It is called "flotation" sulphur because it separates out in the purification process in an extremely finely divided, or "colloidal," form and floats to the top of the purification liquid in the form of a froth. Due to its fineness of particle size, this form of sulphur has been found to be especially well adapted to use as a fungicide in spray or dust form.[19] It also has been found to have curative effects on simple forms of skin disease when used as a constituent in soap.

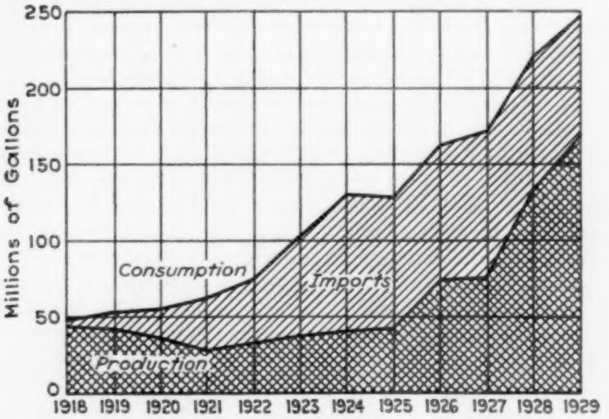

Fig. 7 Factors of United States Consumption of Creosote Oil

There are three modifications of the sulphur-recovery processes:[20] the "Thylox," "Ferrox," and Nickel processes, all using the same apparatus. The common principle of these processes is scrubbing the gas with a liquid containing sodium carbonate and a metal compound (iron or nickel) in solution or suspension. The foul solution then passes to a tank in which fine streams of air are blown up through the liquid, causing the sulphur compounds to be oxidized and the liquid regenerated for further use. The sulphur floats to the top of the liquid and collects in a froth, overflows to a slurry tank, and is filtered off from the water.

The Thylox process uses a clear solution of the purifying reagents and remains clear except for the precipitated sulphur, which consequently is recovered in a pure form. The Ferrox process uses a suspension of an iron compound and therefore yields a sulphur contaminated with iron. However, this should not be objectionable, and perhaps it may be favorable in its use as an agricultural fungicide. The Nickel process uses nickel in place of iron and is used only for oil gas and water gas, as the cyanogen compounds in coal gas consume too much nickel.

"Gas Purification Processes." Pamphlet Published by The Western Gas Construction Co., Fort Wayne, Indiana.

All of these processes remove hydrogen cyanide (HCN) from the gas and about 95 to 98 per cent of the hydrogen sulphide. The remainder is absorbed in an iron oxide catch box.

Thiocyanates. It is a simple matter to introduce a slight modification in the liquid purification process and recover ammonium thiocyanate,[21] which is converted by heat to thiourea. Thiourea can be condensed with formaldehyde to form resins resembling bakelite. This product can be molded or machined into a variety of shapes, either transparent or colored.

The recovery process consists of scrubbing the gas after leaving the secondary washer cooler with weak ammonia liquor, which reacts with part of the hydrogen sulphide in the gas and forms ammonium sulphide. Some finely divided sulphur is then dissolved in the ammonium sulphide to form ammonium polysulphide, with which the gas is scrubbed to form ammonium thiocyanate by reaction with the cyanogen compounds in the gas.

Thus research will probably develop some financial return for another impurity that must be removed from coal gas before it is sent out through the distribution system. Of course, these are minor by-products, but they illustrate the constant thought that is being given to all the details of by-product recovery.

PHENOLS FROM STILL WASTES

Another important example of solving a troublesome waste-disposal problem with at least a partial credit from a salable by-product is the dephenolizing of ammonia-still wastes. Most coke-oven plants use the direct system of ammonia recovery. Such plants produce an average of 30 gal. of still waste per ton of coal carbonized. Plants using the indirect system produce about 90 gal. per ton. Total phenols (including cresols and other phenol derivatives) in ammonia-still wastes from direct-recovery plants average about 2 grams per liter (0.017 lb. per gal.), but may be as high as 4 grams in some cases.[22]

The discharge of such untreated still waste into a public water supply is objectionable because the phenols give rise to a disagreeable taste in the water. Modern water supplies are usually chlorinated. The chlorophenols produced in this process give a medicinal taste to the water even in dilutions as high as 50 or 100 parts per million.

Three different processes have been developed and are now in use at a number of plants for removing the phenols from this waste water. Two of the processes depend on removing the phenols in the vapor phase and the third by extracting the phenols with solvents.

Heffner-Tiddy Process. In this process advantage is taken of the volatility of ammonium phenolate. The ammonia liquor is preheated to 98 deg. cent. or higher, and enters the still countercurrent to the ammonia gas leaving the still. Ammonium phenolate is formed in the vapor state and goes on into the gas, or can be scrubbed out with caustic solution.

Koppers Vapor-Recirculation Process. In the Koppers vapor-recirculation process the hot liquor from the free-ammonia still is sprayed down a tower against an ascending stream of steam and gas or air, which vaporizes the phenols and carries them out of the liquor, which is then returned to the fixed-ammonia still. The phenol-bearing vapors are then scrubbed with caustic soda solution in another part of the cycle, forming sodium phenolate, from which phenol may be recovered by treatment with carbon dioxide or sulphuric acid.

An interesting interutilization of by-products resulting in appreciable savings consists of using the same caustic soda solution first in the dephenolizing tower and then in the benzol washer. Blast-furnace gas containing 22 to 24 per cent of carbon dioxide is then bubbled through the sodium phenolate solution, liberating phenol. After separating the phenol the residual solution containing sodium carbonate and bicarbonate is utilized in the liquid purification plant.

Solvent Extraction Process. In this process the ammonia liquor before entering the still is subjected to a countercurrent extraction with benzol or light oil. The phenols dissolve in the benzol, which is in turn extracted with sodium hydroxide solution, forming sodium phenolate, from which phenol is produced by treatment with acid or carbon dioxide.

Amount of Phenols Recovered. The amount of salable phenols recovered varies somewhat with the type of recovery process used and coke-oven-plant conditions. An average figure for American plants is 0.35 lb. per ton of coal carbonized. Four producers reported a total of 85,000 gal. of crude phenols recovered from ammonia-still waste in the United States in 1929.[23] In 1930, additional plants installed or contracted for have a potential total capacity of 250 million gallons of ammonia liquor, corresponding to 3 million pounds of phenol annually. It is probable that the amount of phenol from this source will increase considerably as new dephenolizing plants are completed.

In the Ruhr district of Germany 12 dephenolizing plants are treating 528 million gallons of ammonia liquor annually and producing 6,600,000 lb. of phenol.

In this connection it is interesting to note that the combined U. S. production of natural phenol from coal tar (not including phenol from ammonia liquor) and synthetic phenol in 1929 was 24 million pounds,[23] as compared with 10 million pounds in 1928. More than 80 per cent of the production was made synthetically from benzene.

BENZOL AND LIGHT OILS

As shown in Fig. 3, benzol products have been a steady source of income to the coke-oven operator during the last 10 years, despite the declining prices of gasoline in recent years. Approximately one-half of the 1929 production of crude light oil was sold as motor benzol at an average unit price of 16 cents per gallon. The higher price of benzol as compared to gasoline is due to its high "anti-knock" properties. It is blended with petroleum gasoline for the production of "premium" motor fuels. There is also an excellent foreign market, 33 million, from a total production of 135 million, gallons of crude and refined benzol being exported[24] in 1929. One-half or more of the benzol exported went to Germany.

As seen from Fig. 6, a permanent increase in average yield of light oil per ton of coal carbonized of from 2.7 to 2.9 gal. took place in 1924. This increase, due largely to the adoption of higher carbonizing temperatures and technical improvements, has been held ever since.

The principal recent improvement in benzol recovery has been in the refining process. Activated carbon and other solid absorbents have been tried as a substitute for oil absorption at certain European plants without practical success.

In washing benzols with sulphuric acid to remove gum-forming constituents, it is recognized that appreciable quantities of light oil are lost due to the drastic action of the strong acid. Progress has been made in Europe in reducing this loss by using a limited amount of less concentrated sulphuric acid. Also, in the United States Jacobson[25] has reported on a new process of benzol washing known as the "Ufer" process, which has been introduced at the plant of the Hamilton Coke and Iron Co., at Hamilton, Ohio. This process avoids the production of the usual "acid sludge," the disposal of which is difficult and from which the spent acid can not be recovered readily. It also reduces light-oil losses. Jacobson states that:

> In the Ufer process, after the benzols have been agitated with sulphuric acid of a suitable strength, a certain amount of water is added to the agitator; agitation is then continued, after which the mixture is allowed to settle. Due to the addition of water, no sludge results, but instead the resins remain dissolved in the light oil, leaving a clear sulphuric acid below, which is suitable for further use in the ammonium sulphate saturator. On distillation of the light oil, the resins remain in the still residue.

Resins From Coal By-Products

Progress has been made in the utilization of the coumarone and indene compounds in light oil for the production of resins. These resins are now on the market and are used in rubber cements, printing inks, varnishes, lacquers, and driers. While this source of resin is at present of minor importance, coal is the parent substance of most of the synthetic resins which have entered into a large variety of uses, such as insulating panels, dials, and other parts of electrical apparatus (the largest use), pens and pencils, ornamental fittings, smokers' articles, novelties, etc. With the cheapening of the raw materials for resin plastics, much larger uses, such as molded furniture, interior trim, and various utensils, are in prospect. Bakelite, the best known of these resins, is made from formaldehyde and phenol, and phenol is produced from coal, both by extraction from the tar and by synthesis from benzol. The marked increase in the production and sales of phenol is largely due to the rapid increase in output of synthetic phenol resins. The total 1929 production of 33 million pounds of synthetic resins of coal-tar origin represents more than a 50 per cent increase over 1928.[26] Also, the cyanogen compounds in coal gas can be converted to thiourea, another source of resin plastics.

Cresol is also used for resins, and much experimental work has been done in recent years on making resins from the complex tar acids which comprise 20 to 30 per cent of low-temperature tar. If commercial success is ultimately achieved in such utilization of low-temperature tar it will help the cause of low-temperature carbonization, since this process yields, per ton of coal, from 20 to 30 gallons of tar, of which nearly a third is tar acids and higher phenols. Without some such special use of low-temperature tar, it is worth no more than its fuel value.

Tar and Tar Products

Next to coke and gas, tar is the most important product of coal carbonization. The average value of tar per ton of coke produced has been gradually increasing since 1913, as shown in Fig. 3. This is due both to increasing yields (Fig. 6) and increasing unit price (Fig. 5).

The expansion of metallurgical coke plants using 100 per cent high-volatile coal and developments in operating practice are responsible for the larger yields. The increased average price is due largely to expansion of demand for creosote oils for wood preservation and tar for protective coatings and road oils.

The total tar production for 1929 was 681 million gallons,[27] of which about 50 per cent was distilled and the remainder used as liquid fuel.

An important development of the last two years is the partial refining of tars at coke-oven plants. In 1928 these plants produced 12 million gallons, and in 1929, nearly 27 million gallons. Many of these stills are of a new continuous type, developed by the Barrett Company.[28] They are internally heated by the sensible heat of hot coke-oven gases. Creosote oil is recovered by fractional condensation.

The rapid increase in consumption and production of creosote oil is shown in Fig. 7. Since 1927, the importation of creosote oil has been declining, and this trend is likely to continue.

The disposal of the large quantities of pitch has always been more or less of a problem to the tar refiner, since the pitch residue is usually more than half of the original tar before distillation. However, uses are expanding. The extensive new pipe-line systems have increased the consumption of pitch and saturated felts in built-up coatings for protection from corrosion. The soft pitch is used extensively in road construction, and pitch coke has been shown to be advantageous for certain metallurgical purposes where a coke fuel free from ash or sulphur is desired.

Hydrogenation of Coal Tar

Inasmuch as 50 per cent of the tar produced in this country is burned as a fuel, its value is set by the market price of the fuel oil with which it must compete.

This situation would also hold true with low-temperature tar if it were produced in commercial quantities. Although much research has been done on finding new uses for low-temperature tar, no real commercial success has yet been achieved. Since a large part of low-temperature tar consists of hydrocarbons similar to those found in petroleum, it is amenable to cracking for the production of motor fuels, and it may also be hydrogenated by the Bergius process in the same way as petroleum. However, the yields of gasoline are less in either case than from petroleum.

It is reported that the I. G. organization in Germany is producing 100,000 tons per annum of synthetic gasoline by hydrogenating lignite tar.

In the United States, the Standard Oil Company of New Jersey, through its Development Company, joined with the I.G. in the further development and commercialization of this method as applied to the conversion of heavy oils and residues to gasoline and the production of high-grade lubricating oil. Extensive research has been conducted and is still in progress in simplifying the equipment and broadening the process, so that now it is described by Haslam and Russell as "a flexible method of treating and refining by the use of hydrogen which should have a wide application in the oil industry."[29]

Several commercial plants have been built in this country for hydrogenating petroleum. There is no question but that low-temperature tar could be treated in similar plants if and when a low-temperature carbonization industry is developed.

Summary

In summarizing the trends and recent developments in the by-product coking of coal, it is most gratifying to note the steady gain in value and yield of by-products during the last 15 years. The design of ovens and by-product-recovery equipment has been constantly improved. Practically every new installation in recent years has had some mechanical or process improvement giving greater capacity, better quality of product, better yields, lower costs, or new by-products.

The by-product oven has not only displaced the beehive oven as a producer of metallurgical coke, but it has in recent years taken an important position in supplying base-load gas for city use in conjunction with coke for the domestic fuel trade. It is probable that further extensive developments in this direction will be arrested to a considerable degree in regions that will be served by long-distance natural-gas pipe lines and possibly by the increasing amounts of refinery gas now becoming available. At present these refinery gases and liquefied gas, such as propane and butane, are supplementing rather than displacing coke-oven gas. The future interrelation of these various types of gases is difficult to predict.

The declining prices of ammonia, due to cheap synthetic ammonia, have made the profitable recovery of this by-product a real problem. European investigators have attempted to avoid the purchase of sulphuric acid for ammonia recovery by utilizing the sulphur in the coke-oven gas. Two new processes for the conjoint recovery of sulphur, ammonia, and cyanogen compounds have been developed in Europe and are being given large-scale tryouts. In America, the sulphur-recovery purification process is making excellent progress and promises to give a new by-product sulphur peculiarly adapted to fungicidal and agricultural purposes. The problem of ammonia-still waste disposal has been solved. Phenol, the troublesome constituent of these wastes, is recovered in salable form, 85,000 gal. of crude phenols being obtained in 1929.

Improvements have been made in light-oil refining which reduce light-oil losses in the washing process, and a larger proportion of coke-oven tars are now being refined, with a resultant increase in the production of creosote oil.

Much work has been done in attempts to develop new uses for low-temperature tar, but it cannot be said that any material commercial outlet, other than utilization as a fuel, has been developed.

FSP-54-5

Grindability of Coal

By R. M. Hardgrove,[1] Fullerton, Pa.

This paper points out the need for a method of determining the grindability of coal and outlines a method by which a prepared sample is partly pulverized and the new surface produced is measured in accordance with Rittinger's Law. Two types of grindability machines, the mortar and pestle and the ball mill, are described, and test data obtained from both types are compared. The relation between pulverizer capacity and grindability is discussed. A representative list of the coals of the United States and Canada is presented showing their grindabilities and the relation between grindability and volatile content. The relation between the grindability of petroleum coke and its method of manufacture and volatile content is discussed.

The testing of power-plant equipment has reached a high stage of development, and the Test Codes of the Society have been helpful in recommending the most accurate methods and standardizing the procedure and calculations, with the result that test data obtained from different plants can be compared quite readily.

The general use of pulverized coal in power plants has added pulverizers to the list of equipment to be tested. Up to the present time pulverizer tests have been quite incomplete and unsatisfactory because there was no method of determining the grinding characteristics of coal. It is similar to testing a boiler without being able to obtain the calorific value of the coal.

Accurate estimates of the performance of new equipment have been difficult to make as there was no way to predict the grindability of the coal that would be used.

In the selection of the best coals to use there are many factors to be considered such as price, freight rates, calorific value, fusing temperature of the ash, and proximate analysis, all of which are quite accurately known or can be determined on a laboratory sample.

If accurate knowledge of the grindability and abrasive qualities of the coal could be determined as easily as the fusing temperature, it would be of considerable help to the coal buyer.

Thus the need for a standard grindability method has been felt by both manufacturers and users of pulverizing equipment, and such a method applies to ores, rocks, cement, and other materials as well as to coal.

The work done in pulverizing certain materials has been investigated by various authorities, and Rittinger's Law, which states that the work done in grinding is proportional to the new surface produced, is generally accepted as being approximately correct. This theory was first proposed by Rittinger in 1867, but was not definitely proved until 1924 and 1925 by Martin.[2] Measurement of the surface of all the particles in a sample has been accomplished on silica by measuring its rate of chemical reaction or the time required to dissolve the sample in hydrofluoric acid. Mechanical screening methods seem to be more practical, however, and if one considers a 1-in. cube split into eight $^1/_2$-in. cubes, each of these small cubes will have three new faces in addition to the three old ones, or the surface of each $^1/_2$-in. cube is just double the original surface. Rittinger's Law can therefore be restated, that the work done in grinding is proportional to the reciprocal of the diameter of the particles.

The method of determining grindability may be outlined as follows:

1 Prepare the coal sample so that all particles are practically the same diameter.

2 Subject this sample to a definite process of pulverizing.

3 Screen this partly pulverized sample and determine the increased surface produced.

4 Based on Rittinger's Law, the final surface of the sample is obtained by applying constants proportional to the reciprocal of the diameters of the particles. The new surface produced is obtained by subtracting the original surface.

5 The relative grindability is obtained by comparing the new surface to that obtained in a similar way on a coal selected as a basis for comparison.

In deciding upon the size of particles in the prepared sample to be tested, it was felt that it should be at least as fine as culm so that tests could be made on that material. The coarser the material the less surface units it possesses, which is an advantage; but more of the sample will be rejected as being too fine, which is a disadvantage. A sample prepared so that all will pass through a 16-mesh screen and all be held on a 30-mesh screen seems to satisfy the requirements the best. All of the work reported in this paper was done on samples sized between these limits.

In preparing the sample it is crushed in a coffee mill, which produces the least amount of fines, until all will pass through a 16-mesh screen, after which the material finer than 30-mesh is screened out and rejected. A definite weight is then selected from this sample.

Table 1 shows the size of screens used in the final screening of the partly pulverized sample. In the second column is given the opening of each mesh in inches. In screening the sample it was assumed that the material between each interval, such as between the 100- and 140-mesh screens, has an average diameter which is the average of the openings of the 100- and 140-mesh screens, or 0.00495, and similarly for the other intervals. The

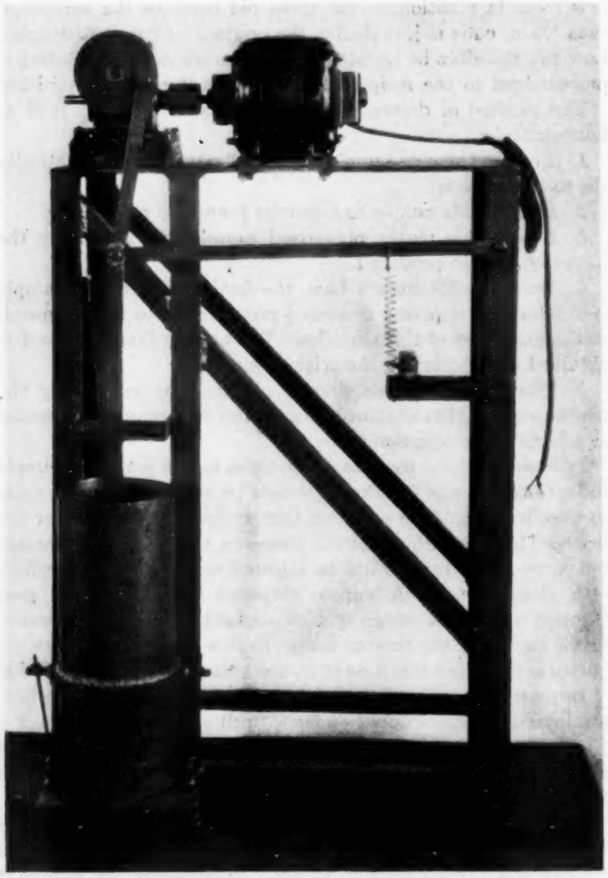

FIG. 1 MORTAR-AND-PESTLE TYPE OF GRINDABILITY MACHINE

fourth column gives the reciprocals of these average openings for the intervals used, which are the constants used in calculating the surface units.

By using a large number of screens of close intervals, a good separation of the final product into various sizes can be obtained. The material through the 300-mesh screen is, however, more difficult to evaluate except by elutriation or other tedious methods which are considered impractical for this purpose. It was felt, however, that much of this material is considerably finer than 300-mesh, and a constant of 1000 is used, which is about double the reciprocal of the opening in a 300-mesh screen. This really assumes that the material through 300-mesh screen will have an average size of 0.001 in., which probably is not far from the truth.

Table 2 gives a sample calculation of surface units on a sample which originally was between the 16- and 30-mesh screens.

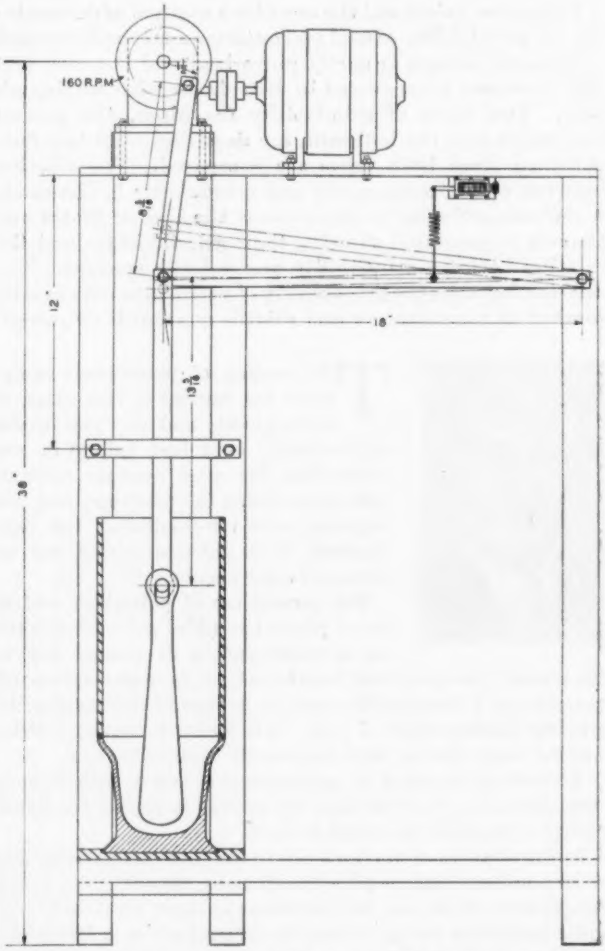

FIG. 2 MORTAR-AND-PESTLE TYPE OF GRINDABILITY MACHINE

Multiplying through by the various factors and adding them up, it is found that 19,740 surface units were produced upon this sample. The original sample being between the 16- and 30-mesh screens, had 2900 surface units before pulverizing, which

TABLE 2 SAMPLE CALCULATION OF SURFACE UNITS

Screen mesh	For Illinois coal run on ball mill, per cent of sample between these two screens		Factor		
16–30	24.4	×	29	=	708
30–60	36.0	×	61	=	2196
60–100	13.8	×	129	=	1780
100–140	7.2	×	202	=	1454
140–200	3.8	×	285	=	1084
200–230	1.6	×	377	=	602
230–300	2.4	×	465	=	1116
Through 300	10.8	×	1000	=	10800
Final surface units					19740
Less original surface units					2900
New surface units					16840

NOTE: If new surface units of standard sample is 29,961, grindability = 16,840 ÷ 29,961 = 56.2 per cent.

must be deducted; thus giving 16,840 new surface units. If the new surface units of a standard sample treated in the same way were 29,961, the grindability is taken as the ratio between these two, or 16,840 divided by 29,961 equals 56.2 per cent.

Description of Apparatus

Mortar and Pestle. Figs. 1 and 2 illustrate the first grindability machine made, which consists of a mortar and pestle with a motor and gearing for raising the pestle and letting it drop on the sample of coal in the mortar at the rate of 160 strokes per minute. The travel of the crank is just a little more than the distance the pestle is raised above the bottom of the mortar, and the speed of operation is such that the fall of the pestle due to gravity is a little slower than the actual travel of the crank, so that a true dropping motion of the pestle is produced. However, it does not travel in a true vertical motion, due to the angularity of the radius arm which tends to give the pestle a swinging motion, permitting it to hit in various positions, thus working all over the bottom of the mortar. The mortar was made sufficiently deep to avoid any appreciable loss of material while grinding.

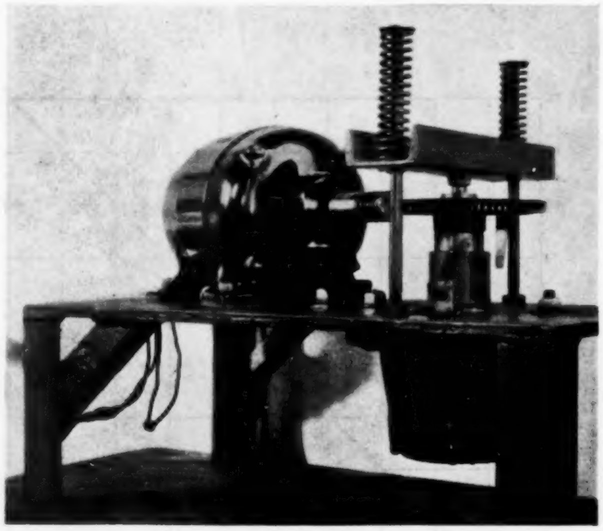

Fig. 3 Ball-Mill Type of Grindability Machine

Ball Mill. Figs. 3 and 4 illustrate the ball mill which was used in the later work. The eight 1-in. balls roll on a stationary ring and are driven from above by a rotating plate, at a speed of 21 r.p.m. A definite downward pressure is exerted on this upper plate by means of the two springs, and the result is a rolling action under pressure very similar to commercial pulverizing mills where large rolls or large balls are rolled against grinding rings or tables, the force being obtained either by centrifugal force or by springs. Dead weights were used during some of the work and gave results equal to those obtained with the springs and are more permanent. Several other minor features are being improved upon.

A small tube mill, using steel balls of a mixture of sizes, was tested in comparison with the first two types. Two other machines were built and tested, but the results from these were not promising enough to warrant inclusion in this paper.

In selecting a coal that would be called 100 grindability, with which all others could be compared, it was found that the semibituminous coals from the New River and Pocahontas fields in West Virginia and from the Upper Kittanning seam in Somerset and Cambria Counties, Pennsylvania, had about the same grindability, and were the easiest-grinding coals to be found in this country. It seemed logical that one of these should be chosen, and the most convenient one was the coal from Somerset County, Pennsylvania. Referring to Table 5, the grindability values given for New River coals average 98 while those for Pocahontas coals average 104.

Characteristics of Grindability Machines

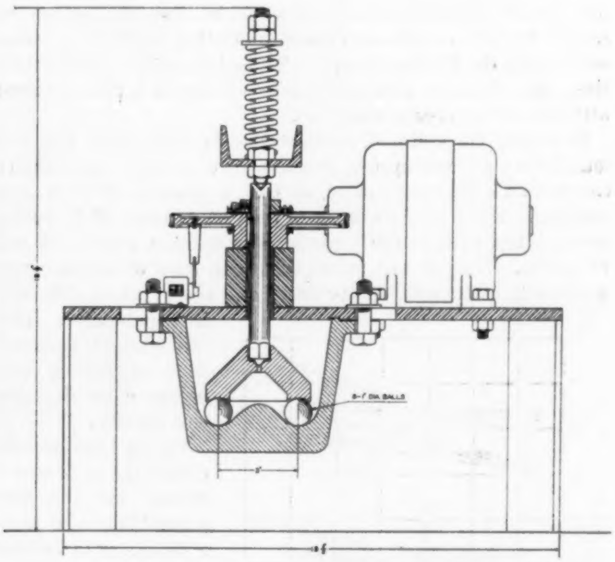

Fig. 4 Ball-Mill Type of Grindability Machine

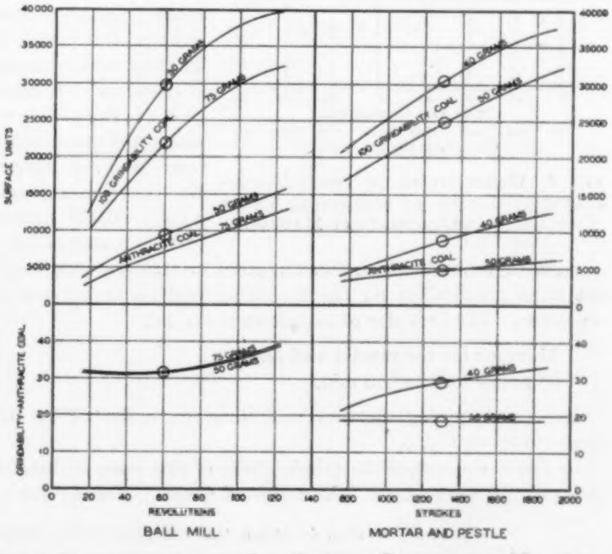

Fig. 5 Characteristics of Two Types of Grindability Machines, Using Various Sizes of Samples

In bringing out the characteristics of the different types of machines, Fig. 5 represents a series of results using this 100-grindability coal and a low-grindability anthracite coal from the Upper Pottsville district near Mahanoy City, Pennsylvania. The results on the mortar and pestle were obtained using a speed of 160 r.p.m., which was found to give the most consistent results. Results for two different sizes of original samples, namely, 40 and 50 grams, are plotted. The surface units on the 100-grindability coal are about 25 per cent higher for the 40-gram than

TABLE 3 CHECK DETERMINATIONS OF SURFACE UNITS ON THREE TYPES OF GRINDABILITY MACHINES

	Ball mill, 60 rev. (Surface units)		Mortar and pestle, 1300 strokes (Surface units)		Tube mill, 1400 rev. (Surface units)	
	100-grindability coal	Anthracite coal	100-grindability coal	Anthracite coal	100-grindability coal	Anthracite coal
	29,448	9,620	30,050	8,250	36,407	12,052
	29,938	9,818	28,975	7,957	36,712	10,080
	29,432	9,848	30,300	8,949	26,403	9,851
	29,852	9,486	31,310	9,340	26,490	9,683
	29,818	9,854	29,202	8,181	26,601	7,621
	30,544	9,946	30,647	7,684	44,306	8,450
	30,232	9,782	30,680	8,748	25,489	10,678
	30,304	9,966	30,895	8,852	29,278	10,295
	29,840	9,548	31,030	8,503	27,704	9,489
	30,198	9,636	31,170	9,055	30,005	8,938
Average	29,961	9,800	30,426	8,552	30,998	9,714
Maximum variation from average	529	186	1,451	788	13,408	2,338
Per cent	1.76	1.9	4.8	9.2	43.0	24.0

they are for 50-gram samples, as would be expected, but on the anthracite they are almost double, indicating too large a charge when using the 50-gram sample. The grindability of the anthracite, using 40 grams, also agrees more closely with that obtained with the other types of machines.

In testing the ball mill, as illustrated in Figs. 3 and 4, it was found that a lower spring pressure gave a flatter grindability curve than a higher pressure, so that a pressure of 30 lb. was adopted. Fig. 5 shows a series of tests made using 30 lb. spring pressure and with two different sizes of samples, namely, 50 and 75 grams. Here it was found that both sizes of samples give practically a flat grindability curve and a very small difference in grindability. This characteristic is important in testing materials of varying specific gravity.

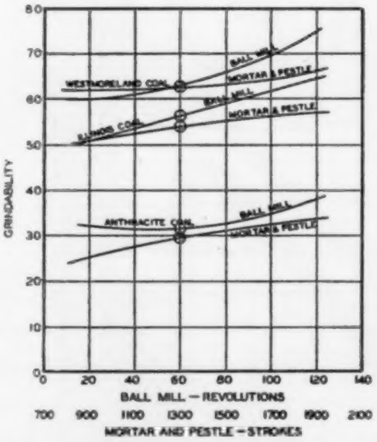

FIG. 6 GRINDABILITY OF THREE REPRESENTATIVE COALS AS OBTAINED, USING TWO TYPES OF GRINDABILITY MACHINES

On all types of machines the surface-unit curves for the 100-grindability coal show a tendency to become horizontal at the higher revolutions as the increased number of fines cushion the grinding. The best working range is therefore at a number of revolutions where the curve has a more uniform slope. By choosing approximately 30,000 surface units as a standard for each, it was found that points can be obtained that give practically the same grindability for the anthracite coal on both types of machines. The best size of sample seems to be:

40 grams for the mortar and pestle
50 grams for the ball mill.

The points giving the best conditions are indicated by the large circles on Fig. 5.

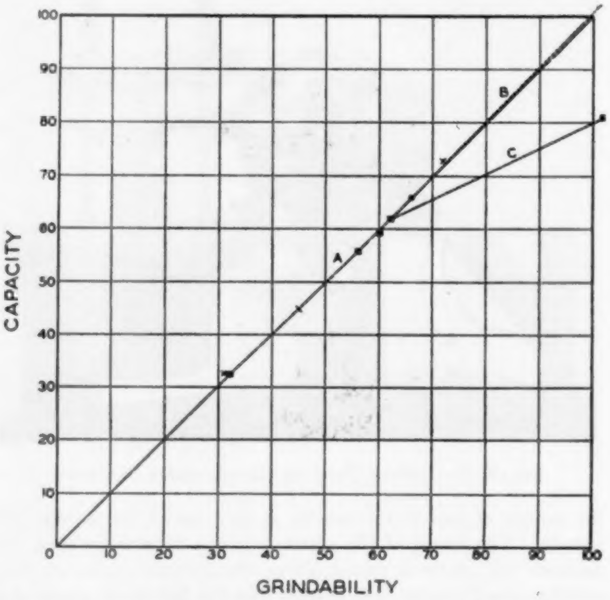

FIG. 7 RELATION BETWEEN MILL CAPACITY AND GRINDABILITY

In Fig. 6 are plotted the grindabilities of this same anthracite coal, Illinois coal, and a Westmoreland County, Pennsylvania, coal. For ease in comparing the two types of machines the abscissas are plotted so that the best number of revolutions coincide.

By properly choosing the working conditions, practically the same grindability of all three coals can be obtained with both types of machines. Preference for either type depends upon its ease of manipulation and the ability to duplicate results rather than on any real difference in the scale of the results obtained.

It is quite evident that in order to establish a standard method various laboratories must use the same size of sample, the same number of revolutions, the same speed, the same method of screening and calculation, and preferably the same type and size of machine.

The tube mill was tested in a similar manner, and the results gave in general about the same values as the other two types, but they were so inconsistent that they have not been included. In Table 3 are listed the surface units for 10 consecutive tests on the 100-grindability coal and the anthracite coal on the mortar-

TABLE 4 MILL CAPACITIES AND GRINDABILITIES OF POINTS PLOTTED IN FIG. 7

and-pestle, ball-mill, and tube-mill types. The consistency of the results clearly places the ball mill first, the mortar and pestle second, while the tube mill is so erratic that it is eliminated.

The ball mill is quite easy to clean and is entirely closed during grinding. The mortar and pestle is easy to clean, but loses some fine dust during grinding. The tube mill is very difficult to clean as it is necessary to brush off each ball in collecting the sample. The result is that the average operator will lose about 4 per cent of the sample with the tube mill, whereas with the mortar and pestle less than 2 per cent will be lost, while with the ball mill less than 1 per cent will be lost.

In calculating the results it was assumed that any material lost was finer than 300 mesh, and this is probably true for the most part, but the fact that more is lost in the manipulation of the tube mill partly explains why its results are not as consistent.

COLLECTING SAMPLES

As the coal is found in the mine, the different layers have different grindabilities, and it is only natural that in the mining, handling, and shipping operations the softer coal should be broken down into the smaller sizes while the harder coal remains in the larger lumps. It is therefore quite essential that a proper sample be taken which includes the correct proportion of larger lumps and fine sizes. To do this requires just as much care as is necessary in obtaining a sample for calorimeter determinations, and a sample for grindability determinations should be taken in the standard manner of sampling coal, quartered down, and crushed until it is of a size suitable for sending to the laboratory. The effect of taking an improper sample is clearly brought out by a series of grindability determinations made on a coal which had been separated into three sizes at the mines. Each one of these sizes was run separately, and the following results were obtained:

Size	Grindability
On $1\,{}^{1}/_{4}$-in. bar screen................	82
Over ${}^{3}/_{8}$-in. hummer screen..........	89
Through ${}^{3}/_{8}$-in. hummer screen...........	104

The establishment of a definite grindability scale that is in general use would be of great value even though the numbers of the scale had no exact relation. However, if this scale can bear some definite relation to mill capacity it will be still more useful. In Fig. 7 are plotted the relative capacities obtained by grinding material of various grindabilities on the same pulverizer. Curve *A* represents three points obtained with different materials in a closed-circuit grinding system with relatively coarse grinding. The material being ground was cushioned very little by fine products and therefore can be said to follow its true grindability quite closely. The points match the theoretical relation as shown by the dot-and-dash line. Points on the line *B* were obtained by grinding coal in a tube mill equipped with an external classifier where a high recirculating load was used, which means that the grinding parts were scavenged quite completely. This also checks the theoretical curve. Curve *C* represents five points obtained from air-swept mills with internal classifiers which shows four points, having grindabilities of 62 and less, checking the theoretical curve quite closely, while the fifth point, having a grindability of 102, shows a lower capacity. This is to be expected, for most of these mills are designed for coals having a grindability around 50 to 70, and the air conditions are designed for that type of material. When one tries to realize the full added capacity by grinding a much softer coal, the scavenging is much less complete and the mill parts are cushioned with fines. This means that the relation between maximum capacity and grindability depends greatly upon the type of mill and the exact conditions of its operation, and that relations anywhere between the curve *C*. or lower, and the theoretical curve can be obtained.

Each coal itself has only one grindability under all conditions, and the design and application of pulverizers should be suited to the capacity and grindability.

It has been suggested that standard capacity ratings of pulverizers should be on the basis of 100-grindability coal. With coals varying in grindability as they do, any standard capacity ratings are misleading, but if such a rating were used it would be much better to rate them at 50 or 60 grindability where the capacities are much less affected by the conditions of operation, as is brought out in Fig. 7.

On the basis of Fig. 7, it seems that the scale established is a very reasonable one, even though it requires individual interpretation with different types of pulverizing mills.

Since a mill usually takes about the same power when it is fully loaded, irrespective of how many tons it is producing, it follows that the power per ton is inversely proportional to the maximum capacity, and therefore inversely proportional to the grindability of the material.

During the four years that this method has been in use over 2000 samples have been tested. In Table 5 are given the grindabilities of representative coals from the various parts of the United States and Canada. In a number of instances several samples from the same mine have been tested. These results have been averaged, and the sixth column gives the number of samples represented, and the maximum, minimum, and average grindabilities are listed. Fig. 8 is a map of the northeastern section of the United States showing the actively mined regions with identifying numbers which match the numbers given in Table 5.

In general there is a relation between the volatile content of the coal and its grindability, as illustrated in Fig. 9. Coals between 16 and 28 per cent volatile are usually of high grindability, and this decreases as the volatile increases, but there are so many exceptions to this trend that determination of volatile is not a definite guide to grindability. The Pennsylvania anthracites show a remarkably uniform variation from very hard in the eastern end of the field to quite soft in the western end, as will be seen by comparing the grindabilities in Table 5 with the map.

Table 6 shows the grindability of a number of petroleum-coke samples with a partial description of the process by which the coke was produced. There seems to be some relation between grindability and volatile as brought out in Fig. 10.

Conclusions

1 There is a definite need for a practical laboratory method of determining the grindability of coal and other materials.

2 Of the three types of machines tested, both the mortar and pestle and the ball mill give results consistent enough for most purposes, but the ball mill gives the best checks on repeated determinations. The tube mill is not consistent enough to warrant its use as a grindability machine.

3 The relation between grindability and pulverizer capacity will have to be determined for each type of pulverizer and the conditions under which it is operated. With very complete scavenging of fines from the grinding parts, the capacity becomes very nearly proportional to the grindability.

4 Thorough and accurate procedure is necessary in obtaining representative field samples that contain the correct percentage of coarse coal and fines, otherwise the laboratory determination of grindability will be misleading.

5 Table 5 lists the grindabilities of representative coals of the United States and Canada that should prove useful to all users of pulverized coal. The agreement between various samples from the same mine is in general fairly close.

6 Petroleum cokes have a much wider variation in grindability than coals, and show a definite trend for the grindability to increase as the volatile increases.

7 The general use of grindability determinations will necessarily require standardization, and it is to be hoped that the A.S.M.E. Test Code Committee will propose a definite method for the determination of the grindability of coal and other materials at an early date.

Discussion

W. W. Pettibone.[3] The paper presents data and information of real value to every one interested in pulverized coal. Efforts to have the equipment and methods described in the paper at least tentatively adopted by the A.S.T.M. Test Code Committee should be encouraged by the A.S.M.E., also by the coal-mining industry.

Certainly, it is reasonable to believe that "grindability" will eventually be included in coal specifications by purchasers of coal for use in pulverizers. At the present time with the manufacturer basing the power consumption and capacity of his equipment upon fuels of more or less known grindability, it is essential for the purchaser of fuels for this equipment to know that the fuels offered are not going to either reduce the equipment capacity or result in materially increased power consumption unless compensation is obtainable in fuel cost.

Fuel specifications now cover other more or less physical items of the fuel such as ash content, moisture, and ash-fusion point, and with the relationship shown of pulverizer capacity and grindability, coal purchasers very likely will eventually include grindability in their specifications where fuels are to be pulverized. If in the case of a 100 grindability coal the power consumption is 13 kw-hr. per ton, then a 75 grindability coal would probably mean about 17.3 kw-hr. per ton, or a 33 per cent increase in power consumption per ton.

The author says that a general relation exists between the volatile content and grindability, but it is questioned whether this general relation is of sufficient value to be of any merit. He qualifies his general statement by reference to the many exceptions to this trend. From Fig. 9 of the paper there is a variation in grindability of 35 per cent volatile coals ranging from 37 to 67, or some 81 per cent. Similarly at about 24 per cent volatile the range of grindability is from about 88 to 120, or about 36.5 per cent. Some of the Arkansas semi-anthracites with a volatile content of about 15 per cent are extremely soft and friable, as is also the case with some of the Colorado sub-bituminous coals, which are quite high in volatile content, so that with so many exceptions and such wide variations in the relationship between volatile matter and grindability we should look for some other relationship if it exists. In this connection the writer is wondering whether determinations of the specific gravities of these various coals might not give a better yardstick by which to correlate the grindabilities of such coals. With the specific gravities varying from 1.10 in the case of some lignites to about 1.35 in the case of Maryland and Pennsylvania bituminous coals and to about 1.50 in the case of anthracites, it appears that some possible relation exists between density and grindability. If so, then this offers a fairly quick, easy, and portable method of approximating a knowledge of this important characteristic of coals for pulverizing. The hardness of coals varies from practically nothing in the case of some lignites to 2.5 to 3 in anthracites, and the specific gravity similarly changes. Hardness and density apparently have some relationship, and certainly hardness and grindability are closely related.

---

[3] Chief Engineer, Fuel Efficiency Engineering Corporation, Birmingham, Ala. Mem. A.S.M.E.

F. H. Dechant.[4] The paper is extremely interesting from the standpoint of calibration of coal on the basis of grindability factors. It should be of interest and real value in the determination of economics of pulverized-fuel-plant installations. In connection with anthracite coal, in which we in our region are particularly interested, it would be of further interest to know whether the grindability factor of the seam coal, that is, a composite of the coal vein, would show the same factor as the fines.

It has been the writer's belief that certain anthracite-mine operations could be conducted more profitably on the basis of shipping pulverized fuel than on the production of market-sized anthracite, so that the grindability factor immediately becomes important in reaching conclusions along this line of thought.

Ralph A. Sherman.[5] Although it has been understood that pulverized-fuel manufacturers and testing laboratories have been making tests on the grindability of coal for several years, this is the first published paper to come to the writer's attention. The author is to be congratulated on having carried this pioneer work on a difficult problem to the point where it warrants publication. Because of the importance of the problem to the manufacturer, user, and the coal producer, which the author has rightfully emphasized, the paper should bring forth considerable discussion and probably be followed by other papers on the subject.

Rittinger's Law, on which the author based his work, has been proved correct by the work of Martin and his associates, to whom the author refers, but credit should also be given to the work of Gross and Zimmerly[6] in this country, who have done some valuable research on the work done in crushing.

Three major considerations govern the determination of the grindability of coal:

(1) The selection of the sample
(2) The method of applying the work
(3) The measurement of the surface produced.

The author has called attention on the seventh page of the paper to the care necessary in the selection of the sample and has shown the relatively large differences in the grindability of the different sizes of the same sample of coal. The method of preparing the sample by grinding to pass all through 16 mesh and rejecting the part that passes 30 mesh appears to be fundamentally incorrect. Although the coffee-mill type of grinder undoubtedly produces the minimum of fines, the amount will vary with the grindability of the coal, and if any part is rejected, the sample is not representative of the whole lot. Unless data can be presented to prove that this rejection does not affect the results, a basic requirement of an acceptable method must be that no part of the sample be rejected.

Although, because of the wide choice offered, the selection of a method of applying work to the sample may lead to considerable difference of opinion and discussion, this consideration would appear to offer the least difficulty of the three named. It is important that the method selected applies the same work to all samples and that the loss of fines be prevented. The author indicates that the latter feature made the so-called ball-mill machine preferable to the other types used, but it has the added advantage to the Fuller Lehigh Company that it simulates the type of application of work in their type B mill.

The writer has seen no report of an investigation to learn whether coals will stand in the same order of grindability if the crushing is done by impact, by attrition, or by various combinations of these two methods. This question should be investigated, for until this definite information is available each manufacturer will prefer a test machine which simulates the action of his particular type of mill, whereas for standardization it is obviously desirable to have but one type of laboratory test apparatus.

The real problem in the development of a grindability-test method is that of the determination of the surface produced by the work done. The author has calculated the surface from sieve tests down to 300-mesh material with an arbitrary size factor assumed for all coals for the under-300-mesh material. The sieve-test method is doubtless acceptable from the standpoint of accuracy and rapidity down to 200 mesh, but it is less desirable for finer sieves. Difficulty is experienced with even the 200-mesh sieve with certain "sticky" semi-bituminous coals.

The author has calculated the mean size as the arithmetical mean of the two sieve sizes, $(d_1 + d_2)/2$, but as the chief interest is in surface, the mean taken should be the square root of the mean of the squares, $\sqrt{}(d_1^2 + d_2^2)/2$.

The basis for the assumption of an average size of 0.001 in. for the under-300-mesh material is not stated in the paper. Unless it could be definitely proved that this is a correct figure, and it does not appear reasonable that it should be for all coals, such an assumption should not be made. As shown in the sample calculation in Table 2, although only 10.8 per cent by weight of the sample passed 300 mesh, this represented 10,800 of the 19,740 surface units produced, or 54.8 per cent. Therefore, it is extremely important that this surface be determined more accurately.

Elutriation was mentioned by the author as a possible means for the determination of the size, but the writer agrees from experience that this is a tedious and not too accurate method.

The method which has been adopted in the study of the process of the combustion of pulverized fuel at the Battelle Memorial Institute to determine the average size and surface of the under-200-mesh coal is that of microscopic counting. The microscope must be the final standard for the determination of the dimensions of particles of this size, and although tedious, it has been found that much less time is taken for a determination in this way than by air elutriation.

The method is essentially that described by Perrott and Kinney[7] and consists in mounting a sample of the pulverized coal on a slide in Canada balsam, and by comparison of the particles at 100 or 200 magnifications with a calibrated cross-ruled slide placed in the eyepiece, the number of particles of different sizes in a sufficient number of fields is counted to give a good average. The percentage by weight of the various sizes is calculated from $nd^3/\epsilon nd^3$, where n is the average number of particles of a diameter d. The average diameter which is significant as to surface may be calculated from $\epsilon nd^3/\epsilon nd^2$. The specific surface of a spherical or cubical particle is given by $S = 6/\rho d$, where ρ is the density. The product of the fraction by weight of each size by the specific surface gives the total surface of each size in one gram of the sample.

[7] Perrott, G. St. J., and Kinney, S. P., "The Meaning and Microscopic Measurement of Average Particle Size," *Jour. Amer. Ceram. Soc.*, vol. 6, 1923, pp. 417–439.

Table 7 shows the results of the determination of the surface of two samples of coal ground in a conical ball mill, a semi-bituminous coal from the Sewell bed ground so that 79.2 per cent passed a 200-mesh sieve and a Hocking No. 6 coal of which 79.0 per cent passed a 200-mesh sieve. The specific surface was calculated on the assumption of a density of 1.4 for both coals.

It will be noted that, although the percentage passing through the 200-mesh screen was only 0.2 per cent greater, the surface per gram was 60 per cent greater for the Sewell than for the Hocking coal. For both coals over 95 per cent of the surface and, therefore, by Rittinger's Law, over 95 per cent of the work were represented in the under-200-mesh material and 23 to 25 per cent in the 0.002 mm. particles. The average sizes of the under-200-mesh particles were 0.015 and 0.025 mm. for the Sewell and Hocking coals, respectively. Expressed in inches, these values are 0.0006 and 0.001, as compared with the value of 0.001 inch which the author assumed for the under-300-mesh material.

TABLE 7 CALCULATION OF SURFACE OF PULVERIZED COAL FROM SIEVE TEST AND MICROSCOPIC COUNT

Mesh	Mean size, mm.	Fraction by wt., per cent	Specific surface, cm.²/g.	Total surface per gm. of sample, cm.²	Fraction of total surface, per cent

	0.005	1.2	8570.0	102.8	7.2
	0.002	1.5	21400.0	321.0	22.6
		100.0		1426.0	100.0

These data indicate, as would be expected, that one value cannot be arbitrarily taken for the size of the sub-sieve particles. Some method must be developed for the rapid and accurate determination of the size. The microscopic method described is considered more accurate and less time consuming than air elutriation, but has sources of error in that long particles are considered as cubes; also the particles below 0.002 mm., of which there must be a great many, are not counted. Other methods of surface determination are probably possible, and the problem is worthy of extensive research.

The writer does not intend to imply by the criticisms offered that the data presented in the paper are not of value. On the contrary, they are of great value because of the large number of samples reported and the associated data on the coal; the industry owes the author and his company its thanks for making the data available. Further research may prove that the methods used by the author are entirely suited to the purpose, but the writer wishes to emphasize that the research is necessary before a standard test for grindability may be adopted.

Author's Closure

Mr. Pettibone's discussion adds a new angle to the grindability problem by comparing it to the specific gravity. In general, there seems to be a trend in that direction, but it is believed that coals such as lignite which change their grindability considerably with weathering do not change their specific gravity proportionally. The grindability test described in the paper does not take materially longer than a specific-gravity determination, and the same accuracy in collecting and preparing a representative sample is necessary.

In reply to Mr. Dechant's question as to whether the seam coal has the same grindability as the fines, it is believed that the fines would always show a higher grindability than the seam coal as it is the softer portions of the seam that break down into fines

Mr. Sherman has presented a very helpful discussion on the method of measuring the sub-sieve sizes produced in the determination of grindability. The use of microscopic counting is useful in some types of research work, but is quite tedious for a standard routine test like a grindability test.

Due to the small size of the sample used on the slide, it is very difficult to get a representative sample, and duplicate slides often give widely differing results. It is quite noticeable that the specific surface, in square centimeters per gram, for the extremely small sizes, becomes a very large number. As a result, a very small change in the fraction by weight-per cent makes a very big difference in the total surface per gram of sample, and if the microscopic count were carried down to 0.001 mm., a point would be reached where the accuracy would have to be so great that it is prohibitive.

Theoretically, the use of microscopic counting seems correct, but inasmuch as practically all specifications and standards are adopted on a compromise basis between what is wanted and what is available, the screening method which will yield check results on the same sample repeatedly seems to be not only the simplest but the best method.

As stated in the paper, the application of grindability results to actual mill capacities depends on the completeness of scavenging and will require different interpretation on different mills, but the establishment of a definite grindability scale which is reliable is still the working tool needed.

The samples tested by Mr. Sherman, being about 79 through 200 mesh, represent the usual finished product of the pulverizer. In the grindability test, however, the work of grinding is stopped far short of this point, where only about 10 per cent 200 mesh is produced and the sample contains only a few per cent finer than 300 mesh, and the errors in their measurement do not affect the final result as much.

The adoption of the constant of 1000 for the weights finer than 300 mesh was based on obtaining relative results that would check with actual mill performance rather than on actual measurements of the sizes of the particles produced.

Burning Oil-Refinery Waste Fuels in a Modern Steam Plant

By H. J. KLOTZ,[1] BOSTON, MASS.

Unsalable by-products in the refining of crude petroleum present a disposal problem. Such undesirable by-products are the acid and alkaline sludges and acid tar, the residues from the purification of lubricating oils and gasoline by the use of sulphuric acid, and the fine coke, or breeze, screened from the salable lump petroleum coke. Refineries were forced to burn the sludges to effect their removal. The chief problem was to get them into condition to be pumped. Louisiana Steam Products, Inc., entered into contract with a large refinery to supply their steam and electric requirements from a plant that would burn non-merchantable refinery waste fuels up to 50 per cent of the total heat content of the fuel required. The equipment used in this installation is described.

THE refining of crude petroleum to secure the materials in commercial demand, principally gasoline, kerosene, and lubricating oils, is accompanied by the production of several by-products. Markets have been developed for most of these, and they are sold in such forms as fuel and gas oils, paraffin, road oils, and coke. In addition to the marketable by-products, there are several that are not only decidedly unsalable, but which have been real problems to the refineries as regards their disposal. Such undesirable by-products are the acid and alkaline sludges and acid tar, which are the residues from the purification of lubricating oils and gasoline by the use of sulphuric acid. Another unsalable residue is the fine coke, or "breeze," screened from the usually salable lump petroleum coke.

The proportions of the unsalable residues vary with the types of processes employed, the grades of crude refined, and the commercial products desired. Improvements in refinery processes are reducing the proportions of unsalable residues so that the oil refineries seem to be headed toward a position comparable to the enviable one of the meat packers, which, as tradition has it, "utilize everything but the squeal." Until this utopia is reached, however, the refineries must continue to struggle with the problem of disposing of these residues. Some of the sludges are, in fact, becoming more difficult to handle even though the proportionate quantities produced are being decreased.

The nature of the acid sludges, being normally of a heavy, pitch-like consistency at atmospheric temperatures, is such that the refineries for many years disposed of them by hauling to dump piles. The material is far from constituting a desirable fill, however, and the refineries were finally forced to burn the sludges as a means of effecting their disposal. The utilization of the heat from their burning was of secondary importance, and consequently high efficiency of burning was not usually tried for. The big problem was to get the sludge in condition to be pumped and burned and to build tanks and pipe lines to withstand the extremely corrosive characteristics.

Great credit is due the men in the various refineries who tackled this problem and worked out schemes which met their particular conditions. The most widely adopted method of burning is by the use of steam atomizing burners, which have been installed under practically all types of boiler. Another method of burning which has been employed to a rather limited extent in some refineries uses a rotary kiln into which the sludge is fed in a semi-solid state by a suitable conveyor. This method avoids the necessity for maintaining the sludges in a state of fairly uniform fluidity, as is required when they are burned in suspension by spraying from any of the usual types of oil burners. The heat liberated by burning the sludges in the rotary kiln is ordinarily made use of by passing the products of combustion over the heating surfaces of a boiler. This method of disposal requires a highly special type of design which cannot be readily adapted to conventional boiler-plant layouts where it is desired to burn sludges in conjunction with other fuels in the same furnaces.

One refinery has developed a sloping grate stoker on which the sludge is burned in a semi-solid state directly in the boiler furnace. This method requires that sludge be burned continuously to protect the stoker. Also, experience indicates that the stoker equipment could not be maintained in a boiler furnace operating at very high ratings and using preheated air for combustion.

Louisiana Steam Products, Inc., was confronted with a different phase of the problem from that presented to the men directly in the refineries. A contract was entered into with a large oil refinery to supply their steam and electric power requirements from a separately owned plant to be built for this purpose adjacent to the refinery. An important condition in the contract was that refinery residuals which were designated as "non-merchantable but burnable refinery waste fuels" must be burned in the new plant up to 50 per cent of the total heat content of the fuel required. This proportion was such as to absorb the entire output of these residuals at the time of making the contract. The residuals are bought on a heating-value basis at a price which, in conjunction with the rates at which steam and electric energy are sold, requires that they be burned as efficiently as natural gas and fuel oil, which are the normal and emergency fuels, respectively, making up the balance of the plant fuel requirements.

In addition to the requirement of obtaining maximum efficiency of burning, it was desirable, in order to keep the cost

---

[1] Assistant Chief Power Engineer, Stone & Webster Engineering Corporation. Assoc-Mem. A.S.M.E. Following graduation from the University of Illinois in 1912, Mr. Klotz was for two years an instructor in the mechanical engineering department of Rensselaer Polytechnic Institute. From 1914 to 1917 he was in the operating engineering department of the Illinois Traction System, engaged in all branches of engineering connected with public-utility operation. After service in the army, Mr. Klotz became associated in 1919 with the Stone & Webster Engineering Corporation, where his work in the power division has embraced supervision of station operation and investigations connected with the design of new plants and rehabilitation of existing equipment. Special combustion problems have occupied a large part of his time.

Presented at the Fourth National Fuels Meeting, Chicago, Ill., Feb. 11 to 13, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

of the plant to the minimum, to obtain the highest possible capacity per burner. The adoption of mechanical-atomizing burners rather than the steam-atomizing type was clearly indicated when to the foregoing considerations was added the desirability of keeping steam losses to the minimum in the plant, which was to operate at high ratings on 80 per cent treated make-up water, containing about 175 parts per million of total solids.

The choice of burners was made against the advice of every one consulted that had had experience in burning sludge. The possible advantages to be gained by using mechanical-atomizing burners appeared to warrant taking the chances involved, and operating results have justified the decision. One marked advantage stood in favor of the project in that a new plant was to be built specifically designed to burn large quantities of sludge where heretofore sludge had to be burned in existing plants.

The character of the acid sludges, which constitute about 85 per cent of the liquid residuals burned, is indicated by the following data on typical samples of the two varieties:

	Lubricating acid sludge	Acid tar
Specific gravity, as received	1.084	1.052
Moisture or weak acid content, per cent	39.68	47.51
Acidity of weak acid, per cent	32.58	35.21
Acidity of sludge, per cent	12.93	16.73
Weight per gallon, pounds	9.03	8.76
Heating value, B.t.u. per pound	10,940	9,525

While these analyses are given as typical, the predominating characteristic of sludges is their extreme variability. The moisture or weak-acid content varies through a range of from about 30 per cent to 50 per cent, and on somewhat rare occasions may go even higher. The corresponding acidity of the sludge may vary through a range of 10 per cent to 20 per cent. Such variations in moisture content cause a wide variation in the consistency of the sludge and require special treatment for the individual batches in order to get them in proper condition for atomization.

Of the remaining 15 per cent of the sludges which are non-acid in character, about one-half are strongly alkaline. The latter so-called "neutralized sludge" is the result of treating the heaviest grades of acid sludge with caustic soda in order to make them fluid enough to be pumped.

The total quantity of all sludges necessary to burn amounts to about 2000 bbl. per day.

Lubricating acid sludge, which is obtained from the purification of lubricating oils and is usually referred to merely as "acid sludge," is of an extremely viscous consistency and must be constantly agitated by open steam jets to prevent solid particles of pitch from settling out. Constant flow through the burner supply piping and recirculation to the supply tank must be maintained for the same purpose. If the sludge is allowed to stand in the piping, it will harden to almost the consistency of coke, requiring its removal by mechanical means. Sludge which has thus hardened can be restored to a burnable condition only by remelting in an agitating tank.

Acid tar, which is obtained from the purification of gasoline, is much lower in viscosity than acid sludge and does not usually have to be agitated with steam jets, but gradual settling out of solid particles will occur if it is allowed to stand too long without being circulated. Although acid tar is more readily handled and atomized than acid sludge, it is the most corrosive of all the liquid residuals. As the two products frequently have practically the same acid content, the difference in corrosive attack is probably due to the inhibiting effect of the lubricating-oil content of the acid sludge.

The alkaline sludges, which are low in viscosity, are readily handled and delivered for atomization through the same steel pumps, piping, and burners provided for fuel oil. The brass lines used for the acid fuels would of course be attacked by the alkali. The only problem encountered in the combustion of the alkaline sludges is that deposits of sodium sulphate are formed which, at times, tend completely to clog the gas passages, especially in the superheater section, and have a very marked fluxing action on refractories when this fuel is burned in conjunction with coke. Extra provisions in soot-blowing equipment are necessary in order to remove these deposits.

Another variety of sludge burned, which there is comparatively little to dispose of, is known as "wax tailings." Aside from the fact that this fuel becomes entirely solidified at atmospheric temperatures, it is pumped and burned as readily as any good fuel oil and is handled similarly in every respect.

Another waste fuel which is obtained in many refineries, but which has not been available for this installation, is known as "Dubbs' residuum." A typical analysis of this fuel is as follows.

A.P.I. gravity, deg. Baumé	7
Flash point, Pensky Martin, deg. fahr.	120
B. S. & W., per cent	30
Viscosity, Saybolt Furol, sec. at 122 deg. fahr.	200
Sulphur, per cent	1.3

This material in its worst form is reported to contain a very considerable amount of carbon in non-colloidal suspension, but experience has shown that it can be handled readily and burned with the equipment used for alkaline sludge. In combustion this fuel also presents about the same problems in fluxing furnace refractories and, to a minor degree, in deposits on boiler and accessory heating surfaces.

FUEL-HANDLING EQUIPMENT

Lead-lined tanks are used for receiving the acid sludge and acid tar from the refinery in batches of 500 to 800 bbl. It is not possible to store these sludges, so they must be received as produced and burned with as little delay as possible. As mentioned, the acid sludge must be constantly agitated by open steam jets in order to keep it of proper consistency for pumping and burning. With all of the sludges, constant flow through the supply piping and recirculation to the supply tank must be maintained in order to prevent stoppage of the lines. When shutting down a line, the piping should be thoroughly blown out with steam, and if an acid-fuel line is to be out of service for an extended period, it is desirable to circulate fuel oil through it in order to effect as complete purging of the corrosive elements as possible.

Cone bottom tanks are used for all the sludges. The general construction of the tanks and the vents provided in the top are shown in Fig. 1. Each tank is provided with a ring of steam jets in the bottom for agitating the acid and alkaline sludges.

Reciprocating pumps of a type which has been in general use on acid sludges for many years have been adopted for handling the liquid fuels. Due to the higher pressures required for mechanical atomization of the sludges, the pumps for this installation are necessarily of more rugged construction. No springs are employed on the pump valves, which are of the plain rectangular block type. The so-called acid-resisting bronze furnished by the manufacturer has been entirely satisfactory in the case of the pumps handling acid sludge. The increased severity of the action of acid tar is clearly demonstrated by the more rapid deterioration of the pumps handling this fuel, and special alloys are being tried in order to obtain liners and valves which will suitably resist its action for longer periods. Up to date one of the phosphor bronzes has proved to be the best material tried for this service.

For piping to handle the acid sludge and acid tar, red brass, which is 85 per cent copper and 15 per cent zinc, has been found entirely satisfactory. The same material, or slight modifications of it, containing 0.5 per cent to 1 per cent lead, has been found satisfactory for valves in the acid-sludge lines. As has been found in the case of the pumps, the combination of corrosion and erosion which is encountered in the flow through valves is apparently much more severe in the acid-tar lines, and valve material which will be more resistant to the action of this fuel is now under investigation. Gate valves have been used exclusively and have been entirely satisfactory on the acid-sludge piping. On the acid-tar lines, however, the gate valves which have failed are to be replaced with cocks, as it is believed that the type of construction embodied in cocks greatly reduces the severity of the erosive action of this fuel.

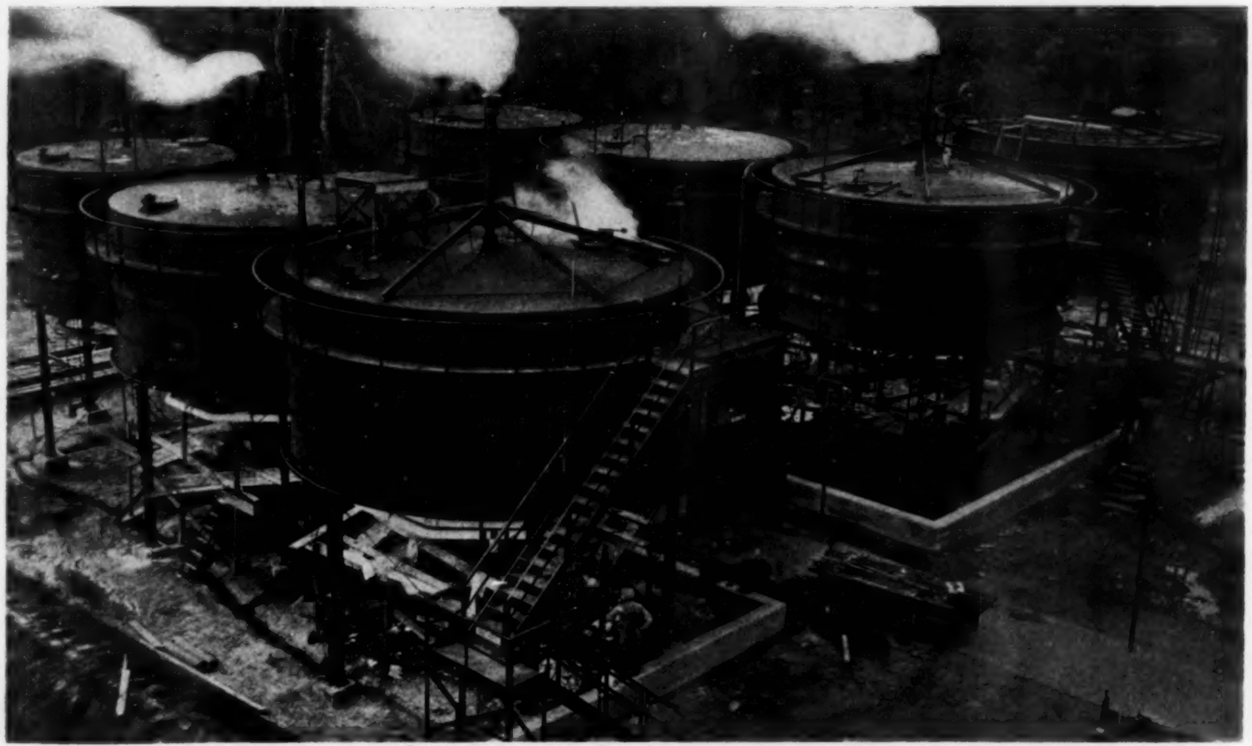

FIG. 1 LIQUID-WASTE-FUEL TANKS

BURNER DESIGN

It is impossible to make viscosity determinations on the sludges by any of the usual methods, because of the tendency for solid particles to settle out. The arrangement and proportions of the mechanical burner tips and the pressures and temperatures necessary for atomization were therefore based entirely on spray tests conducted in the open by spraying the sludges against a vertical steel plate placed about 3 ft. in front of the spray tip. This afforded an excellent method of studying the quality of atomization obtained under various conditions.

As the result of these studies, tips were developed which differ from those generally used in mechanical burners only to the extent that the central opening from which the fuel is sprayed is larger and the slots which feed the central chamber in the type of burner selected are fewer in number and larger in cross-sectional area to avoid as far as possible the marked tendency to clog any small opening which is characteristic of a fuel of this type. The burners have been satisfactory from the standpoint of capacity and quality of atomization secured. Up to 3000 lb. is atomized per burner per hour, which corresponds in heat release per burner to about 1800 lb. of normal fuel oil. The appearance of the furnace when burning sludges compares favorably with that accompanying the burning of a good grade of oil. The flashing into steam of the high moisture content of the sludges is probably responsible for an effect, as the fuel leaves the burner, which is slightly different from that usually observed with mechanical burners, and is probably partly the cause of a slightly longer flame. Occasional solid particles in the fuel stream are evidenced by streamers of flame or "sparklers," which extend beyond the main body of flame, occasionally striking the rear wall. No detrimental effects on the rear walls have been observed from this action.

Acid sludge is supplied to the burners at pressures between 190 and 200 lb. per sq. in. and at temperatures of from 225 to 275 deg. fahr. The temperature required depends upon the characteristics of the particular batch of sludge being burned. For acid tar the corresponding pressure and temperature conditions are 150 to 160 lb. per sq. in. and 165 to 175 deg. fahr. The range in temperatures required with acid tar is not so great, as this fuel is not normally so variable in consistency as acid sludge.

To obtain the high temperatures required to burn acid sludge with mechanical burners it is of course necessary to heat the fuel in a closed-type heater. This heating is being satisfactorily accomplished, so far as thermal transfer is concerned, in a four-pass fuel-oil heater of standard design, with the tubes and tube sheets constructed of a brass of special composition. The material initially selected for the sludge-heater tubes has shown a service life of only about six months. Tests are now under way looking to the selection of material to give a somewhat longer life.

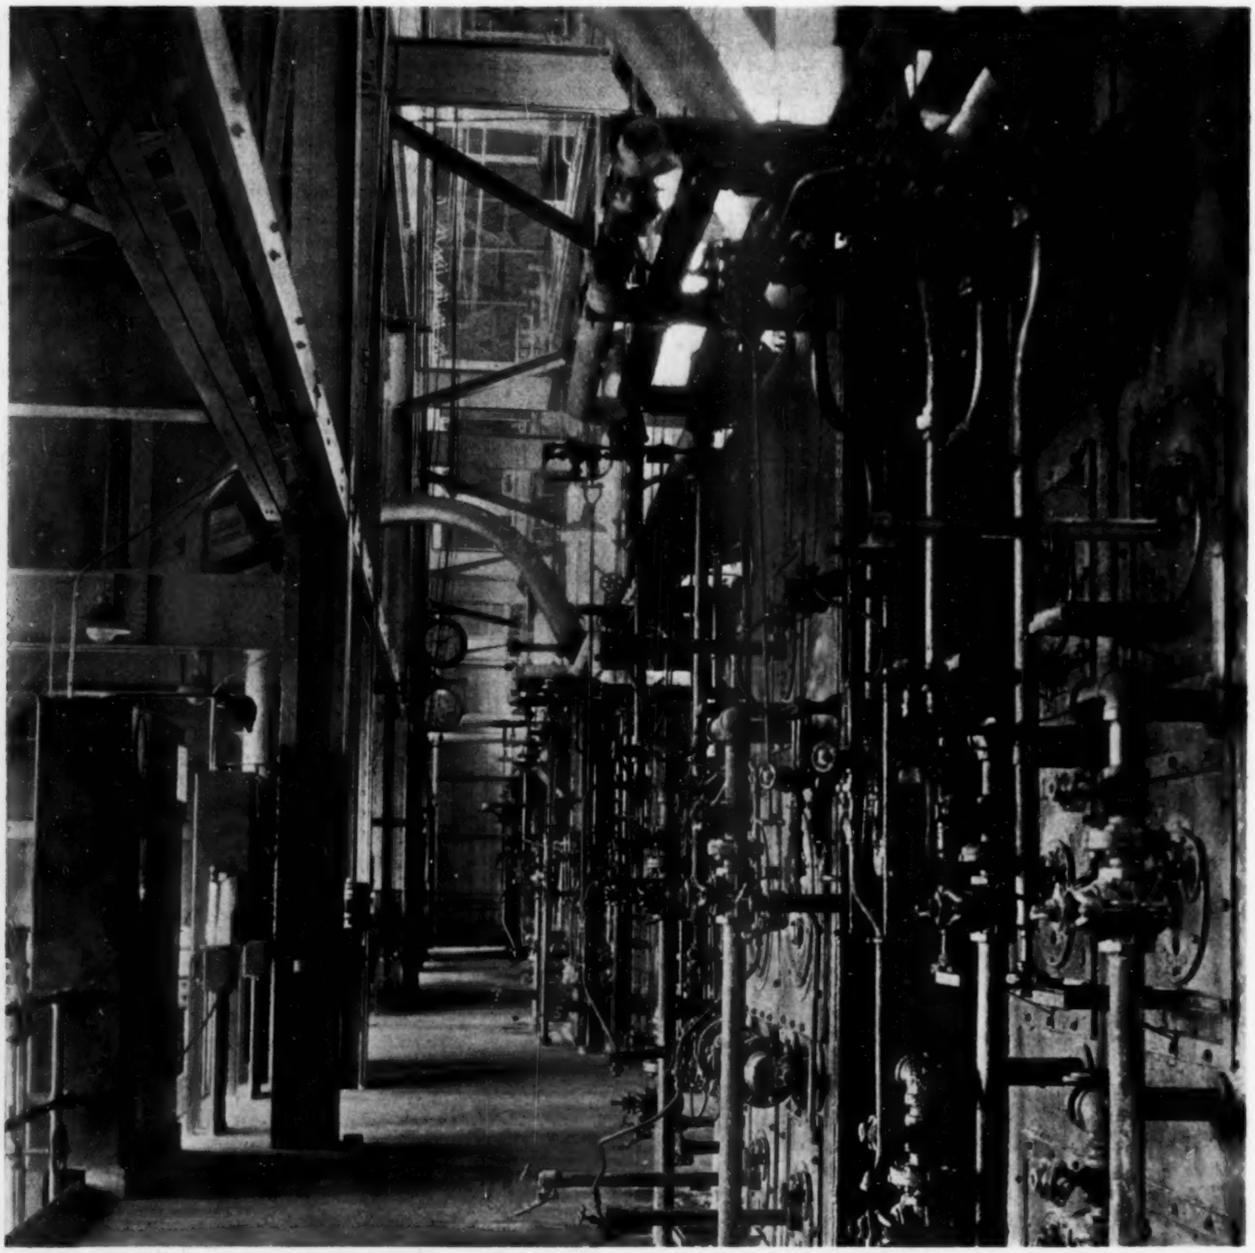

FIG. 2 FIRING AISLE AND BURNER FRONTS AT LOUISIANA STATION

MATERIALS FOR BURNERS

The material used for the burner tips is of course subjected to rather high temperatures and has to withstand a strong erosive action as well as the corrosive attack of the acid fuels. Up to the present aluminum bronze has been the most satisfactory of the materials tried. Investigations are being made with the object of finding some material which will give longer life in this service. Experience so far has included a number of bronzes and some of the best-known ferrous alloys. The majority of the latter have shown extremely short life, some lasting less than five hours on acid tar, but as there are many of the alloys of this class still to be tried, it cannot yet be stated with assurance that non-ferrous materials are the more suitable for this service.

Trials are also to be made of burner tips made of non-metallic materials, such as fused quartz and glass. There seems to be little question of the ability of these materials to withstand the effects of corrosion and erosion, but they may be unsuited to resist the mechanical strains resulting from abrupt temperature changes, as well as those incident to forcing the tips against the burner barrel to make the necessary tight joint.

The extremely accelerated test of materials which is afforded by their use for burner tips is being supplemented by a comparison under less severe conditions. In both the acid-sludge and acid-tar burner supply lines, sleeves are being installed which have been fitted with several successive rings of different materials to be tested. The various specimens are separated by glass rings as an insulating medium to prevent the possibility of gal-

vanic action which might occur with the different materials in contact. Comparison of results from the two types of test will enable a choice to be made, under strictly comparable conditions, of the best material for service with these fuels.

Fuel-Burning Arrangement

Combination gas and oil or gas and pulverized-fuel burners are used throughout the installation. Two of the four boilers, which are of 1400 hp. rated capacity, but designed to produce a maximum of 350,000 lb. of 600 lb. pressure, 750 deg. fahr. total temperature steam per hour, have 18 burners each. The other two boilers have 17 burners each, due to the additional space required by the two pulverized-coke burners. All burners on all boilers except the two combination gas and coke burners are arranged for burning gas, oil, or alkaline sludges. Acid sludge and acid tar can be burned on only the two bottom rows of burners on all boilers. The distribution of sludges to the various boilers was arranged to simplify the fuel-supply piping as much as possible. Reference to Fig. 2, which shows a view of the firing aisle and boiler fronts with the burner and piping arrangement, gives some indication of the large amount of piping necessary, even with a comparatively simple arrangement. Of the three headers shown crossing the top of the burner panel of the boiler in the foreground, one is for fuel oil and alkaline fuels, one is for acid fuels, and the third supplies steam for blowing out individual burner connections, which is necessary when changing burners. When an entire waste-fuel line is blown out, steam, air, or fuel oil for this purpose is supplied through the pump suction connections. Compressed air is satisfactory for this purpose on the acid-tar lines only, and is used to avoid the abrupt temperature changes accompanying the use of steam, which frequently causes leaks in the joints on the brass pipe lines. The two bottom rows of burners have connections to both fuel headers, while the top row of burners is connected only to the steel header for supplying alkaline fuels or fuel oil.

The gas header is below the operating floor, with individual connections to each burner, as shown for the middle and top rows. The connections to the bottom gas burners are below the floor, with the operating stems for the gas cocks shown at floor grade. The pulverized-coke supply pipes to the two boilers in the foreground are shown by the two long bends crossing over the firing aisle.

The multiplicity of piping and valves for the various fuels and steaming-out service necessarily introduces rather complex operating features. It has been found, however, that alert and intelligent operators with experience on either oil or gas firing quickly grasp the special features and handle the operation satisfactorily.

The location of the burners in the setting and the furnace proportions are clearly shown in Fig. 3, which is a cross-section of the plant, including a furnace and boiler setting. Three rows of six combination gas and oil burners were used on two of the boilers, while on the other two, three of the combination gas and oil burners were replaced with two combination gas and pulverized-fuel burners for burning petroleum coke.

For the coke burning, one pulverizing mill of the ball-and-tube type and two combination gas-and-coke burners per boiler have been provided for two of the boilers in the plant. Only one of the burners is connected to a pulverizer at present, a second burner being provided for the possible future addition of a second mill for each boiler. Each mill and burner is capable of pulverizing and burning about 3 tons per hour. The arrangement of the coke-pulverizing equipment is shown in Fig. 3.

Operating Results

No difficulty has been experienced in the operation of the coke-pulverizing equipment. It has not been operated long enough to provide any data on wear or maintenance cost. As the coke comes from the stills it is practically pure carbon with an ash content usually less than 1 per cent, but owing to the fact that the coke supply for this installation is coming largely from a yard storage, there are considerable quantities of foreign matter, which produce a very objectionable slag. This slag adheres to the lower row of slag screen tubes in the boiler and attacks the brickwork of the front-wall burner panel. The fluxing action is particularly severe when the coke is burned simultaneously with one of the alkaline fuels. Because of the unusual bulk of the ash there is also a gradual accumulation of slag on the flat bottoms of the furnaces which it is expected will require periodic melting and tapping off through a slag opening provided in the two furnaces arranged for coke burning.

Acid Fuels Have No Bad Effect on Surfaces

No detrimental effects from the burning of the acid fuels have been noted in the furnaces or on the heating surfaces of the boilers and economizers. Apparently, however, there is some corrosive attack upon the chrome-iron alloy of the soot-blowing elements in the vicinity of the superheater. Soot deposits from the acid fuels on surfaces at economizer temperatures and higher, in marked contrast with those from the alkaline fuels, are comparable in amount with those normally encountered with commercial fuel oils. Because of their potential corrosiveness, however, it is advisable to include adequate provision for continual, thorough removal of the acid-fuel deposits, preventing any long-standing accumulation.

To avoid corrosion in the air heaters, it was initially planned to limit the use of acid sludges to rates of operation high enough to insure that the gases would be kept above the dewpoint in passing through the air heaters. In actual operation, however, it was found that deposits adhered to the plates and local corrosion followed, due to the consequent cooling of the coated portions of the plates below the dewpoint. In order to maintain sufficiently high temperatures under all conditions of load and initial air temperatures, arrangements have been made for returning heated air to the preheater inlets, and on one of the preheaters, air connections have been reversed to give parallel flow of gas and air, and an air-tempering steam-coil heater has been installed in the air duct leading to the preheater. The steam heater is normally employed only during starting and light-load periods. The combination of steam heating and recirculation permits constantly maintaining all portions of the plates above a temperature of 250 deg. fahr. if desired. Both experimental investigation and operating experience, however, indicate that 225 deg. fahr. is well above the dewpoint accompanying the highest percentage of sulphuric-acid vapor which is to be expected when burning the largest proportions of acid fuels contemplated in this installation and affords entirely adequate protection from corrosive attack.

Preventing Deposits on Preheater Plates

One of the most important factors in avoidance of preheater corrosion would seem to be the prevention of deposit accumulation on the plates. It has been found necessary to install special blowing elements to insure reasonably thorough cleaning of the air-preheater plates by steam during operation and to supplement the steam blowing by periodic washing with an alkaline solution when the boilers are out of service.

It is considered that the various problems encountered with the unusual fuels burned at the Louisiana Station are no more than to be expected in a plant where such pioneering features were involved. Operating results clearly indicate that the plant is burning these residuals at capacities which are much higher than in general attained and at efficiencies comparable to the best of the normal fuel-oil and gas installations.

Discussion

L. A. Mekler.[2] It is gratifying that refinery waste products are now being used as fuel, not only by the refineries, but by other industrial fuel users. It appears from Mr. Klotz's paper that mechanical atomization of sludges is the only satisfactory method of burning them. There are a number of sludge-burning installations which use steam atomization for sludges that can be pumped, with satisfactory results. Steam-atomized sludges are burned, not only in boilers, but in the heaters of topping and cracking units, which require much closer control than most boilers.

Rotary sludge burners also give satisfactory results with sludges that can be pumped, and particularly for sludges that cannot be pumped. Up to date the rotary burners are the only means of burning sludges of solid or semi-solid consistency. Rotary burners are now built in capacities up to 6000 lb. of sludge per hour, and the improved-design burners give practically no trouble with linings and driving mechanism. Where excessive wearing out of refractories in the wall opposite the burner was found, it could usually be traced to admixture of the earthy material with the sludge which fluxed the wall. When this material was eliminated, most of the trouble with the setting was eliminated.

On installations where only 60 to 70 per cent of the total load of the furnace is taken care of by the sludge burned, it can be advantageously burned in modified steam-atomizing burners with refinery or natural gas acting as the atomizing medium. The use of gas for atomization assists the burning of the sludge, since with this type of atomization the sludge particle is surrounded by an easily ignitible medium which assists the combustion of the sludge. One of the standard burners now on the market is designed to use either steam or refinery gas for atomization. The gas is admitted into the burner near the tip through a tangentially placed opening so that the gas forms a layer between the sludge stream and the body of the burner tip. In this way the erosion and corrosion of the tip by the sludge are greatly minimized.

One operator has complained that the petroleum coke burned in the plant gave most of the trouble. This is rather an extraordinary occurrence. Pulverized petroleum coke is an ideal fuel for power plants. It has a high B.t.u. value, a very low ash content, and as a general rule requires less power for crushing and pulverizing than most of the coals used for the purpose (15.5 to 16 kw-hr. per ton of coke crushed and pulverized).

A public-utility company in the Mid-Continent field purposely built one of its power plants in the neighborhood of refineries which produce large quantities of petroleum coke so as to use this coke as fuel. The writer visited the plant, and the superintendent said he would rather burn petroleum coke than any other fuel he can get. The management is also quite satisfied with the performance of the plant. The boilers produce 135,000 lb. of steam per hour with a fuel consumption of approximately 1 lb. of petroleum coke per 1 kw-hr. The efficiency of the boiler and air preheater is 82 per cent; 15.5 to 16 per cent CO_2 is obtained in the products of combustion under full-load conditions.

Most of the trouble reported by the users of petroleum coke is due to improper handling of the coke before it enters the burner. The trouble due to moisture in the coke will be eliminated if it is kept in storage for at least 24 hours before it is fed to the crushers and pulverizers. A set of grizzlies between the hopper and the crusher with another set of grizzlies between the crusher and the pulverizer will eliminate most of the pitch that is occasionally found in the coke, as well as most of the large pieces of cable and other stray iron. Crushing to about one-quarter to one-half size in the crusher and a magnetic separator will eliminate most of the small iron that is found in the coke entering the pulverizer.

---

[2] Combustion Engineer, Universal Oil Products Company, Chicago, Ill. Mem. A.S.M.E.

If the coke was stored for years in a pile and became mixed with dirt and other outside materials before it was used, the burning of the coke would be quite troublesome. Fresh petroleum coke properly handled should not give any trouble.

K. L. Martin.[3] The paper presented by Mr. Klotz is interesting as treating the unusual case when a public utility is located close enough to a refinery so that waste fuel can be piped from one to the other. In the more usual case where the refinery has to dispose of its own wastes, the objection has been made that the use of commercial fuel oil as a flux to produce a liquid which can be burned in a mechanical atomizer is not economical, and preference has been shown for atomizers which have sufficiently large passageways, so that they will burn the sludges as they come.

It has further been observed that the general trend of modern power practice has been toward the use of larger units. Larger turbines and boilers and higher steam pressures, ratings, and superheat are being used. Stokers and pulverized-coal burners have followed the development of water-cooled furnaces and bigger boiler settings so rapidly that what is a record today is commonplace tomorrow.

As meeting both the requirements of a burner suited to viscous fuels carrying large particles of carbon in suspension and designed for the burning of large quantities of oil efficiently, attention is directed to a combination gas and oil burner, capable of evaporating 90,000 lb. of steam from a single burner with interchangeable steam and mechanical atomizers. This means a B.t.u. release of 132 million per hour per burner, resulting from the burning of approximately 900 gal. of oil per hour.

With this unit, it is only necessary to pipe such fuels as may be available to the vicinity of the burners, and connect the fuel to be burned to either a steam or mechanical atomizer mounted in the same register. The heavier fuels would be kept in constant circulation in the usual way past the burner connections, but whatever reached the burner would be atomized and burned. The steam and mechanical atomizers are readily interchangeable, and, one may be substituted for the other in a few seconds. The smallest oil passageway in the steam atomizer is $^5/_{16}$ in. in diameter and in the mechanical $^3/_{32}$ in., and the orifice is $^1/_4$ in., all of which are large enough to pass any material likely to be carried in suspension and will operate for hours without clogging.

Where it is available in refinery work, it has proved very advantageous to use high-pressure still gas for atomizing. In one refinery, gas at 130 lb. pressure has been used in this way. A very rapid flame propagation is obtained, and the high temperature results in complete combustion of solid material in suspension, and a higher furnace temperature is also maintained.

The use of these registers means that about one-third of the usual number of burners are employed. The advantages are stronger furnace-wall construction, ease of regulation and control, and less flame interference.

R. C. Vroom.[4] The paper by Mr. Klotz was most interesting, as the writer was connected with the preliminary experiments leading to the development of the sludge-burning equipment now in use at Louisiana. Furthermore, he recently visited the station and was much impressed with the satisfactory results being obtained with the waste fuels. Furnace conditions were excellent, and in fact as good as could be expected when firing ordinary fuel oil, and the excess air was low. The "sparklers" and longer flame with sludges mentioned in the paper seem not to be due essentially to the fuels being fired, but to the fact that occasionally there are employed tips which have been eaten out by the corrosive action of the acid.

The author has referred to the complexity of the operation, due to the great number of valves and the large amount of piping on the furnace fronts. As he has stated, it seems to be quite easy for the operators to become familiar with the proper procedure. The apparent complexity of the installation is greatly increased by the fact that it was impracticable to run the leads to the individual gas burners inside of the windbox. Had this been done, much of the piping on the furnace fronts would have been eliminated.

While it is true that there is a certain advantage in designing a station initially for waste-fuel firing as compared with using waste fuels in a plant already designed, it is a mistake to lay any particular stress on that fact as it tends to minimize the difficulties overcome at Louisiana. There are a great many things about that installation which are so different from previous practice that it is a distinct achievement to have made such a success of it, even though it was designed initially for firing waste fuels. Burner capacities are materially higher than are ordinarily encountered, water-cooled furnaces are employed, and the maximum capacity (based on boiler heating surface alone) corresponds to 850 per cent of builder's rating and this with about 80 per cent make-up water from the Mississippi River. Furthermore, a very important factor in the operation of this plant is that the fuels are not donated; they have to be purchased at a price per B.t.u. comparable to that paid for the standard fuels employed. In most refineries, the combustion of sludges has been largely for the purpose of getting rid of them.

Mr. Klotz has stressed the importance of circulation, throughout the waste-fuel system. Dead pockets where fuel can settle are extremely undesirable with unstable fuels of the nature employed as they will easily solidify or drop out carbon. It should be noted that when firing the sludges, gas is always fired simultaneously in the same furnace. Sometimes coke is fired also. The reason for using the gaseous fuel together with the sludges is that the sludges provide only about 50 per cent of the total heat input required for the plant. Furnaces are water cooled and partly refractory faced, and there are no ignition arches such as are sometimes employed when firing sludges.

In connection with the question of burner capacity, one of the speakers has raised the point that it is not a difficult trick to spray large quantities of oil. It is perfectly true that gas-oil sprays for use in carburetors are designed for 40 or 50 gal. per min. However, the writer would greatly hesitate to apply for fuel firing in power plants a spray having the coarseness of atomization produced by some of these sprays. It is not a particularly difficult trick to spray a large quantity of fuel, but it is not an easy thing to design an atomizer which will spray it in sufficiently fine form to permit its combustion. While the proper admission of the combustion air to the fuel spray is highly important, still the question of the production of the spray should not be considered as something simple.

In view of the difficulty that has been experienced due to a deposit forming on the heating surfaces of the boiler when firing alkaline fuels, it probably will be wondered why acid and alkaline fuels are not fired simultaneously. Although rather unfortunate results were obtained during preliminary spray tests before the plant was put in operation, when acid and alkaline fuels were mixed by mistake, still both fuels have been fired simultaneously by the same atomizer. Whether this simultaneous combustion will do away with the deposit can be determined only by operating experience. However, the neutralized sludge, which is an alkaline fuel, originally was an acid sludge and was neutralized by the addition of soda. Therefore, except for what excess soda was added, there would appear to be no chemical reaction due to the simultaneous combustion of acid and alkaline fuels, and it is possible that the deposit on the tubes is formed by the neutral salt resulting from the neutralization of the sludge.

---

[3] President, Engineer Company, New York, N. Y. Mem. A.S.M.E.

[4] Chief Engineer, Peabody Engineering Corporation, New York, N. Y. Assoc-Mem. A.S.M.E.

Waste fuels are becoming of increasing importance and their efficient combustion must be given due consideration wherever they are produced. Even ordinary fuel oils on the market are generally blends or mixtures, and oils of a given gravity often have characteristics altogether different from those of the same gravity used 10 years ago.

AUTHOR'S CLOSURE

Mr. Mekler states that it would appear from the paper that mechanical atomizing of sludges is the only satisfactory method of burning them. It was not intended to give this impression. As pointed out in the paper, special conditions which apply to the design and operation of Louisiana Station, such as the high rates of operation necessary and the need for a furnace design adapted to the burning of gas and pulverized coke, as well as liquid refinery residuals, necessitated the adoption of a method for burning the sludges in suspension. The mechanical-atomizing type of burner was selected rather than the steam-atomizing type because of the need to limit the make-up water requirements, which were necessarily higher than desirable in this station, and also to limit the amount of water vapor in the exit gases, increase of which would tend to add to the corrosion problem in the preheaters and flue-gas connections.

It is true that the burning of clean petroleum coke in combination with gas or fuel oil should give no difficulty, but freshly produced coke as well as storage coke with a high percentage of impurities, when burned in combination with alkaline sludges, has produced troublesome slag deposits.

The large-capacity burner described by Mr. Martin is very interesting and gives promise of valuable future developmets.

Mr. Vroom in his discussion has emphasized further the point which was brought out in the paper that the residual fuels are purchased at a price which requires that they be burned with the highest possible efficiency to obtain favorable operating costs.

The simultaneous combustion of acid and alkaline sludges has been tried and has been found to give greater difficulty on some occasions than the burning of alkaline sludges separately from the acid fuels. The uncertainty of the results of burning alkaline sludges is due, probably, to the lack of uniformity in the alkaline content of the fuel as delivered by the refinery. As the amount of neutral salts in the products of combustion must depend on the available alkali and sulphate radicals in the fuels burned, it is readily seen that any excess of alkalinity in the alkaline sludges would produce greater deposits of sulphates if such fuel is burned in conjunction with acid sludges.

Studies of methods of processing and burning the residuals are continuing to be made in order that the difficulty due to deposits on the heating surfaces will be minimized.

FSP-54-7

Pulverization and Boiler Performance

By E. H. TENNEY,[1] ST. LOUIS, MO.

While much has been said about the effect of varying degrees of pulverization, this paper gives specific and practical information on the relationship of pulverization of coal to boiler performance. The paper contains a resume of theoretical studies and actual tests that have been made in the past by other investigators and a recapitulation of the factors and theory of effects of fineness of grind on the combustion of pulverized coal and design of furnaces, mills, and boiler arrangements. Results are given of efficiency tests made at Cahokia with various finenesses.

IN THE last six years, during which time the use of pulverized coal in the operation of large boiler furnaces has been greatly increased, the question has been repeatedly raised as to the relationship between the degree of pulverization and boiler performance. In a general way it seems to have been agreed that coarse pulverization results in unsatisfactory and incomplete combustion in the furnace, and that the finer the coal is ground the better the resulting furnace condition. During these years no extensive research has been undertaken for establishing the necessary coordination between theoretical and practical considerations, and work is still being carried on, more or less in the dark, in endeavoring to establish a balance between the economics of milling coal and burning it, without very much being known of the technical details involved.

Inasmuch as this particular problem of pulverized-coal burning has become one which obviously is going to continue indefinitely, it seems appropriate to consider briefly some of the problems involved in the light of these years of experience. If such a discussion will have pointed out some of the questions which eventually must be solved and if it to some small degree stimulates the realization of the need of further study and investigation, the time will have been well spent.

Certainly the degree of pulverization affects a sufficient number of the phases of pulverized-fuel burning to offer a variety of angles from which to study the problem. The combustion of pulverized coal may be considered as a mechanical and chemical problem, and both of these phases are closely concerned with the degree of pulverization. The delivery of coal through piping and burners, its turbulent dispersion through the air supply, and its flotation through the furnace are mechanical functions of the size and weight of the particles. The heating and ignition of the dust cloud, the distillation of volatile content, and the combustion of the solid particles are thermo-chemical reactions hastened or retarded by greater or less fineness.

Fundamental data on the burning characteristics of powdered fuel are so meager, however, as to be of little value in the practical design or operation of boiler furnaces. When complete facts and data have been developed on the various types of fuels and factors relating to furnace performance, one may reasonably expect them to establish the proper sizing of coal particles. Obviously such a result will be brought about only by intensive research into the fundamental characteristics of pulverized coal.

At first glance the determination and collection of this basic information appear to present a great task, for it is known that the fuel from each mining locality or mine seam has certain peculiarities. However, the completion of work on the classification of coals as announced by Dr. A. C. Fieldner at the meeting of the Fuels Division in 1928[2] should greatly simplify the problem, for component chemical and physical properties of the coal and the performance of any single fuel can then be estimated from a knowledge of its composition. Already some research has been completed both in this country and abroad which has demonstrated that burning characteristics can be so studied, and some of the relations between combustion time, for example, and certain chemical constituents of coal have been established.

Theory of Particle Size

Since the size of the coal particles affects nearly every phase of pulverized-fuel firing, the various steps in the process and their relation to particle size must be considered.

The delivery of the fuel particles into and through the furnace is dependent upon the dust-bearing capacity of the air stream. The rate at which particles of various diameter settle out in still air (terminal velocity) is shown in Fig. 1 (from E. G. Bailey).[3] Coarser particles fall more rapidly than fine, and in design the air velocity must be calculated to overcome the settling factor of the coarsest particles in the length of travel under consideration, whether in a burner pipe or in a furnace. For example, if the vertical velocity of gases in a furnace is 10 ft. per sec., then particles over a 50-mesh sieve, or larger than 0.011 in. diameter, will settle out to the furnace bottom. Thus there is at once a definite limitation to the size of particles, for the coal must be maintained in suspension while being burned.

The burning process is effected in two steps: (1) the heating and ignition of the dust cloud, and (2) the subsequent combustion of the dust particles.

Since the velocity of the dust cloud is greatest at the burner outlet, the ignition period may occupy considerable furnace space, and as one of the major problems of pulverized-fuel firing has been the reduction of furnace volume, the speed of ignition is of consequent importance.

The rate at which the dust cloud becomes heated to the ignition point depends upon these factors:

[3] "Present Status of Furnace and Burner Design for Pulverized Fuel," Trans. A.S.M.E., FSP-50-72 (Sept. to Dec., 1928), p. 177.

(1) The temperature of ignition source (i.e., the temperature of the combustion chamber) and the position of the furnace heat-reflecting surfaces.

(2) The temperature to which the air and particles are preheated before entering the furnace.

(3) The thermal capacity of the dust cloud—which accounts for greater or lesser temperature rise with addition of a given quantity of heat, and which is increased by excess air.

(4) Rate at which heat is conducted to the interior of the particles, which Dr. Rosin[3] connects with the time lag of ignition.

(5) The opacity of the dust cloud, which increases its rate of radiant-heat absorption.

Of these perhaps only the last two are dependent on fineness. The time taken for the heat to penetrate the coal particle obviously depends upon its diameter. The opacity of the cloud (and its coefficient of radiant-heat absorption) is a function of the fineness, as was shown by Lincoln T. Work,[4] who used a turbidimeter as a measure of fineness. The presence of so-called superfines, which are on the order of 20 microns in diameter, hastens ignition, since these particles become heated to the ignition temperature more quickly than the larger ones, after which they impart heat to the remaining particles by their combustion. A quantitative relation between average fineness and the furnace temperature for a given rate of ignition (not the ignition temperature of the coal) is shown in Fig. 2 for one fuel (from Dr. William E. Gibbs).[5] Obviously the advantages due to high fineness permit, as this curve shows, a lower combustion-chamber temperature for the same rapidity of ignition.

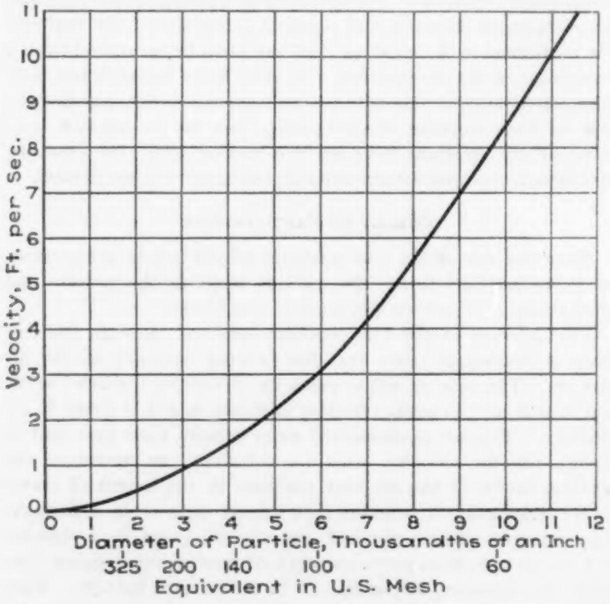

FIG. 1 VELOCITY OF PULVERIZED COAL (SPECIFIC GRAVITY 1.2) FALLING THROUGH STILL AIR AT 70 DEG. FAHR.

Of equal importance to the heating of the dust cloud is that of the ease with which a given coal can be ignited, i.e., the temperature at which ignition takes place. It is known to be lower, the lower the rank of coal, which is commonly attributed to the higher volatile content of the low-rank fuels. Some work has been done, however, which indicates that other characteristics of the coal and its chemical composition are equally important.[6] (See Fig. 4.) In general, however, any factor tending to retard ignition can be offset by greater fineness.

The combustion of the ignited particles requires a considerably longer time period than their ignition, and is therefore relatively more important in seeking high combustion intensity and consequent reduction of furnace size. The rate of combustion may be considered as dependent upon two factors: (1) the combustibility of the coal (or rapidity of its reaction with oxygen) which is generally higher for low-rank fuels of high reactivity,[7] and (2) the rate of contact with oxygen at the interface between the dust particle and the air supply.

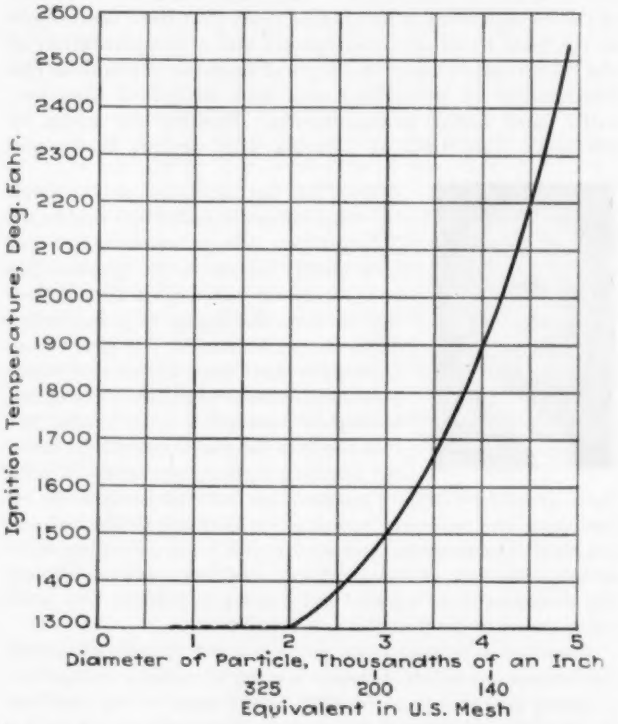

FIG. 2 VARIATION OF THE COMBUSTION-CHAMBER TEMPERATURE FOR IGNITION OF PULVERIZED COAL WITH FINENESS

Photographic studies made of burning fuel particles indicate that the combustion takes place in two stages[6,8]—the release and combustion of the inflammable volatile matter and the combustion of the remaining coke particle. Since the combustion of volatile matter is rapid, the reason for the high combustibility of low-rank, high-volatile fuels is apparent. The combustibility of the remaining coke particle, however, seems to be dependent upon the reactivity of the coal. The reactivity of a fuel follows its rank, somewhat, but the reactivity of the coke particle in the pulverized-fuel furnace is apparently also affected by the furnace temperature, as shown in Fig. 3, based on photographic data collected by Griffin, Adams, and Smith, U.S. Bureau of Mines.[8] The relation between furnace temperature and combustion time is shown for three finenesses. The surprising result is that the higher the combustion chamber temperature the slower the combustion, i.e., the temperature coefficient is negative. The explanation for this relation given by Dr. Fieldner is that coke formed from coal at higher temperatures is known to be less reactive than coke formed at lower temperatures, and in the pulverized-fuel furnace the particles are first formed to coke during the combustion cycle. The higher-temperature furnace consequently results in slower burning. The negative temperature coefficient is exactly opposite to the accepted opinion and should be substantiated, but if and when it is substantiated, then another reason exists, in addition to that of Dr. Rosin,[9] for lower furnace temperatures.

[7] "Reactivity" is a laboratory determination found by exposing pulverized samples to air in a furnace at 100 deg. cent. for three hours, the reactivity being the weight of oxygen absorbed per 100 grams of sample.

[8] "Rate of Burning of Individual Particles of Pulverized Fuel," *Industrial and Engineering Chemistry*, vol. 21, no. 9, p. 808 (Sept., 1929), Griffin, Adams, and Smith.

The chemical reaction between oxygen and the dust particle is so rapid that the rate of delivering the air supply to the particle is probably more important than the combustibility of the coal. This rate of oxygen reaction is dependent upon these factors:

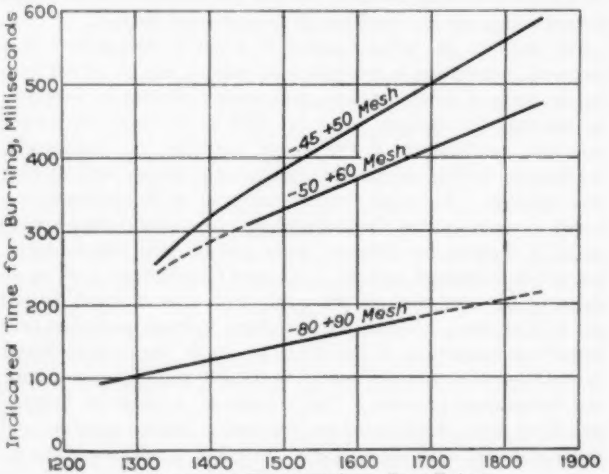

FIG. 3 TIMES FOR BURNING PULVERIZED COAL OF THREE SIZES AT VARIOUS FURNACE TEMPERATURES

(1) The specific surface of the dust (ratio of the area of coal to its mass).

(2) The proportion of air mixed with the dust and the manner in which it is supplied.

(3) The temperature of combustion space, which also determines the rate of chemical reaction between the fuel and air.

(4) The relative motion between the dust and the air.

These points can advisably be considered in some detail, as follows:

(1) Since the combustion reaction between the coal particle and its air supply can take place only at the interface between the two, the advantage of great fineness on this point is apparent. It is probably that the greatest single benefit from fine coal is due to the increase of surface exposed to the air supply.

(2) Each particle of coal dust requires for complete combustion a volume of air 35,000 times greater. The dispersion of the coal particles evenly and quickly into the center of such spheres is important and obviously requires considerable turbulence. The success of turbulent firing in commercial furnaces bears out this point. The delivery of air to the particles is naturally accelerated with excess air, the quantitative effect being shown in Fig. 4. It may be noted that the combustion time in these curves (based on experimental data) is given in fractions of a second, whereas in present commercial practice from two to four seconds are available. This indicates to a certain extent the margin of progress possible, although experimental results under ideal conditions cannot be reached in commercial furnaces. It does suggest, also, that, ignition permitting, there may be a limited advantage in superfines, since the combustion must be timed to the larger particles.

(3) A high temperature of the combustion space has been previously mentioned as retarding combustion, probably by forming a coke particle resistant to oxygen. If so, this effect must be sufficient to offset other combustion factors which are hastened by high temperature, for in general the rate of oxygen reaction increases with temperature, and the oxygen molecules diffuse through the gaseous products of combustion surrounding the coal particles more quickly. The net quantitative relation between furnace temperature and combustion rate has been referred to in Fig. 3, which should probably be accepted with reservations for the present.

(4) Much has been said about the effects of relative motion between the coal particles and the air. Any such relative motion tends to scrub away the products of combustion and facilitates the further delivery of fresh air. The advantages of turbulence in this respect have been advanced, and undoubtedly turbulence does aid this action. It seems more likely, however, that the advantage of turbulence is due more to the mixing of air and dust. In Fig. 1 is shown the velocity at which coal particles fall in still air. This terminal velocity for coal passing through 175 mesh is 1 ft. per sec. or less. As the velocity of the gases through the furnace are more on the order of 10 ft. per sec., the terminal velocity assumes less importance, and the finer the coal the lower the terminal velocity. Further, the relative motion due to turbulence is greatest immediately on leaving the burner in the ignition space, where it is needed least. With very coarse particles, however, say those over 60 mesh, a relative motion between air and particle may be material and may help considerably in reducing the amount of unburned carbon.

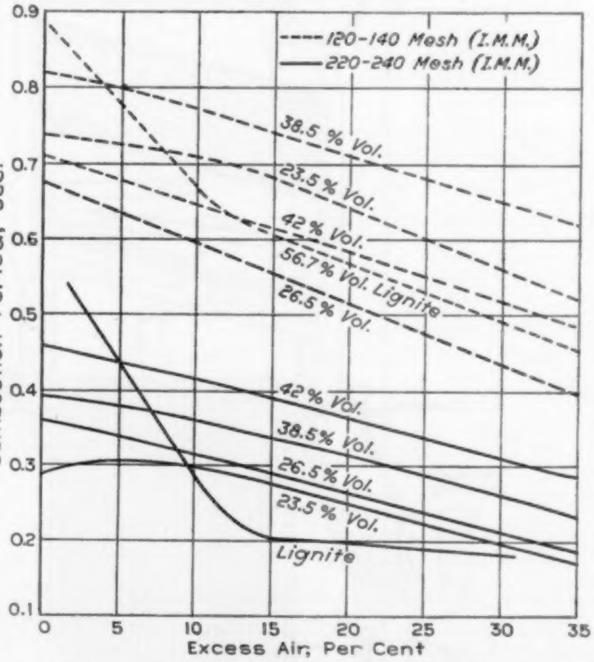

FIG. 4 VARIATION OF COMBUSTION PERIOD WITH EXCESS AIR, RANK, AND FINENESS OF COAL
(*Rev. de l'Ind. Min.*, Jan. 1, 1924, no. 73, p. 1, Audibert.)

One final factor in the subject of fineness of grind assumes considerable importance in practice, i.e., the effects of very coarse particles on slag "birdnesting" in the boiler generating tubes. Apparently results in commercial installations alone can establish the limitations on this point. The fusing of the ash, the path of the gases through the furnace, and the furnace shape all have a bearing on results. The slagging tendency has had much to do with the limit of 1 to 2 per cent over 40 mesh generally established by operators. On the other hand, recent developments in flame directions and in arrangement of boiler tubes to avoid birdnesting have been quite effective. Three methods may be used separately or together: (1) wide spacing of lower generating tubes to prevent slag bridging over and to chill to solidity the heavy particles of molten ash, (2) directing the flame toward the hearth in slag-tap furnaces so as to throw out the heavy particles which are then burned on the floor, and (3) the use of properly placed slag blowers. These devices as applied commercially must be watched for developments.

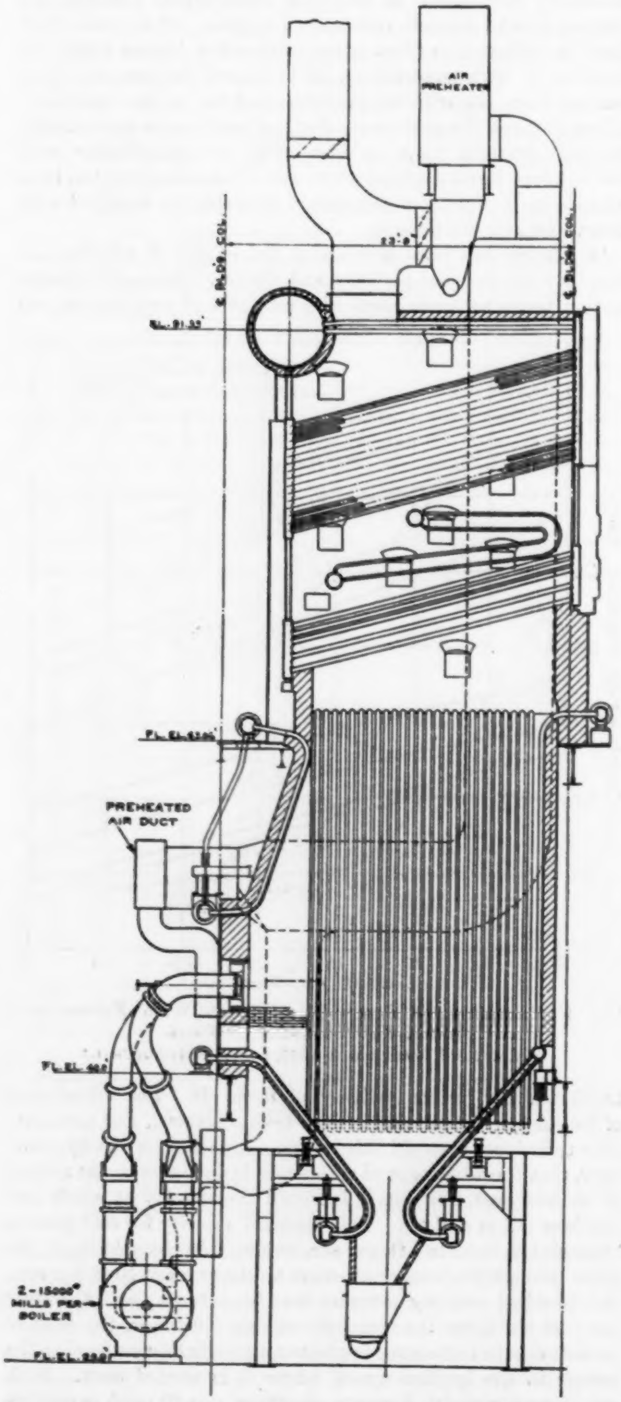

FIG. 5 BOILER NO. 17, ON WHICH FINENESS TESTS WERE MADE

The theoretical and experimental relations between the degree of pulverization and the ignition and combustion of pulverized fuel have been traced. The commercial balance between these factors and the cost of a high degree of pulverization furnish an economic problem—the resultant boiler efficiencies, investment costs, and operating costs all to be considered. The problem for a plant already in operation, the problem as viewed for a plant now being designed, and the problem for improvements toward which one can work are all separate and distinct.

The problem of "what fineness of grind to design for" in a proposed installation is one which at present can be solved only on the basis of what previous experience indicates is desirable. In general, the furnace must be sufficiently large to permit complete combustion of the larger particles, or, conversely, the fineness need be no greater than furnace volume and burning time requires. Although the experimental work previously referred to suggests that these considerations would permit a wide range of fineness for different fuels and furnace temperatures, practice is in general uniform, with most installations working on about 65 per cent through 200 mesh, with over 40 mesh limited to 1 to 2 per cent. Yet with this uniform fineness maximum heat liberations range from 12,000 B.t.u. per cu. ft. per hour to 50,000 in central-station practice and up to 100,000 and higher in marine and locomotive practice. This represents a range in burning time from 3 sec. down to 0.7 sec. for central-station practice, and fineness should vary accordingly. In other words, there are installations where furnaces are either four times as large as theory indicates or coal is being ground to 200 mesh when less than 100 mesh might suffice. The problem quite apparently warrants further attention and study, both by designers and by operators.

CAHOKIA TESTS

The problem as to what fineness to use in a plant already in operation usually becomes one of balancing costs of coal preparation against savings in boiler efficiency. In some circumstances it may be a matter of increasing fineness (and preparation costs) in order to increase boiler capacity, for finer coal giving more rapid combustion may permit higher furnace-heat liberations. The latter possibility, however, is rare, for increased fineness reduces mill capacity, and furnace-heat liberations are usually limited by furnace-wall construction. The first case, i.e., of boiler economy versus preparation costs, was the subject of a number of tests which were made at Cahokia Station.

A series of economy tests were made on No. 17 boiler (Fig. 5),[10] which is an 1801-hp. cold-bottom unit, fired from two 15,000 lb. per hour Simplex unit mills. It was found that at the normal rating of 300 per cent (furnace liberation of 20,000 B.t.u. per cu. ft. per hour) a wide range in fineness could not be fired because the mills, fans, and burner piping were designed for comparatively fine coal and became choked with large quantities of coarse coal. To permit a range of 45 to 75 per cent through 200 mesh, it was therefore necessary to operate at about 200 per cent rating, or 13,000 B.t.u. furnace-heat liberation. To this extent the tests are of more value for study than for practical use in establishing regular plant practice. The wide range of fineness, however, gave an interesting set of conditions to observe.

The tests were with weighed water and coal, of six to eight hours' duration, and sufficient data were taken to calculate boiler efficiency and to record the operating conditions affected by coal size; namely, CO_2, combustible in flue dust, proportion of ash to the stack, stack-gas temperatures, and mill-power consumption. It was realized that proper fineness samples were very important, although difficult to obtain, so each mill outlet was sampled by a vacuum-cleaner sampler at nine different points in a square cross-section of the mill discharge at some distance from the fan. The sampling pipe was held at each of the nine points for 5 min., and the resultant 45-min. composite was automatically corrected for stratification, and an accurate sample was insured. Flue dust was collected in five cyclone-separator samplers spaced across the uptake. Pit ash was weighed and the quantity of stack ash was determined by difference.

---

[10] Reproduced from *Mechanical Engineering*, vol. 50, no. 10, p. 772, Oct., 1928.

The test results are shown in Table 1 and are plotted in Figs. 6 and 7. The tests from *A* to *K* are arranged in descending order of fineness through 200 mesh. It may be noted that a high CO_2 of 17 per cent (18 per cent excess air) was held throughout. This point was determined by smoke, the air adjustments being made to avoid unburned hydrocarbons. In this way all the loss due to incomplete combustion was evident as unconsumed carbon in the flue dust and pit ash, which reaches 15.7 per cent and 7.0 per cent, respectively, with the coarsest coal. In regular operation at 300 per cent rating the excess air would be increased to about 25 per cent and the unburned carbon would be about half that shown, but it was believed that the method followed at the lower rating gave a truer indication of relative economy due to coarse coal. In this way it was also possible to maintain a very uniform stack temperature, and altogether the number of observable variables was reduced to the minimum. It is very possible that higher economies could have been found by varying the relation between excess air and flue-dust loss, which indicates how really complicated the whole problem of fineness is and the amount of further investigation necessary to accurately determine good operation.

There has previously been shown (Fig. 1) the relation between particle size and gas velocity necessary for combustion in suspension. At the rating at which these tests were made, between 3 and 4 sec. are available for combustion, and the flame travel is about 40 ft., or 10 to 13 ft. per sec. Particles between 40 and 50 mesh therefore would tend to fall to the furnace bottom.

This is borne out by the test data. Tests from *A* to *H* have a quite uniform pit loss with unburned carbon up to 1.6 per cent. At test *I*, where the coal screened 4.9 per cent over 40 mesh, the pit-carbon loss went up to 1.9 per cent, and when the coal above 40 mesh exceeded 7 per cent, on tests *J* and *K*, the pit loss rose sharply to 3.4 and 7.0 per cent unburned carbon. The cause was apparent in the furnace, where a large number of "sparklers" were seen to settle to the pit. The fact that the amount of ash to the pit did not increase in like proportion is due to the fusing tendency of the ash (fusion point 2000 deg. fahr.); with the finer grinds the small particles of ash fuse together in the top of the furnace and can be seen falling down into the pit.

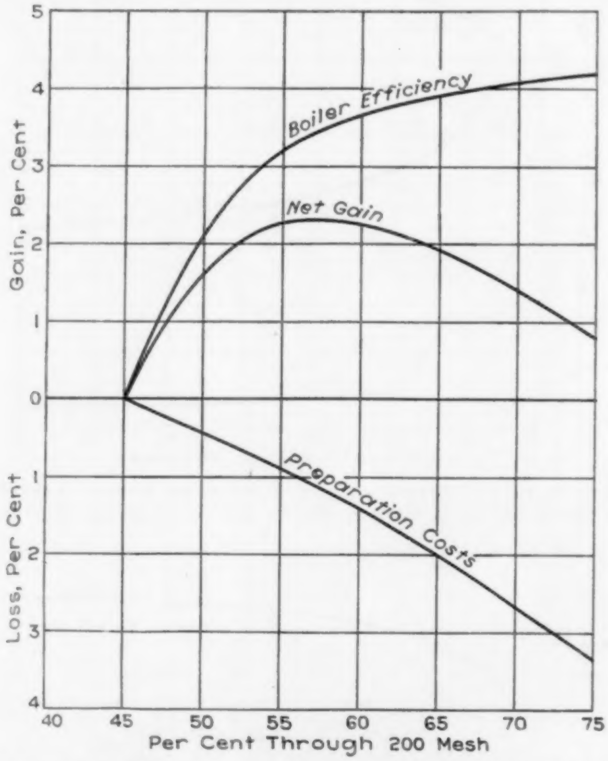

Fig. 8 Per Cent Gain or Loss in Boiler Efficiency and Coal-Preparation Costs Versus Degree of Pulverization, Boiler No. 17, Cahokia Station

(Points boiler efficiency gain from Fig. 7. Loss due to extra coal-preparation costs shown as per cent of cost of coal and equated to equivalent per cent points of boiler efficiency. Lower curve subtracted from upper to give net overall gain expressed in equivalent per cent points of boiler efficiency.)

The southern Illinois coal burned has a volatile content of about 34 per cent, is free-burning, non-caking, and is readily ignited. The dust cloud was observed to be shortened with the finer grinds, but it is doubtful if, at this low rating, any gains in ignition time are of importance. With constant excess air the furnace temperature was uniform, and there was no opportunity to establish any relations between ignition, combustion, and furnace temperature.

The very low amount of excess air (18 per cent), without smoke, indicates the completeness with which the air supply was delivered to the separate coal particles, a result due in great part to the turbulent method of firing. The consistent increase in unburned carbon to the stack as the coal becomes coarser measures the increase in burning time required for the larger particles. In practice there is a partial compensation on this point, for, as the particle becomes larger and its combustion time increases, its tendency to settle out lengthens its stay in the furnace. It may be seen in tests *J* and *K* that only when the size of the particle causes it to fall rapidly does the pit loss become excessive. A tendency also noted on these runs was for slag to adhere to the lower boiler tubes, and it is doubtful if operation could have been continued longer than 24 hours.

It may be noticed that in each test a great portion of the coal that passes through 200 mesh also passes through 325 mesh. Such sizes come under the head of "superfines," which under certain conditions are considered quite necessary for satisfactory ignition and combustion. There is no way of measuring their value in this particular installation. Combustion time is available for much coarser particles, but on the other hand the smaller particles are more easily dispersed into the air supply. This is another important point which must await further investigation.

The boiler efficiency, of course, summarizes all losses, and, allowing for test inconsistencies, the net result is shown by the curve of Fig. 7. It is seen that the curve breaks when the fineness falls below 55 per cent through 200 mesh, and sharply when below 50 per cent. There is no gain when the fineness exceeds 65 per cent.

The desired range for operation is dependent upon the efficiency gained compared with the additional cost of preparation. The latter is made up of power costs and maintenance, which can be assumed as paralleling the power consumption of kilowatt-hours per ton, which can be seen to consistently drop with coarser coal. This cost in cents per ton has been converted into percentage of total coal cost and plotted with 45 per cent through 200-mesh coal as a base in the lower curve of Fig. 8, and is algebraically added to the net gain in boiler efficiency above. (Both percentages are equated as per cent points of boiler efficiency.) The central curve represents the net gain, and the best point of operation is at 57 per cent through 200-mesh.

Although these tests are in no way a complete answer to the problem of degree of coal pulverization, they do suggest the general method by which the problem can be attacked by the operator. There has been discussed the consistent relation between fineness and the possibilities of design, and there have been indicated the complexity and the importance of the problem, for almost every phase of pulverized-fuel firing is closely related to particle size. If the advantages of this form of fuel firing are to be fully realized, then additional research is imperative if a slow trial-and-error method of development is to be avoided.

Discussion

M. K. Drewry.[11] Industry is indebted to the author for the considerable work expended to evaluate optimum coal fineness in actual practice. His concise summary of combustion-rate influences is also valuable.

That higher furnace temperatures actually decrease combustion rapidity is surprising. It has long been felt that benefit derived from designing for higher temperatures was slight, but it was not anticipated that combustion was thereby actually handicapped. The test data showing a halving of combustion rapidity as temperatures are increased from 1200 deg. fahr. to 1800 deg. fahr. are of interest. It supports the contention that combustion troubles in all-metal cooled furnaces at low ratings are entirely due to poor mixing, not lowered furnace temperature.

High admission temperatures of coal and air apparently have a rapid influence on increasing combustion rates. Experience with 650 deg. fahr. preheated air and 350 deg. fahr. supply-coal temperature has shown that low carbon loss is very easily attained with the assistance of this initial preheating. Reaction rates multiply with enormous rapidity, since they double with each 20 deg. fahr. temperature increase at low ranges and 100 deg. fahr. increase at higher ranges.[12] Preheating outside the furnace reduces the period when slowest reactions occur. Large air heaters, heating primary and secondary air to high temperatures, help furnace reactions markedly.

[11] Assistant Chief Engineer, Power Plants, Milwaukee Elec. Ry. & Light Co., Milwaukee, Wis. Mem. A.S.M.E.

It seems timely that still lower excess air be used than the present average of 25 per cent. Large savings in size of all heat-absorbing equipment can be effected if combustion efficiency is not decreased. More attention to the combustion process, as encouraged by this paper, is desirable.

L. E. Griffith.[13] It costs money to pulverize coal! In practically all the papers on the subject of coal pulverization in the past this fact has been more or less ignored. The author has given a paper which definitely takes this into account and has carefully and thoroughly covered all the factors in the relationship between fineness and efficiency of combustion. He has tabulated results of actual tests showing this relation for a given set of conditions. This tabulation and the curves drawn from the data indicate an increasing efficiency with increase in fineness. It is to be noted, however, that the slope of the fineness-efficiency curve continuously decreases and will tend to ultimately become zero. On the contrary, the slope of the curve showing cost of preparation plotted against fineness would tend to continuously increase.

The law of diminishing returns has been well established and certainly applies to the pulverization and burning of coal. This law is well illustrated by Fig. 8 in the paper. While there is a continuous gain in boiler efficiency by increasing fineness of pulverization, there also is a continuous increase in preparation cost, and the curves indicate that in the case of the unit involved in the author's tests above 57 per cent through 200 mesh the increase in preparation cost is greater than the gain in efficiency and that to pulverize coal to any greater degree would represent an actual loss in the cost of steam production.

As far as the effect of fineness is concerned, Mr. Tenney can make steam in the particular boiler mentioned at the rating operated at the lowest cost per thousand pounds when the coal is pulverized to about 57 per cent through 200 mesh.

Within the last two years there have been papers intending to show the degree and kind of fineness that can be obtained with different types of pulverizing equipment. These papers have given data from which conclusions were drawn that certain types of pulverizers gave a greater degree of fineness or gave a greater percentage of extreme fines. The assumption has been made in these papers that a greater degree of fineness was necessary, and consequently the conclusion was drawn that the particular type of pulverizer which gave the greatest degree of fineness as indicated by the data tabulated in the paper was the most desirable type of pulverizer. The fallacy in such reasoning is clearly demonstrated by the paper.

It has been rather conclusively established that, in the absence of an objectionable percentage of larger particles, high efficiencies can be secured, with proper burner design, if pulverization is maintained at points ranging from 50 to 80 per cent through a 200-mesh screen—depending upon the characteristics of the coal and the furnace involved. The mere process of securing this degree of fineness produces the desirable ratio of so-called "superfines."

Of importance also is the requirement that the pulverizing equipment be capable of maintaining, uniformly, the desired character of pulverization over the necessary range of load demands.

It is to be hoped that the relationships established in the author's paper will encourage further experiments of this character with various types of coal and various forms of furnace installations. It will undoubtedly be found that certain groups of coals for a given set of furnace and operating conditions will have a particular fineness as being the most economical, while other groups will have different degrees of fineness as being the most economical. It is probable that the low-volatile Eastern coals will show the highest degree of fineness for the maximum return—first, because of extreme friability and, second, because of difficulty of obtaining complete combustion of fixed carbon. The second group might be considered as coals which are typical of the Pittsburgh district. It is probable that the desirable degree of fineness in such coals will be found to lie between that of low-volatile Eastern coals and Mid-Western bituminous coals such as that used in Mr. Tenney's plant. This will be due to the fact that such coals do not, in general, possess the same friability or free-burning characteristics encountered with Mid-Western coals.

An accumulation of such data in any given plant should emphasize the importance of giving proper consideration to the effect of the cost of fuel preparations upon the overall cost of steam production.

R. H. Morris.[14] The paper should do much to clarify the situation regarding size specifications for pulverized fuel, and if one can judge by the alacrity with which mill manufacturers attempted to reply to Mr. Work's paper of two years ago, the situation can stand considerable clarification.

From the data in Table 1, apparently it makes little difference whether the fineness be specified as a definite percentage through a 200, 100, 60, or 40 sieve. Replotting Fig. 7 with efficiency against the percentage through any sieve in the series will show that the boiler efficiency always drops below 85 per cent between the *H* and *I* tests, as is shown for 200 mesh. This confirms the opinion that those favoring specifications calling for a minimum percentage through 40 or 48 mesh differ from those calling for a minimum percentage through 200 mesh, only as evaluating an article in dollars differs from evaluating it in cents. The 200 designation dealing with smaller units is perhaps more accurate, but takes more time and care, so that perhaps an intermediate sieve, say 100, would be the most practical one to use. The data given are so consistent that a complete fineness curve could be interpolated or reconstructed from any single given point.

Rosin showed, as early as 1927, that pulverized fuel, when plotted with cumulative percentage against sieve size, gives a characteristic curve, the shape of which depends only upon the absolute fineness of the dust and is practically independent of the kind of pulverizer and kind of coal. This is well substantiated by the author's data for a particular coal and mill, but apparently is in direct conflict with Work's conclusions and the inferences to be drawn from his Figs. 1, 2, 3, and 5.

Unfortunately Work did not mention the kind of coals to which his data apply. There is considerable difference in the characteristics which, as plotted, indicate a distinctive difference in product due to both coals and mills. Careful examination of the data in specific cases, such for instance as *H*-2 for hammer mills, shows that it agrees with certain tube-mill samples over the entire range. With all tests plotted on a single sheet, it is doubtful if samples from several mills could be identified.

Undoubtedly the differences shown are directly attributable to the classifier action, which is not and should not be considered as characteristic of the mill except in so far as certain manufacturers have made it so.

Distinct differences in hammer-mill and tube-mill sizes, shown by a distribution of superfines in Work's Fig. 5, are easily explained in the light of Rosin's work. Rosin shows that decreasing the fineness from about 90 per cent through 200 mesh to 80 per cent through 200 mesh changes the distribution of product, expressed as per cent per micron, from a peak of about 4 per cent at 15 microns down to about 2 per cent at 30 microns. A further decrease in fineness to 40 per cent through 200 mesh reduces the peak to about 1 per cent at 60 microns. Work's superfine data covered two samples, one 58 and the other 78 per cent through 200 mesh, more than sufficient to account for the difference in distribution of sizes, even though both samples had been taken from the same mill. It is likely that a careful analysis of Work's data would substantiate Rosin's claims that the characteristic curve is independent of the type of coal and mill.

Tenney's data over the complete range should be correlated with similar data from other installations having different mills and coals. Bureau of Mines investigations show differences of as much as 50 per cent between hand-sieve and machine-sieve methods. Even when the A.S.T.M. specifications are followed, discrepancies in testing make the data useless for absolute values, although relative results are satisfactory for home use. In order to place data from different plants in such shape that the results might be interpreted, it would be advisable to give details of the sampling method and equipment used in sample preparation and the sieve procedure followed.

No one has determined how necessary these superfines really are, although as the author has pointed out, the matter has been investigated theoretically by Rosin, whose conclusions, well backed by theoretical and experimental data, are not always in perfect accord with accepted theories. Apparently within the grinding limits of practice, from 30 to 45 per cent of the coal as fired is below 25 microns. If this 30 to 45 per cent of superfines were screened out, what would be the effect on combustion?

The question is of considerable interest in connection with the power required for grinding—that is, mill efficiency as well as for combustion. In connection with the efficiency of grinding mills, Gross and Zimmerly of the Bureau of Mines (Serial 2952, July, 1929) determined that the efficiency of mills (the ratio of laboratory determinations to actual power consumption of the mills) was 44.8 per cent. This they considered high.

However, after determining that 200 mesh or 74 microns was the proper size, they found that 90.2 per cent of the power expended in grinding was expended uselessly in producing superfines which were not only useless but in some cases a distinct disadvantage. The useful grinding efficiency of the mill was only 4.25 per cent.

If 50 or 25 micron fuel particles are found to be the minimum size necessary to give good results, it is possible that coal-mill useful-work efficiencies are also in the neighborhood of 4 per cent and that work which should require 0.5 to 1 kw. per ton is taking 15 to 25 kw. The possible power saving should be sufficient to warrant experimental work to determine the minimum size necessary, if for no other reason than to find out if this useless power expenditure is an inherent loss like the condenser loss or if it can be eliminated by proper pulverizer and classifier design.

The work of Gross and Zimmerly is not, of course, directly comparable with coal mills. They were working with wet tube mills grinding galena, sphalerite, pyrite, and gangue and in which there was a considerable circulating load of superfines due to the classifier action. The work does, however, indicate the low useful efficiency of grinding mills. Furthermore, they discovered that although the total load of 3000 tons per day was only about 33 per cent gangue, this material absorbed 71.2 per cent of the total useless work, most of which was expended on the superfines.

This brings up the possibility of pulverizing fuel in two stages, with some arrangement of cleaning in between to eliminate a large portion of the ash and inert substances found in the poorer grades of coal. Taken in itself the power saving from eliminating the necessity for grinding the ash and slate and producing superfines might be negligible, but taken with the decreased mill maintenance and improved furnace conditions, the combined benefits of such a practice might make it practical as further refinements in operation are demanded.

M. A. Mayers.[15] The writer notes a few points in connection with the theoretical data presented in this paper.

In the first place it is unlikely that the reactivity has any effect on the burning time in boiler furnaces. Determinations of the reactivity of coke with air show that all cokes have the same reactivity above temperatures in the neighborhood of 1100 deg. fahr. and that the temperature coefficient of reactivity becomes less at this temperature than at lower temperatures. This indicates that some other factor than reactivity governs above this range of temperature.

In partial explanation of the negative coefficient of combustion velocity shown in Fig. 3 of the paper, the laws of the kinetic theory of gases may be invoked. It can be shown that the number of mols of a gas that impinge on a unit of surface in unit time is given by

$$Q = \frac{p}{\sqrt{(2\pi RT)}}$$

where Q = number of mols of gas
p = pressure of gas
R = gas constant
T = absolute temperature

It is evident that this would result in a decreasing frequency of contacts between combustible matter and oxygen as the temperature increased, and hence in a negative coefficient of combustion velocity with temperature.

It is interesting to note from Fig. 4 that the combustion time varies approximately as the diameter of the particle. The writer has made calculations that indicate that this should be the case and is pleased to find experimental justification for this conclusion.

H. G. Lykken.[16] In Fig. 7 the author has plotted boiler efficiency against percentage of 200-mesh material, showing an apparent increase in efficiency with increase of percentage through 200 mesh. In Table 1 are given the data from which the curve is taken.

In this table it will be noted also that as the percentage of 200 mesh increases, there is a decreasing percentage of coarse material in the mixture. In column A, with 72.8 per cent 200 mesh, there is 11.3 per cent on 100 mesh and only 2.7 per cent on 60 mesh; whereas in column K, with 47 per cent through 200 mesh, there is 34.2 per cent on 100 mesh, 17.1 per cent on 60 mesh, and 7.4 per cent on 40 mesh.

In so far as the lower efficiency was accounted for in a large measure by a higher percentage of carbon in the ashpit and particularly in the flue dust with the coarser grinding, should not the curve have been boiler efficiency plotted against the percentage of material on 60 mesh?

---

[15] Coal Research Laboratory, Carnegie Institute of Technology, Pittsburgh, Pa. Jun. A.S.M.E.

[16] Chief Engineer, Unipulvo System, Strong-Scott Mfg. Co., Minneapolis, Minn.

Was it not the higher percentage of coarse material, 7.4 per cent on 40 mesh, 17.1 per cent on 60 mesh, and possibly 34.2 per cent on 100 mesh, that caused the loss rather than the lesser percentage of superfines?

A test as to the value of a higher percentage of superfine in reality means nothing unless a series of tests can be run having the identical amount of coarse particles, for the reason that it is patent that it is the coarse material going out unburned that causes most, if not all, of the difference in loss.

By observation, tests, and extensive experience, the writer has failed to get any smaller flame volume, better furnace condition, or better efficiency by increasing the superfine when maintaining an equal degree of elimination of coarse particles—say, everything through 60 mesh. It may be possible that the ideal condition calls for very little superfine. It is the writer's opinion that if all material passed 50 to 60 mesh with the bulk passing 100 mesh, little or nothing can be gained by more than 30 to 40 per cent passing 200 mesh or finer.

It is the coarse material that affects efficiency, not percentage of superfine, and milling specifications should be based upon the degree of fineness at the lower end of the scale, such as all through 50 mesh, 60 mesh, or whatever the requirement may be, letting the percentage of 200 mesh take care of itself. Specifying fineness by a given requirement through 200 mesh does not adequately specify the material, because a given percentage of 200 mesh may mean a much larger percentage of coarse with one type of mill than with some other type.

Ralph A. Sherman.[17] The author discussed the combustion of pulverized fuel from a somewhat different viewpoint from the majority of papers in the past. It is considered a hopeful sign that perhaps we are to get away from the usual paper presenting the relation of burner designs to boiler efficiency or similar subjects and study the more fundamental aspects of the combustion of pulverized fuel.

The writer first wishes to correct the misinterpretation which the author has placed upon the terminal velocities of particles. Particles of coal falling in a viscous medium, such as air, do not continue to accelerate under the influence of gravity, but attain a terminal or equilibrium velocity which depends upon their diameter, their density, and on the kinematic viscosity and the density of the medium. If a particle has a terminal velocity of 10 ft. per sec., gases moving upward at this velocity will maintain the particle in suspension, but it is not true, as the author states, that gases moving with the same horizontal velocity will keep the particle in suspension. For horizontal movement of gases the terminal velocity gives the downward component and is extremely useful in calculating the velocities required in moving coal in ducts or in furnaces. Attention should be called to the fact that in addition to the curve which the author presents in Fig. 1, which is taken from Gibbs, "The Dust Hazard in Industry," Audibert[18] has conducted some experimental studies to determine the terminal velocity and developed an empirical formula for its calculation. Blizard[19] analyzed his data and developed a formula which showed the interesting fact that the terminal velocity should be independent of the temperature of the gas. However, in some recent work by the writer on the sizing of pulverized fuel by rising air currents it appeared that Stoke's law gave better results than the Blizard-Audibert formula.

The author has called attention to the work of Audibert, Godbert, and Griffin, Adams, and Smith on the mechanism of combustion of pulverized coal and has reproduced some of the curves from their work. These investigations are extremely interesting and valuable, but it must be emphasized that, because of the much different conditions from boiler or industrial furnace practice, extreme care must be used in the application of their results to practice. Audibert measured the time of completion of combustion as the time at which the CO_2 content of the gases become constant. He did not sample the dust to determine the carbon content nor did he show how closely the total oxygen content of the gases checked with that originally fired with the coal. His findings that the time of burning of the coal increased with the volatile content is in direct variance with all practical experience.

The work of Griffin, Adams, and Smith was done at temperatures considerably below that in practical furnaces, and the number of particles was so small that they were surrounded by air with the normal content of oxygen in air throughout the period of burning. Dr. S. P. Burke, formerly director of research, Combustion Utilities Company, and now with the West Virginia University, has made a mathematical analysis of the mechanism of combustion which is said to explain the negative temperature coefficient. This is to be given shortly in the publication of the American Chemical Society.

The author has called attention to the wide difference between the burning times of 0.2 to 0.4 sec. found by these various workers for pulverized-coal particles and the time of 2 to 4 sec. which a particle remains in a boiler furnace. There is some question, however, whether the coal remains this long in the furnace. This time is ordinarily calculated from the rate of gas flow in volume per unit time and the total volume of the furnace. It is known that the gases do not fill the entire volume; therefore, the rate of flow is greater and the time in the furnace is less than are normally calculated. The discrepancy between experiment and practice must remain high, and more experimental data are needed to understand all the factors thoroughly.

The data which the author presents on the tests at Cahokia and the conclusions which he draws appear entirely reasonable. Because of the difficulty of close control of all conditions in a boiler installation as is shown by the points which fall off the smooth efficiency curve, a boiler furnace is not well suited to an accurate study of the combustion process, although any results on experimental furnaces must finally be proved there.

Henry Kreisinger.[20] The paper contains useful data on the relation between fineness of pulverized coal and plant efficiency. The data shows that with Illinois coal there is no material gain in the plant efficiency in increasing the fineness of coal beyond 55 per cent through 200-mesh screen, and that there is a decided drop in the plant efficiency when the fineness is increased beyond 60 per cent through 200-mesh screen. What is gained in higher boiler efficiency is more than offset by the increased cost of pulverization. The fineness of 55 per cent through 200-mesh screen for Illinois coal has been recognized as the most economical fineness, and has been used as a standard in the adjustment of the mills. For other kinds of coals the most economical fineness increases in general with the percentage of fixed carbon of the coal, because high-fixed-carbon coals are, as a rule, more difficult to burn than high-volatile coals. It is a common experience that when high-fixed-carbon coals are burned in pulverized form the flue dust contains large percentage of combustible unless the coal is pulverized to a higher degree of fineness.

[20] Consulting Engineer, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

The foregoing statement of experience seems to be at variance with the results obtained by Audibert and shown in Fig. 4 of the paper. Audibert's results apparently show that more time is required to burn coals containing a high percentage of volatile matter than coals with small volatile-matter content. This is particularly true of the lower group of curves which give the time required for combustion for the coarser coals. In this group of curves the individual curves align themselves according to volatile matter, the coal with the highest volatile matter being at the top and that with the lowest at the bottom of the group.

The upper group of curves is not so consistent. The coal with the lowest volatile matter happens to be the second from the top instead of being at the bottom of the group. This lack of agreement is very likely due to the method of determining the time required for the combustion. In these experiments it has been assumed that the combustion was complete when the percentage of CO_2 in the products of combustion became nearly constant. No determination of the percentage of combustible in the flue dust was made. If Audibert had stated the completeness of combustion in the same manner as the author—that is, by determining the percentage of combustible in the flue dust and ashpit refuse—the curves of Fig. 4 would have arranged themselves in different order. Those who have done work on commercial installations know that the only way to find out how complete the combustion is, is to determine the amount of unburned combustible both in solids and gaseous state.

It is a common fault of many a casual observer of combustion of powdered coal in commercial installations to assume that the combustion is complete at the end of a visible flame. Only the volatile matter burns with visible flame. The combustion of fixed carbon which is left after all the volatile matter has been distilled off and burned continues to burn without any visible flame. The only way to determine how far this combustion of the fixed carbon has progressed at any section of the path of the gases is to sample the solids and determine the percentage of combustible.

Much has been said and written about the reactivity of different forms of carbon or the reactivity of coke from different coals or coke made in different ways. Some of the experiments conducted with the object of determining such reactivity seem to indicate a rather great difference between the reactivity of coke from different coals or coke made in different ways, but when the methods of experimentation are changed the results are also changed. The reactivity of carbon may be defined as the rate at which the carbon combines with oxygen when free oxygen is supplied to the surface of the carbon particles at the furnace temperature, which is about 2000 deg. fahr. or higher. Such definition should at least hold when we speak of reactivity in connection with burning pulverized coal.

One of the methods used for the determination of the reactivity of fixed carbon from different coals is to burn the coal or coke in a fuel bed 4 to 6 in. thick and analyzing the gases collected at different heights in the fuel bed. With some coals free oxygen may be all used up in combustion 3 in. from the grate. With some other coals the free oxygen may disappear 4 to 6 in. from the grate. When the free oxygen has been all combined, the resulting CO_2 is being reduced to CO by the passage through the upper layers of the fuel bed. The reactivity of the carbon is supposedly indicated by the height from the grate at which the oxygen disappears and by the percentage of CO_2 reduced to CO in the upper layers of the fuel bed. In such experiments the sizing of the coal or coke and the shape of the pieces and their arrangements in the fuel bed are very important factors. If the size and the shape of the pieces is such that they form a compact bed and form very irregular and narrow passages for the air and other gases in their upward flow through the fuel bed, the indicated reactivity of the carbon will be high. Thus, when the experiments are conducted with lignite or lignite char, it is found that free oxygen disappears 2 to 3 in. from the grate and practically all the CO_2 is reduced to CO by the time the products of combustion reach the top of a 4-in. or 6-in. fuel bed. It is generally concluded that the reactivity of carbon in lignite is very high, but such conclusion is questionable. The lignite and lignite char disintegrate when heated. Although the fuel when added at the top of the fuel bed may be of definite size, this size changes by the heating of the fuel as the fuel moves down from the surface to the grate. By the time the fuel reaches half-way through the fuel bed, the pieces disintegrate into much smaller pieces and form a compact fuel bed with very narrow and zigzag passages for the air and the gases. This change in the size and arrangement of the pieces causes the free oxygen to disappear much nearer the grate than with fuels that do not disintegrate. For a similar reason the CO_2 is reduced to CO more completely in the upper layers of the fuel bed. If an experiment were made with anthracite coal of a size similar to the pieces of lignite in the lower part of the fuel bed, very likely the anthracite might show as high reactivity as the lignite.

Another factor which may lead to false indication of the reactivity of the carbon is the distribution and the quality of ash. If the ash is uniformly distributed throughout the mass of coal and has such physical properties as will make it to adhere in a layer to the pieces of coal after the carbon in the surface has burned, this layer of ash will tend to prevent direct contact of oxygen with the carbon under this layer of ash. Such fuel will give indication of very low reactivity. However, the cause of this apparent slow burning of the carbon is not a slow combination of oxygen with the carbon, but a lack of sufficient contact of the oxygen with the carbon due to the layer of protective ash. Anthracite coal shows such behavior particularly with low rates of combustion where the velocity of gases passing the surfaces is too low to scrub off the layer of ash. When anthracite is burned in a house-heating furnace, the fire may go out at times. The material left on the grate seems to be nothing but ash. If, however, this ash is taken out and thrown on the ash pile, a good rain will wash the layer of ash and expose to vision good black coal that will burn easily when put back into the fire. Among such coals the Rhode Island graphitic coal shows this behavior to a very marked extent. For a period of half an hour to one hour after a fresh charge has been added to the fire, the coal will burn freely with intense heat. After this period the fire gradually becomes dull and may go out unless the layer of ash on the pieces of coal is scrubbed off by actively raking the surface of the fuel bed. After such raking the fire again becomes bright and hot. An open wood fire behaves in a similar way. After the carbon in the surface layers has burned off, the remaining layer of ash prevents contact of oxygen with the carbon under this layer of ash, and the fire becomes dull and may go out. If the fire is agitated with a poker, most of the ash is shaken off the wood, and the fire will brighten up again.

The apparent difference in the reactivity of different metallurgical cokes may be due to the distribution of ash in the coke. Before coal is charged into the coke oven, the coal is reduced to a small size and the ash is thereby distributed more uniformly through the mass of coal. The ash in some of the coal may be of such a nature that it is not easily scrubbed off the surface by the current of gases, and the combustion of such coke may be slower due to the fact that oxygen does not come in contact with the carbon because of the layer of ash on the surfaces.

Fig. 3 of the paper shows that the process of combustion becomes slower as the temperature of the furnace rises. If we assume that coal burns as fast as oxygen comes in contact with it, we have to account in some way for fewer contacts when the temperature rises. We know that the density of gases decreases as the absolute temperature rises. Therefore, the same volume of gases surrounding a coal particle will contain fewer molecules of free oxygen. However, the oxygen molecules move with higher velocity which is proportional to the square root of the temperature. If it is true that fewer contacts are made, then the effect of reduced density is not quite offset by the increased molecular speed of the oxygen molecules. The effect of temperature on the rapidity of combustion is a factor which deserves a thorough investigation. It is a factor about which there is the greatest divergence of opinion among combustion engineers.

Author's Closure

The information given by Mr. Drewry in reference to more rapid burning when air and pulverized coal are preheated is of interest. It is quite probable that the ignition process is the one most affected by preheating, since, as pointed out in the paper, the ignition temperature is most quickly reached the higher the temperature of the entering air and coal. If, as seems to be the case with some types of firing, the volume of furnace space required for ignition can be greatly reduced by slower coal and air-inlet velocities, better mixing of air with coal, and better radiation of heat into the coal stream, then this particular advantage of preheated air may be of less importance. Where ignition is slow, however, preheated air will undoubtedly be of considerable value. Mr. Drewry is correct in recommending excess air lower than 25 per cent. The boiler described in this test has been successfully operated with 10 per cent excess air. To avoid smoke, however, with rapidly swinging loads, the particular fuel we fire seems to require about 18 per cent in routine operation. Only exceptional conditions can warrant excess air over 25 per cent.

Mr. Griffith brings up the important points that extreme fineness is not always an advantage and that different fuels require different degrees of pulverization. It is becoming apparent that every combination of physical and economical conditions will call for a different mesh analysis.

A very pertinent point is that brought out by Mr. Morris to the effect that, with a given fuel and possibly without reference to the type of mill used, the percentage through one mesh bears a direct relation to the percentages through other meshes.

Mr. Morris's point answers the question of Mr. Lykken as to the preferability of plotting boiler performance against 60-mesh data rather than 200-mesh. Since the percentage through 60 mesh increases with increased percentage through 200 mesh, the validity of deductions from plotted data are independent of the mesh used as a variable. Mr. Lykken is of course quite right in taking the stand that some of the losses caused by low fineness is due to the coarser particles. The percentage through 200 mesh, however, does not come under the classification of superfines, since the latter are ordinarily thought of as 20-micron-diameter particles, whereas 200 mesh is 74 microns. As mentioned in the paper, the tests reported do not permit definite conclusions as to the value of superfines. It would be valuable information if Mr. Lykken would publish his tests where fines were increased while holding the percentage of coarse particles fixed.

Mr. Mayers's mathematical explanation of the negative temperature coefficient adds strong evidence to what laboratory work indicates. The formulas of Burke and Schumann also indicate that combustion speed is reduced by higher temperatures. Mr. Mayers apparently disagrees with Dr. Fieldner in regard to the importance of the reactivity of the coke particle as affecting the combustion time. This is one of the facts which further investigation may definitely determine.

Mr. Sherman is quite correct in pointing out that the terminal velocity of a particle determines the requisite vertical velocity and not horizontal velocity. The text has been so changed. It is quite possible, as he states, that the methods used in research laboratories do not give absolute values comparable with actual practice. The author has made some recent tests of velocity and burning times of pulverized coal during regular plant operation.[21]

It has been found that (allowing for the difficulties of measuring such times in a commercial furnace) the actual burning time is on the order of a half second when air and coal are thoroughly mixed before combustion. This supports the relative accuracy of the work of Audibert and others. The explanation is undoubtedly that suggested by Mr. Sherman, that the apparent burning time as calculated from furnace volume is not a true one, since the whole furnace is not occupied by combustion; in fact, as little as one-eighth may be actively required for combustion.

Mr. Kreisinger gives some very interesting material somewhat in parallel with the studies covered by the paper. It may be pointed out that the reactivity measurements used by Godbert were not determined in a furnace as discussed by Mr. Kreisinger but in a laboratory.

Heat Transfer From Condensing Steam to Flowing Water

Accomplished Through Single Metal Tubes Which Are Completely Surrounded by Air-Free Steam

By A. T. BROWN,[1] NEWARK, N. J.

The method developed in this paper correlates in part some of the known experimental data for heat transfer through single tubes at low rates of heat flow with the experiments made by Geo. A. Orrok in 1910. This method may be used at low rates of heat transfer such as occur in condensers to establish an ideal with which to compare the actual performance. Such a comparison indicates how close the performance of the actual condenser approaches the rate of heat transfer which can be secured with a single tube completely surrounded by air-free steam. The formula for the heat transfer through the film on the water side of the tube is taken from a paper presented by Edwin R. Cox at the 1927 Annual Meeting of The American Society of Mechanical Engineers, and this formula is a development of data prepared by Chester W. Rice. The method given in this paper should prove useful in calculating changes in the rate of heat transfer caused by altering the velocity of the water in the tubes in an actual condenser with the inlet water at the ordinary temperatures, say, above 50 deg. fahr.

DURING 1928 the author was given some data on heat-transfer rates prepared by R. J. S. Pigott, now Chief Engineer of the Research Department, Gulf Production and Pipe Line Companies, and saw that a method might be developed whereby the overall coefficient of heat transfer for a single tube could be calculated. The method given herewith is the result of this study which was made with the idea of applying it in the range covered by condenser practice, and it is not intended as a general solution of the problem of heat transfer.

The conclusions given are reached from data all based upon the reports of the following experiments:

Clement and Garland, 1909 Bulletin, Engineering Experiment Station, University of Illinois.

Geo. A. Orrok, Transactions American Society of Mechanical Engineers, 1910.

Webster, Transactions English Shipbuilders, Scotland, 1913.

McAdams and Frost, Massachusetts Institute of Technology, *Journal of Industrial and Engineering Chemistry*, January and February, 1922.

Tabulation by Chester W. Rice of the results of various experiments, and reported in the *Journal of Industrial and Engineering Chemistry*, May, 1924.

Paper by Edwin R. Cox, presented at the 1927 Annual Meeting of The American Society of Mechanical Engineers. (Trans. A.S.M.E., 1927, PET-50-2.)

Morris and Whitman, *Journal of Industrial and Engineering Chemistry*, March, 1928.

D. F. Othmer, University of Michigan, *Journal of Industrial and Engineering Chemistry*, June, 1929.

Albert Eagle and R. M. Ferguson, Report of the British Electrical and Allied Industries Research Association, read as a paper before the Institution of Mechanical Engineering, Nov. 21, 1930, and reported in *Engineering*, Nov. 28, and December 19 and 26, 1930.

In all of the tests made by Clement and Garland and by McAdams and Frost, the steam surrounding the tubes through which the heat transfer was measured varied from 210 deg. fahr. to 330 deg. fahr., as did the tests made by D. F. Othmer and Webster.

The tests reported by Clement and Garland were made on soft steel tubes, while those reported by McAdams and Frost were made on brass tubes.

In the original report of Clement and Garland, 48.4 B.t.u. per sq. ft. per hour per deg. fahr. difference per foot of thickness was used as the conductivity of the metal of the steel tube, and this value closely approximates the conductivity of wrought iron.

The heat conductivity for soft steel as averaged from the values reported by several authorities is $26^1/_3$, and in the calculations given below the values for the resistances on the water side in the Clement and Garland tests have been recalculated, using the lower value of $26^1/_3$.

Morris and Whitman used a conductivity of 35 for the steel tube employed in their test apparatus, but the author has made no change in the data calculated from these tests.

In the ordinary logarithmic form of the formula for heat transfer from a hot fluid of constant temperature to a colder fluid of varying temperature, it is assumed that the coefficient of heat transfer (the B.t.u. per sq. ft. per hour per deg. fahr. mean temperature difference between the hot fluid and the average temperature of the cooling fluid) is constant for each elementary surface of the tube throughout the length of the tube, and this assumption appears now not to be exactly true.

If one attempts to develop a differential equation by the application of the film theory similar to the classic equation from which the logarithmic form of the mean temperature difference is deduced, unwieldy equations seem to develop. Consequently, all of the data given below have been calculated on the basis of the arithmetical mean temperature differences, which are much easier to use.

The following symbols have been used throughout the calculations and formulas given below:

Let

Q = the total heat transferred per hour (B.t.u.) through the surface S in square feet

---

[1] Mechanical Engineer, United Engineers and Constructors, Inc. Mem. A.S.M.E. Mr. Brown was born in Fairfield, Conn., on October 13, 1880. He attended Fairfield Academy, Park Avenue Institute, the University School, and the Sheffield Scientific School of Yale University, where he received the degree of Ph.B. in 1902.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Birmingham, Ala., April 20 to 23, 1931, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

S = the area of the outer or vapor side of the tube in square feet
d_o = the outside diameter expressed in inches
d_m = the mean diameter of the tube expressed in inches
d_i = inside diameter of the tube expressed in inches
Δt_v = temperature drop from the vapor to the metal of the tube in deg. fahr.
Δt_t = temperature drop through the metal of the tube in deg. fahr.
Δt_w = temperature drop from the inside of the tube to the average temperature of the water in deg. fahr.
T = temperature of the steam outside the tube in deg. fahr.
M.T.D. = ΔT = total overall temperature drop from the vapor to the average temperature of the water = $(\Delta t_v + \Delta t_t + \Delta t_w)$
h_v = total heat transmitted per square foot per hour per deg. fahr. difference between vapor and tube per hour
h_t = same for the metal of the tube
h_w = same for the water film on the water side of the tube
k = conductivity of metal of tube in B.t.u. per square foot per hour per deg. fahr. difference per foot thickness = 63 for Muntz and Admiralty metal tubes = 26.5 average for soft steel
b = thickness of tube in inches
U = coefficient of heat transfer in B.t.u. per square foot per hour per degree of temperature difference overall vapor to water based upon the arithmetical mean-temperature difference

Then

$$Q = SU\Delta T = SU(\Delta t_v + \Delta t_t + \Delta t_w)$$
$$= h_v S\Delta t_v = \frac{12k}{b}\frac{Sd_m}{d_o}\,\Delta t_t$$
$$= \frac{h_w S d_i}{d_o}\,\Delta t_w$$

Let

$\frac{1}{U} = R$ = heat-resistance coefficient overall vapor to the average temperature of the water

$$\frac{1}{U} = \frac{S\Delta T}{Q} = \frac{S}{Q}\,(\Delta t_v + \Delta t_t + \Delta t_w)$$
$$\Delta t_v = \frac{Q}{h_v S}$$
$$\Delta t_t = \frac{Qbd_o}{S\;12k\;d_m}$$
$$\Delta t_w = \frac{Qd_o}{Sh_w d_i}$$
$$\frac{1}{U} = \frac{S}{Q} \times \frac{Q}{S}\left(\frac{1}{h_v} + \frac{bd_o}{12kd_m} + \frac{d_o}{h_w d_i}\right)$$

If we let $r_{v\text{O.D.}}$, $r_{t\text{O.D.}}$, and $r_{w\text{O.D.}}$ represent, respectively, the resistances in the parentheses, we have

$$\frac{1}{U} = (r_{v\text{O.D.}} + r_{t\text{O.D.}} + r_{w\text{O.D.}})\ldots\ldots\ldots\ldots\ldots[1]$$

This is over the whole surface involved.

Note: The resistances must all be expressed on the basis of the outside diameter of the tube.

From the data taken from the various tests and plotted as in Figs. 1 and 2, $r_{v\text{O.D.}}$ varies approximately as some fractional power of Q/S. The actual values can be read from the chart, Fig. 2, which gives the average of the Webster tests and those plotted in Fig. 1.

Then

$$\frac{1}{U} = r_{v\text{O.D.}}\text{ (average of all points from Fig. 2)}$$
$$+ \frac{bd_o}{12kd_m} + \frac{d_o}{d_i h_w}\ldots\ldots[2]$$

It is obvious that there is considerable variation in the data as reported by the various experimenters, but as the values, read from the average line in Fig. 2, together with data (given below) on the resistance on the water side of the tube, check quite closely at low total rates of heat transfer (below 30,000 B.t.u. per sq. ft. per hour) with the tests on overall M.T.D. made by Geo. A. Orrok, the values of $r_{v\text{O.D.}}$ shown in Fig. 2 have been used throughout this paper.

Let

J_w = fluidity (reciprocal of viscosity expressed in centipoises) of the water film at its average temperature $\left(\frac{t_i + t_o + \Delta t_w}{2}\right)$ on the water side of the tube, where
t_i = temperature of inlet water, deg. fahr.
t_o = temperature of outlet water, deg. fahr.

From data in a paper presented by Edwin R. Cox before the A.S.M.E. Annual Meeting, December, 1927. and which was a development of the data presented by Chester W. Rice for the ordinary temperatures involved in condenser work,

$$h_w = \frac{C^{2/3}\,V^{5/6}\,J_w^{1/2}\,G^{5/6}\,C_P^{1/3} \times 10}{K_2 d_i^{1/6}}\ldots\ldots\ldots[3]$$

where C = conductivity of the fluid film in B.t.u. per sq. ft. per hour per deg. fahr. difference per foot thickness = 0.329 for water. (See Table 2, p. 16, Jan., 1922, *Journal of Industrial and Engineering Chemistry*, by W. H. McAdams and T. H. Frost.)

G = specific gravity of film compared with water (assumed for this paper as based upon water at 62 deg. fahr.)
C_P = specific heat of film at constant pressure
K_2 = an experimental constant
V = velocity in feet per second of cooling water over the cross-section of the tube.

or

$$r_{w\text{O.D.}} = \frac{d_o}{h_w d_i} = \frac{d_o K_2}{10 \times C^{2/3}V^{5/6}J_w^{1/2}d_i^{5/6}G^{5/6}C_P^{1/3}}\ldots\ldots[4]$$

Then

$$K_2 = \frac{10r_{w\text{O.D.}}(d_i VG)^{5/6}J_w^{1/2}C^{2/3}C_P^{1/3}}{d_o}\ldots\ldots\ldots\ldots[5]$$

In condenser practice both G and C_P are practically equal to unity, and, consequently,

$$r_{w\text{O.D.}} = \frac{d_o K_2}{10C^{2/3}(d_i V)^{5/6}J_w^{1/2}}\ldots\ldots\ldots\ldots\ldots[6]$$

In order to determine the values of J_w the data plotted in Fig. 4 have been taken, and these values have been used throughout this paper.

For average film temperatures from 35 to 70 deg. fahr., it can be deduced from this chart that (as the curve is practically a straight line between these temperatures)

$$\log\frac{J_w}{0.585} = \log\left(\frac{\text{avg. film temp.}}{35}\right)^{0.81}$$

$$J_w = 0.585\left(\frac{\text{avg. film temp.}}{35}\right)^{0.81}$$

$$\Delta t_w = \frac{Q}{S} r_{w\text{O.D.}} = \frac{Q}{S}\frac{d_oK_2}{3.645(d_iV)^{5/6}\left(\frac{2t+\Delta t_w}{70}\right)^{0.405}}$$

$$\Delta t_w\left(\frac{2t+\Delta t_w}{70}\right)^{0.406} = \frac{Q}{S}\frac{d_oK_2}{3.645(d_iV)^{5/6}} \cdots\cdots\cdots [7]$$

Where t = avg. temp. of cooling water $= \frac{t_i + t_o}{2}$.

$$\Delta t_w(2t + \Delta t_w)^{1/2} = \frac{Q}{S}\frac{d_oK_2}{0.407(d_iV)^{5/6}} \cdots\cdots\cdots [8]$$

Where t = avg. temp. of cooling water $= \frac{t_i + t_o}{2}$.

In the paper by Edwin R. Cox mentioned above, the experimental constant is given as 1/53.5, or 0.0187 in Equation [2] of the paper. The chart of Fig. 11 seems to indicate a value of 0.0175 for a high value of L/d_i for low rates of heat flow.

In the Orrok series of tests made in 1910 on the overall heat transfer through Admiralty metal tubes, the steam was at considerably lower temperatures than in the tests by Clement and Garland, McAdams and Frost, D. F. Othmer, and Webster.

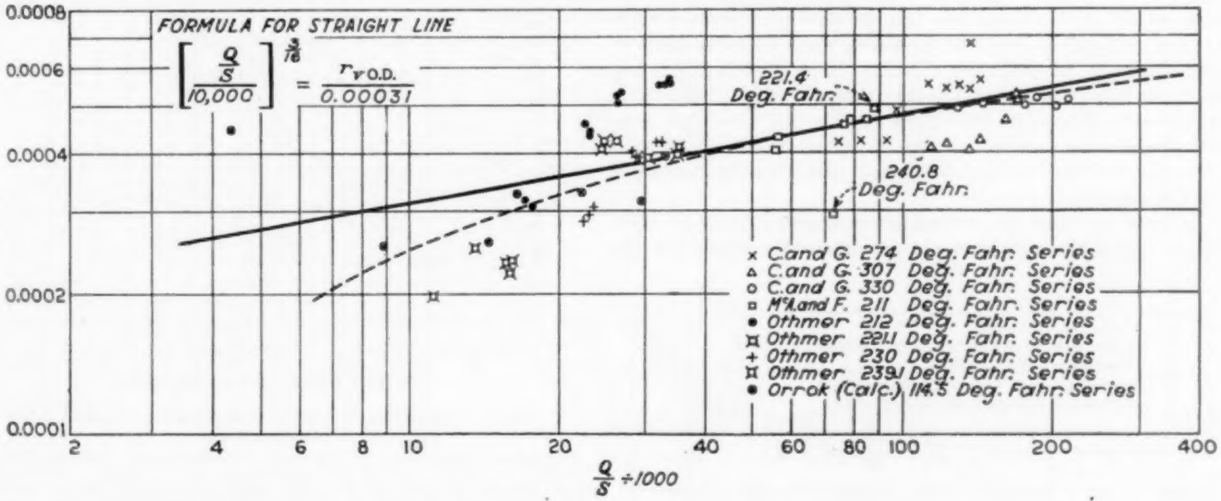

FIG. 1 VARIATION OF $r_{v\text{O.D.}}$ WITH Q/S—VARIOUS TESTS

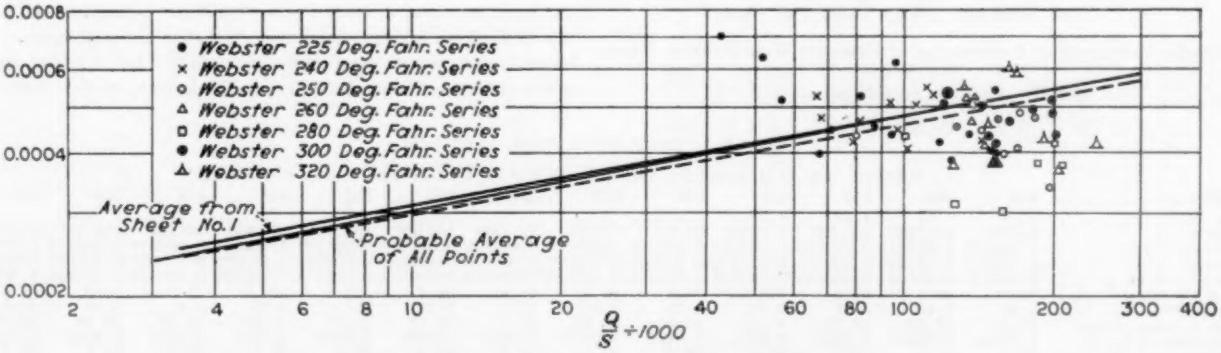

FIG. 2 VARIATION OF $r_{v\text{O.D.}}$ WITH Q/S—WEBSTER TESTS

Also for average film temperatures of 70 to 130 deg. fahr., the chart shows that,

$$\log\frac{J_w}{1.020} = \log\left(\frac{\text{avg. film temp.}}{70}\right)$$

$$J_w = \frac{1.020 \text{ avg. film temp.}}{70}$$

$$\Delta t_w = \frac{Q}{S} r_{w\text{O.D.}} = \frac{Q}{S}\frac{d_oK_2 \quad 11.71}{4.766\ (d_iV)^{5/6}(2t + \Delta t_w)^{1/2}}$$

$$= \frac{Q}{S}\frac{d_oK_2}{0.407(d_iV)^{5/6}(2t + \Delta t_w)^{1/2}}$$

However, as the average resistance of the film on the steam side of the tube seems to be indicated by the dotted line on Fig. 2, we have used these data to calculate the value of the temperature drop Δt_v from the steam to the metal of the tube and from this have obtained values of Δt_w from the observed overall mean-temperature differences reported by Orrok for Admiralty metal tubes.

We have assumed in Table 1 that the exponent of V is $^5/_6$, and have calculated the values of K_2 from Equations [7] and [8], reading Δt_w from the charts, and it is evident that there is nothing consistent in the variation of K_2, assuming that the exponent of V is $^5/_6$ throughout the series of tests, and the only way to secure consistency seems to be the assumption that K_2 is a constant throughout (taking the value as 0.015 determined from the low rate of heat transfer) and then finding the values of the exponent of V in Equations [7] and [8] which will satisfy the Orrok test data. This has been done in Table 2, and the results are plotted on Fig. 3, which would seem to indicate that the exponent of the velocity varies in some way with the rate of heat transfer.

Taking, then, the values of n from the average line on Fig. 3, and reading the values of $r_{wO.D.}$ from the average line on Fig. 2, we are giving in Table 3 a comparison between the actual mean temperature differences as reported by Orrok and the mean temperature differences calculated by means of the method developed in this paper for these tests, which have been picked at random from those reported in the A.S.M.E. Transactions for 1910 by Geo. A. Orrok.

There is a fair agreement even up to mean temperature differences as high as 148 deg. fahr., but the agreement is not always as close as might be desired. However, when we come down to near the range of condenser practice, below 25,000 B.t.u. per sq. ft. per hour, we find that the deviations of the calculated mean temperature differences from those reported by Orrok are generally only by fractions of a degree fahrenheit, and this is in spite of the fact that the values of Δt_w were all read from the charts and are not calculated.

In the worst cases the method seems to give at the very least 85 per cent of the mean temperature differences reported in the Orrok tests, even at rates as high as 216,000 B.t.u. per sq. ft. per hour.

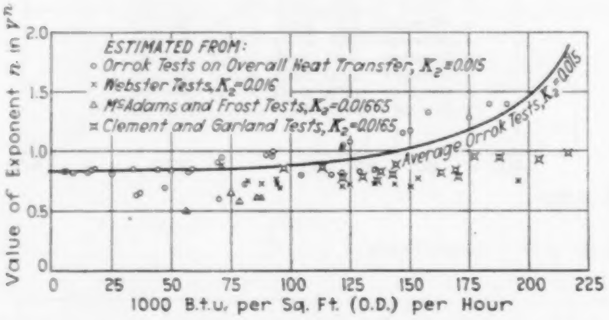

FIG. 3 VARIATION OF EXPONENT n OF VELOCITY WITH RATE OF HEAT TRANSFER
(V = velocity in tube, ft. per sec.)

This seems to establish the fact that for low rates of heat transfer, such as occur in condenser practice, the resistance to the flow of heat on the water side of the tube varies inversely as $V^{5/6}$, or we can say that the value of K_2 assumed (0.015), in combination with Equations [7] and [8] and the resistance of the film on the vapor side and the metal of the tube, can be used to calculate the M.T.D. for a single condenser tube, the same as used in the Orrok tests, when completely surrounded by air-free steam where the rate of heat absorption Q/S is known, or vice versa.

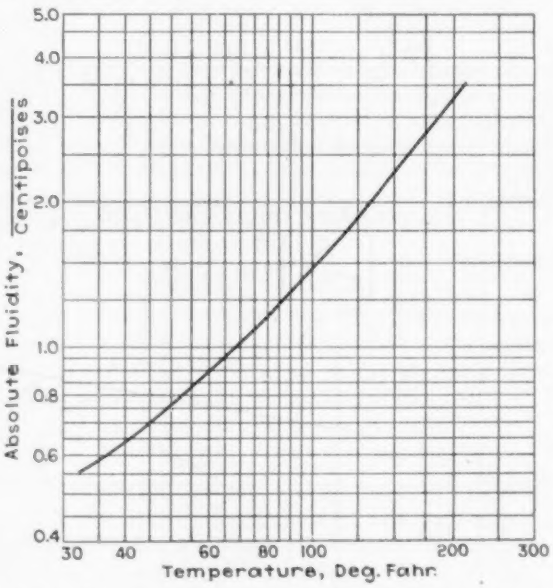

FIG. 4 VARIATION OF ABSOLUTE FLUIDITY OF WATER WITH TEMPERATURE

[Absolute fluidity = 1 ÷ Absolute viscosity. Unit viscosity (metric system) = 1 poise = force of 1 dyne per sq. cm. producing a velocity of 1 cm. per sec. at a distance of 1 cm. Absolute viscosity (metric system), dyne, cm., sec.) = 14.88 × absolute viscosity (English system, poundal, ft., sec.). Data from "Hydraulics of Pipe Lines," by W. F. Durand, p. 262.]

This also seems to be confirmed by recent experiments of the British Electrical and Allied Industries Research Association, which has published some data on the transfer of heat from the tube wall to the water in a condenser tube. These tests are reported in the Nov. 28, 1930, issue of *Engineering*. Three tests, all below 20,000 B.t.u. per sq. ft. per hour, are reported, and in later issues some quite complicated mathematical tables and formulas are published, which the author has not had sufficient time to study.

In these tests (Table 4), where the tube was heated electrically, the length and inside diameter and the calculated value of the experimental constant K_2 were very close to the values in the Soenneken tests reported by Chester W. Rice (see Fig. 11).

The values of K_2 plotted in Fig. 11 from the test data in Tables 5, 6, and 7, on the basis that $^5/_6$ is the exponent of the velocity, are all from tests below 50,000 B.t.u. per sq. ft. per hour, and these points seem to indicate that the value of K_2 increases slightly with L/d_i. The full line in Fig. 11 is assumed from the points as shown, omitting from consideration the single point from a single tube taken in an actual condenser, as in these tests (Table 8) on a single tube in the condenser a separate water supply was applied to each tube under test, the Δt_w was calculated from the observed overall mean temperature differences, and as these tubes were not in the front row at the top of the condenser,

TABLE 2 HEAT-TRANSFER TESTS. INVESTIGATION TO DETERMINE IF n, THE EXPONENT OF V, VARIES. DATA TAKEN FROM TESTS BY GEO. A. ORROK ON OVERALL HEAT TRANSFER

(Δt_w = (observed overall M.T.D. — Δt_v — Δt_i). K_2 calculated from tests 656, 644, 655, and 664)

Q/S O.D.	3,470	10,510	17,500
Δt_w	2.81	8.27	13.46
V	8	8	8
$(d_iV)^{5/6}$	3.96	3.96	3.96
Avg. temp. water	38.70	39.67	40.63
K_2 (base $V^{5/6}$)	0.0166	0.0167	0.0166

as air was undoubtedly present, and the condition of fouling was unknown, the calculated value of K_2 should be and is higher than for a single tube completely surrounded by air-free steam.

As a matter of interest, if we assume that the value of K_2 for the test apparatus used by the following experimenters can be taken from this curve (Fig. 11), we can calculate how the exponent n of V may vary in order to satisfy these test results:

	L/d_i	K_2 chart
Clement and Garland	80.5	0.01650
Webster	60.0	0.01600
McAdams and Frost	97.5	0.01665

By this method the agreement is not good (see Tables 9, 10, and 11 and Fig. 3) between the exponent n of V calculated from the Orrok, the Webster, and the McAdams and Frost tests.

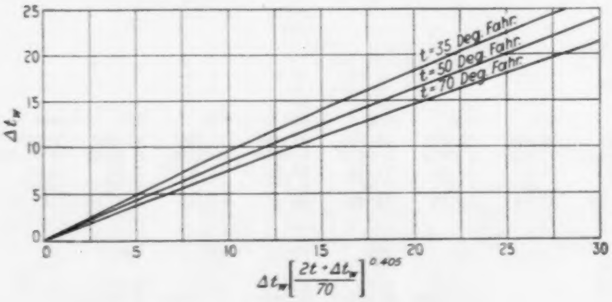

Fig. 5

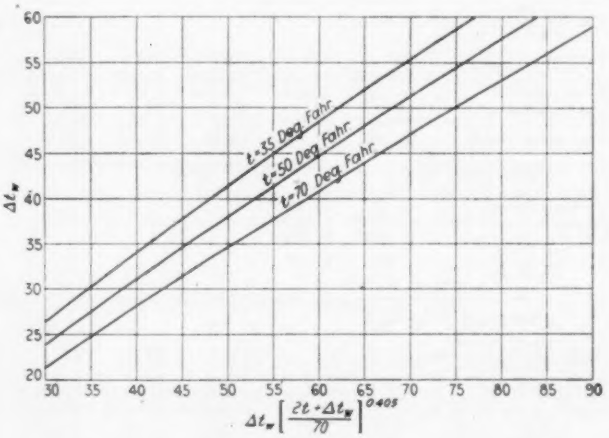

Fig. 6

FIGS. 5 AND 6 HEAT TRANSFER THROUGH WATER FILM INSIDE TUBE (Average film temperature, 35 to 70 deg. fahr.)

$$\Delta t_w\left[\frac{2t+\Delta t_w}{70}\right]^{0.405} = \frac{Q}{S} \times \frac{d_oK_2}{3.645(d_iV)^{5/6}}$$

where Δt_w = drop in deg. fahr. through water film inside tube to average temperature t of cooling water
d_i, d_o = inside and outside diameters of tube, in.
V = average velocity of cooling water over cross-section of tube, ft. per sec.
K_2 = experimental constant
Q/S = B.t.u. per hr. per sq. ft. of external surface of tube.

The Clement and Garland tests appear to be consistent with the calculated results for the Orrok tests at low heat rates, but the exponent n of V appears to rise less rapidly with increasing heat flows than is estimated from the Orrok tests. The same thing appears from the Webster tests.

In view of the considerable variation in the resistance on the

vapor side as shown in Figs. 1 and 2, probably no exact consistency should be expected in the values of the exponent n of velocity V for the various tests.

So far the method given above seems to present a satisfactory basis for the calculation of the heat transfer from saturated air-free steam through a single tube which is completely surrounded by the steam, at the ordinary temperatures and rates of heat absorption encountered in condenser work, and the data for higher rates of heat flow for single tubes shown in this paper are presented for the use of any one interested in following this matter further and are to be used with due caution.

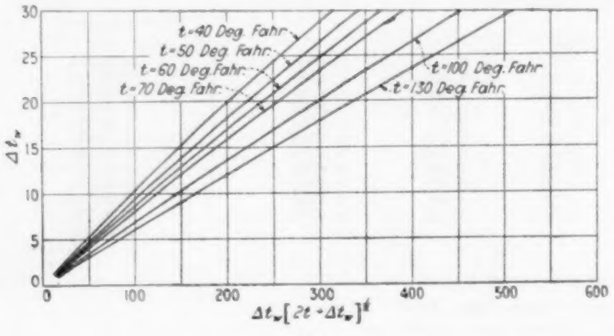

Fig. 7

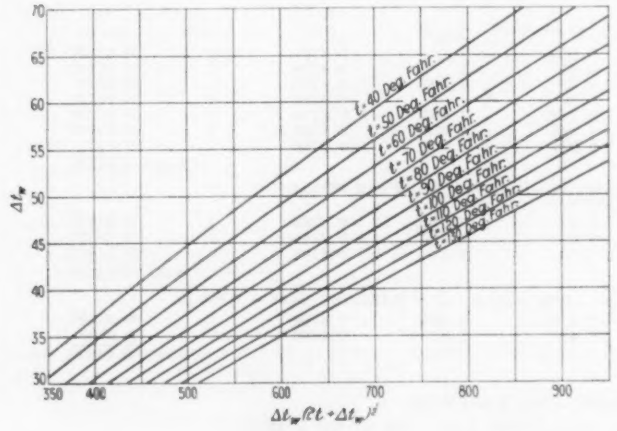

Fig. 8

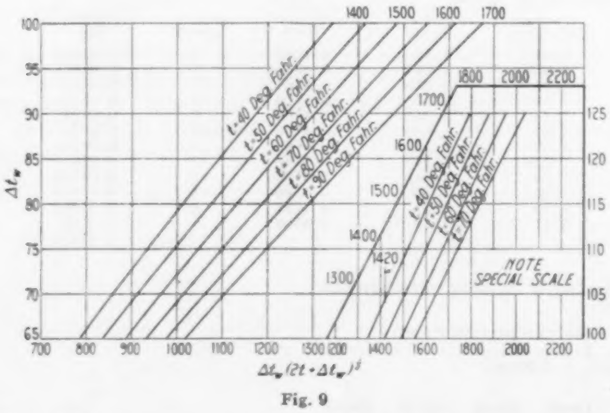

Fig. 9

Figs. 7–9 Heat Transfer Through Water Film Inside Tube
(Average film temperature, 70 to 130 deg. fahr.)

$$\Delta t_w[2t + \Delta t_w]^{1/3} = \frac{Q}{S} + \frac{d_o K_2}{0.407(d_i V)^{5/6}}$$

In a heater, where the tubes are spaced rather close together, or in a practical condenser, all of the surface does not work uniformly, and there are varying amounts of air present in the steam and of scale or dirt on the tubes. Each tube is not completely surrounded by steam, and consequently the total resistance to the flow of heat from the steam to the condensing water will be widely different from the performance of the ideal single tube. If we call $r_{sasO.D.}$, the resistance of the condenser or heater, due to scale, air, and arrangement of surface, we can write,

$$\frac{1}{U} = (r_{vO.D.} + r_{tO.D.} + r_{wO.D.}) + r_{sasO.D.} \ldots\ldots\ldots [9]$$

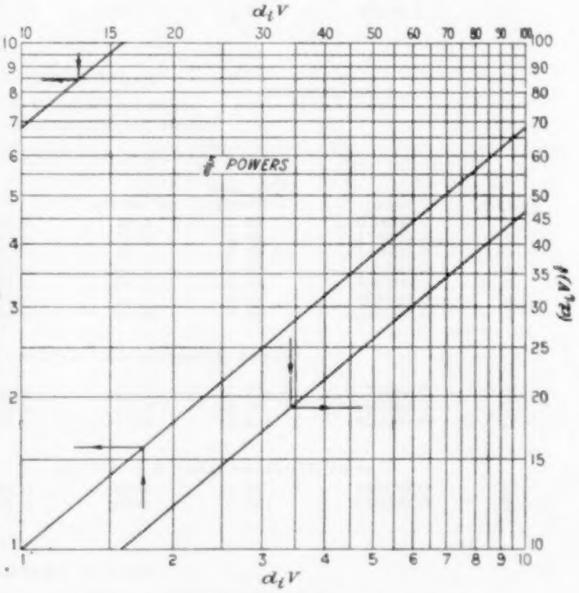

Fig. 10 Chart Giving ⁵/₆th Powers of $d_i V$

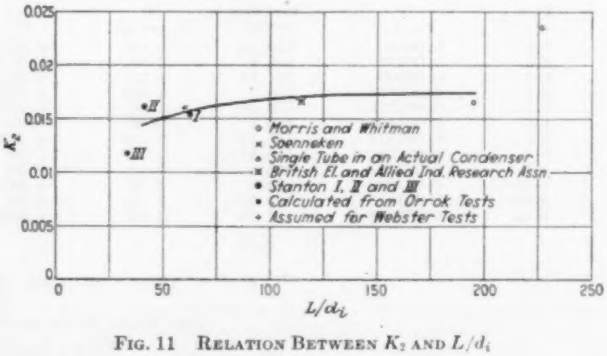

Fig. 11 Relation Between K_2 and L/d_i

The expression in the parentheses covers the value of the theoretical heat transfer of a single tube determined from the method given above, and $r_{sasO.D.}$ is the difference between the actual performance obtained and the theoretical performance which would be obtained if the condenser consisted of a single tube.

In condensers where the tubes are packed closely together, the values of $r_{sasO.D.}$ are usually of the order of 40 to 75 per cent of the total resistance $1/U$.

At present we have no method of calculating the value of $r_{sasO.D.}$ from the design of a particular condenser, and little seems to be known as to how it varies in actual condensers with changing temperatures and velocities of circulating water, but a study should be made to determine the best methods to follow in re-

ducing this factor to a minimum as it has a large effect upon the amount of surface required for a given service.

It would seem that the various manufacturers of condensers should undertake such a study, as only in recent years have they begun to arrange condenser tubes so that the steam can reach the condenser surfaces effectively.

In the tests reported by Orrok in 1910, it was found that the overall resistances varied approximately as the reciprocals of the square root of the velocities for a single tube completely surrounded by steam. This is the sum of the three terms in the parentheses, Equation [9]. This rate of variation has been assumed to hold for an actual condenser and has been used in the past in calculating changes in vacua, due to changes in velocity of the water in the tubes for an actual condenser. A consideration of Equation [9] shows that if the term $r_{sasO.D.}$ is as large as the sum of the terms in the parentheses, such a method would result in corrections for changes in velocity, which would be twice the actual changes that can be secured by velocity change alone. This has actually happened in the experience of the author, where the actual benefits secured by increasing the velocities were about one-half of the expected benefits.

Fig. 12 shows the results obtained by calculating from actual test data the values of $r_{sasO.D.}$ for a two-pass 50,000-sq. ft. condenser, model of 1923; and for the same inlet-water temperature and the same flow of steam there seems to be no change in the value of $r_{sasO.D.}$ with changes in velocity, and, consequently, if the value of $r_{sasO.D.}$ is known for one rate, we should be able to use this method to determine the change in the coefficient of heat transfer due to changes in the water velocity alone, provided there is no change in the amount of air present in the steam and the tubes have the same degree of cleanliness in both cases.

However, this condition does not seem to hold quite so well for a single-pass condenser (see Table 12) where $r_{sasO.D.}$ seems to vary with the velocity and temperature of the inlet water, the greatest change occurring at low temperature, and the variation in $r_{sasO.D.}$ seems much less at higher temperatures of inlet water than at low.

It is evident that further study of test data on condensers must be made to learn how $r_{sasO.D.}$ varies for different designs, if very accurate results are to be secured in calculating changes in vacua due to varying velocities and at all temperatures of inlet water.

In Table 13 a sample calculation for a two-pass condenser is shown.

Using the values of $r_{sasO.D.}$ obtained with one pump operation, it is shown in Table 13 that the overall coefficient of heat transfer in this condenser can be calculated quite accurately for the condition of two-pump operation for the same temperature of inlet water and the same quantity of steam condensed per hour.

In conclusion the data submitted in this paper seem to transfer the problem in condensers from the consideration of the behavior of a single tube to the arrangement of the surface and the

elimination, so far as possible, of scale, dirt, and air, and probably considerable work will be necessary before the variation of the term $r_{sasO.D.}$ is thoroughly understood.

It would seem, however, that there must be sufficient test data in existence which, if compared properly on this basis, would yield clews as to how this factor varies with different conditions, and it is to be hoped that some one will undertake the task for the benefit of the condenser industry.

If we accept the Orrok tests as the criterion in judging condenser performance, the method developed in this paper apparently can be used to calculate quite accurately the mean temperature difference for a single tube completely surrounded by air-free steam for rates of heat flow below 30,000 B.t.u. sq. ft. per hour, and with a lesser degree of accuracy for rates as high as 216,000 B.t.u. per sq. ft. per hour, but its application to an actual heater or condenser cannot be expected to give accurate mean temperature differences until more is known about the behavior of the resistance ($r_{sasO.D.}$) due to the arrangement of the tubes, etc.

[a] Less air leakage than run F.

In its present state this method appears to be useful in correcting the mean temperature difference for changes in velocity of circulating water in the tubes in condenser practice for inlet-water temperature of the order of, say, 50 to 90 deg. fahr. approximately, provided the value of $r_{sasO.D.}$ is known for one state, and then there is no change in any of the conditions except velocity in the tubes.

The results appear to be not so accurate below 50 deg. fahr. inlet. Probably the term $r_{sasO.D.}$ varies more with changing velocity at these low temperatures.

It is to be noted that the changes in the velocities, Tables 12 and 13, are very large (of the order of 75 per cent) and cover the change from one-pump to two-pump operation. If the change in velocity to be covered is, say, only 25 per cent, the difference would obviously be less.

The condenser industry should find this information useful, as it calls attention to the fact that the design of the condenser has as much, if not more, effect upon the M.T.D. than the other resistances ($r_{sO.D.} + r_{tO.D.} + r_{wO.D.}$).

The value of this method must rest largely upon the painstaking work of the various experimenters and the others mentioned, who have developed the formulas and made the experiments on which this method is based, and the author wishes to take this opportunity of extending to them his appreciation of their work.

The data on which Table 12 is based were supplied through the courtesy of the Worthington Pump and Machinery Corporation. The author would appreciate having any errors called to his attention.

Discussion

N. Artsay.[2] A few years ago the idea of comparing the average condenser performance with the possible performance of a single clean tube gained ground, and a great many papers appeared here and abroad dealing with the single-tube results. The comparison has shown such a low efficiency of the condenser-tube banks that several dormant improvements were dug out and incorporated in the designs. So in less than a decade the cooling surface went down from 2.0 to 0.6 sq. ft. per kw.

It should be pointed out that the analysis of separate resistances to heat transfer in single tubes will be of doubtful use for the tube banks, because the controlling resistance for a total condenser bank is on the vapor side and consists of several new resistances or their equivalents which are not sufficiently distinct in a single tube. The list would run approximately as follows:

(1) Decreased vapor temperature toward the inner part of the bank due to the increased partial pressure of air and to the reduction of total pressure of the mixture by hydrodynamic resistance.

(2) Reduction of velocity of steam past the tubes, and consequently the aggravated effect of air due to lack of sweeping effect.

(3) Increased amount of dripping condensate which reduces the exposed metal surface.

(4) The undercooling of exhaust steam, which cannot be detected by the usual thermometers.

(5) Accumulating dirt.

The water side of the cooling surface also presents new problems not encountered in single tubes: dirt, fouling, uneven distribution of flow among the tubes (to the extent of backflow in some tubes of two-pass condensers), liberation of air in top tubes of siphon flow condensers when placed too high, etc.

Taking all in all the mentioned factors encountered in the tube banks far outweigh those determining the performance of single tubes, and before attempting to predict the performance of given tube banks at various water velocities and rates of condensation a great deal more of experimental and theoretical investigation should be made.

Orrok, in his tests, has found that the overall heat transfer is proportional to the temperature difference in power $^7/_8$ which indicates the effect of condensate on the tube surface. In "Technische Mechanik und Thermodynamik," Feb., 1930, E. Schmidt, W. Schurig, and W. Sellschopp report on heat transfer by condensing steam when settling in the form of droplets and in films. High rates of heat transfer were aimed at in these experiments; a 6-in. copper disk placed vertically was cooled on one side by a central jet of water, and saturated steam was on the other side. Total transfers as high as 400,000 B.t.u. per sq. ft. per hour were reached.

The overall heat transfer coefficients B.t.u. per hour per sq. ft. per deg. fahr. obtained were as follows:

	Water velocity, ft. per sec.	Overall heat-transfer coefficient
Polished plate, droplets	16.4	2160
Polished plate, droplets	35.0	3060
Etched plate, 100 per cent film	16.1	945
Etched plate, 100 per cent film	34.5	1050
Etched plate, 30 per cent film	34.5	2750
Chrome-plated disk coated with kerosene, droplets	17.0	2600
Chrome-plated disk coated with kerosene, droplets	33.0	3430
Chrome-plated disk coated with kerosene, droplets	36.0	3550

With the film condensation the limit for overall heat transfer was in the neighborhood of 1100 B.t.u. per hour per sq. ft. per deg. fahr. attained at about 20 ft. per sec. water velocity; any further increases of velocity did not improve the heat transfer. However, with the condensate settling in the form of droplets, the curve of heat transfer versus water velocity was still rising after 35 ft. per sec.

These experiments demonstrate clearly the importance of the vapor side and call for a cautious interpretation of single-tube results. The figures given indicate that in a vertical row of tubes placed in saturated steam the heat-transfer coefficient in the third from the top and in the lower tubes will be practically independent of water velocity due to the dripping of condensate.

Somebody should extend the single-tube experiment providing a determined shower of condensate over the tube and measure the additional resistance.

Nusselt's theory of heat transfer during condensation takes the resistance of dripping condensate as the major factor and checks well with the experimental figures for banks. The splendid performance of Ginabat (Delas) and of the newest Escher Wyss condensers where measures were taken to divert the condensate testifies to the importance of this factor.

AUTHOR'S CLOSURE

Mr. Artsay points out the importance of the resistance on the vapor side of the tube. This is in accordance with the findings of this paper, as the term $r_{ssO.D.}$ in Equation [9] for an actual condenser with perfectly clean tubes seems to cover resistances external to the tube proper—i.e., in the arrangement of the surface and in the amount of air present in the steam, etc. This conclusion is based upon the fact that calculated changes in the term $r_{wO.D.}$, Equation [9], due to changing velocity of water inside the tubes, seem to cover satisfactorily the changes in heat transfer in an actual condenser, provided the flow of steam, the amount of air present, and the temperature of the inlet water are not altered at the same time that the velocity of the circulating water is changed.

It has been known for a long time that the rule of the square root of the velocity for calculating changes in heat transfer in an actual condenser was not exactly correct, and Equation [9] seems to explain why this is so.

At least one manufacturer and one user of condensers are now experimenting with this method, and interesting conclusions may be expected during the coming year.

Development of Pulverized-Coal Firing and Study of Combustion

By HENRY KREISINGER,[1] NEW YORK, N. Y.

This paper reviews briefly the development of burning pulverized coal under steam boilers. It points out the difficulties experienced in the early installations and how some of these difficulties were overcome by changes in the design of furnaces and burners and also by the adoption of more advantageous methods of firing. The paper discusses the present practice in rates of combustion in furnaces of various designs and the factors that set the limitations. A large part of the paper is devoted to a detailed study of combustion of pulverized coal.

THE early installations of powdered coal under steam boilers had furnaces with solid refractory walls. Many of these installations were boilers changed over to powdered coal from stoker firing, and the same design of furnace walls had been used as was then the practice with stoker furnaces. Even the new installations were set with refractory furnaces, although the larger units had the air-cooled hollow-wall construction with the refractory tied to the steel frame for stability.

Some of the first installations were short lived. The furnaces were small, and the refractory walls were rapidly destroyed by erosion of molten ash and by flame impingement. It was this rapid destruction of the furnace walls that held back the application of powdered-coal firing to steam boilers. It became evident that the furnaces must be made large in order to reduce the impingement of flames and to avoid the rapid wasting away of the furnace walls. Large furnaces really meant the removal of the refractory walls from the flame, and giving the flame more elbow room.

The desirability of avoiding impingement of flame against furnace walls made it necessary to employ methods of firing with limited turbulence in the furnace and to admit air in sheets between the flame and the furnace walls. The fact that a large part of the air was introduced into the furnace along the walls resulted in slow mixing and long flame. When higher ratings were required, it was necessary to admit into the furnace a greater excess of air to lower the furnace temperature and thereby reduce the slagging of the ash and the washing away of the furnace-wall refractories.

The removal of the refuse deposited at the bottom of the furnace was another problem in the early installations. The refuse was either fused or became sticky and could not be removed without shutting down the boiler and cooling the furnace. Resort was generally made to large excess air to lower the furnace temperature and to avoid the fusion of the refuse and make its removal easier.

Water-Cooled Furnaces

Greater excess air increased the stack losses and lowered the overall efficiency of the steam generating unit. Therefore, efforts were exerted to reduce the furnace temperature by placing water-cooled surfaces in the furnace. The water-cooled surfaces were placed first over the bottom of the furnace, then over the rear wall, and then by several successive steps over the side walls and the front wall.

With water-cooled furnaces it was not necessary to introduce excess air into the furnace beyond that amount needed for nearly complete combustion, in order to lower the furnace temperature and to avoid slagging of the ash. The lowering of temperature was much more usefully accomplished by allowing the water-cooled walls to absorb part of the heat liberated by combustion. At present practically all large steam-generating units are built with water-cooled furnaces.

The water-cooled walls either replace refractory walls or supply protection to the refractories. Thus, the modern water-cooled furnace makes possible the realization of higher rates of combustion without large excess air, thereby maintaining high efficiency.

The development of water-cooled furnaces removed the limitations to the turbulence in the furnace, and brought about the application of methods of firing with very intensive mixing and more rapid combustion. Impingement of the burning mixture against the furnace walls ceased to be destructive because there were either no refractories to be washed away or because what refractories were used were protected by water-cooled tubes.

Intensive mixing or turbulence fills the furnace space more completely with the burning mixture, so that the furnace volume is more fully utilized in the combustion of coal, which results in higher average rate of heat liberation.

Methods of Firing

Three general methods of firing pulverized coal have been developed; namely, the vertical, the horizontal, and the tangential. The vertical firing was the first to meet with a definite commercial success. It was followed shortly by the horizontal

---

[1] Consulting Engineer, Combustion Engineering Corporation. Mem. A.S.M.E. Henry Kreisinger was born February 17, 1876, at Radnice, Czechoslovakia, where he received his grammar-school education and learned the machinist trade. In 1891 he came to the United States and settled in Chicago, where he worked in machine shops and a foundry and attended evening schools. In 1900 he entered the College of Engineering of the University of Illinois, in 1904 receiving B.S. degree and in 1906 M.E. degree. After graduation he was a fuel engineer with U. S. Geological Survey engaged in testing coals until 1910. From 1910 until 1913 he was a fuel engineer with Clinchfield Fuel Company, supervising the preparation of coal at the mines and instructing the clients in the proper methods of burning coal. In 1913 he returned to the U. S. Bureau of Mines to take charge of the investigation of the economic utilization of fuels, in which position he remained until 1920. During the war he was detailed to test marine boilers for the U. S. Shipping Board. Since 1920 he has been with Combustion Engineering Corporation in charge of tests and research, devoting much of his time to the development of the methods and furnaces for burning pulverized coal under steam boilers. While with the Bureau of Mines he published many bulletins and technical papers on steam boilers and combustion of fuels. Many of the publications contained original research work.

Presented at the National Meeting of the A.S.M.E. Fuels Division, Chicago, Ill., February 10 to 13, 1931.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

firing. Various modifications and combinations of the two methods were devised and put in service. The Gilbert Station of the New Jersey Power and Light Company is an example of a modified horizontal firing. In this installation rows of horizontal burners are placed in opposite walls of the furnaces so that the streams of burning mixture impinge on each other in the middle of the furnace, producing intensive mixing and quick combustion. This modification of the horizontal firing was given the name of opposed firing.

A noted combination of the two methods of firing is used at the East River Plant of the New York Edison Company. Vertical burners firing downward are placed, as usual, in the arches. A set of horizontal burners is placed in the front walls close to the arches. The streams of the mixture of air and coal from the horizontal burners impinge against the streams of air and coal from the vertical burners. The impingement takes place close to the burners and results in quick ignition and intensive mixing. This method of firing has been adopted because at this plant low-volatile Eastern coal is burned which is slow to ignite by straight vertical or horizontal firing. Such combination of firing should be especially useful for burning anthracite coal and coke, which fuels have low volatile matter content and are difficult to ignite when burned in pulverized form. However, on account of the high temperature close to the arch produced by the quick ignition, the arch and front wall should be water cooled to prevent their destruction.

In the tangential method of firing the principle of producing intensive mixing by impingement is carried to the limit. Four sets of burners are placed in nearly the same horizontal plane, one set in each corner of the furnace, the streams of coal and air from each set being directed into the furnace tangent to a circle having a diameter $^1/_4$ to $^1/_2$ of the sides of the furnace. Generally 20 to 50 per cent of the air needed for combustion is supplied with the coal as primary air; the remainder of the air is supplied through the burner around the coal nozzle as secondary air and is forced into the furnace in the same direction as the mixture of primary air and coal.

The streams of mixture of coal and air from the burners in adjacent corners meet at right-angles, and the jets from the diagonal corners move nearly in opposite direction. The impingement of the streams against one another produces a very intensive mixing or turbulence. Due to the fact that the jets are tangent to a circle, the burning mixture is given a rotative motion on its way through the furnace and completely fills the combustion space. Thus, all combustion space is utilized in the burning of the coal, and high average rates of heat liberation are possible.

However, on account of the impingement of the burning mixture against the furnace walls, the tangential method of firing is applicable only to a completely water-cooled furnace. A refractory furnace would not long stand the impingement and the maintenance and outage of the furnace would be high.

There are now several large installations using the tangential method of firing. Among these are two units at the Kips Bay Station of the New York Steam Corporation, having a capacity of 450,000 and 800,000 lb. of steam; three units at the Hell Gate Station of the New York Edison Company, with a capacity of 400,000 lb. each, and two 1400-lb. pressure units at the Fordson Plant with a maximum capacity of 700,000 lb. There are also a number of smaller installations with this method of firing.

Although the corner location of the burners makes it a comparatively easy mechanical problem to fit the burners to a completely water-cooled furnace, the coal-pipe system is somewhat complicated. This is especially true with the direct-firing method where the coal from the mill must be divided into two to four streams which must be piped to different corners of the furnace. To simplify the coal piping and still retain most of the mixing advantages of the tangential firing, a few installations were made with one large burner placed in the bottom of the furnace. The mixture of coal and air is given rotary motion as it is forced up into the furnace from the burner. Although these installations give in general satisfactory results, the combustion is not as rapid as it is with the tangential method of firing. The rotative motion of the burning mixture, completely filling the furnace, is there, but the impingement of a number of streams against one another giving intensive mixing is lacking. When streams of secondary air are admitted through the corners and made to impinge on the rotating mixture from the burner, the results obtained are very near those obtained with the tangential method of firing.

Rates of Heat Liberation

The past experience has demonstrated the best practice for the rate of heat liberation for any furnace design. A few years ago there was a hope for high rates of heat liberation per cubic foot of available combustion space. Predictions were made that the rates of heat liberation would go to or even exceed 100,000 B.t.u. But this hope has not been realized, and it looks as though we are farther than ever from such realization.

At present a good engineering practice is to design refractory furnaces for rates of heat liberation not exceeding 20,000 B.t.u. for continuous operation, and if the ash is fusible, the rates generally do not exceed 15,000 B.t.u. With water-cooled furnaces the rates of heat liberation are limited to 30,000 B.t.u. for continuous operation, with a peak rate of 35,000 B.t.u. Higher rates are the exceptions and require extra good coal and fine pulverization.

The limit to the rate of heat liberation in refractory furnaces is the excessive erosion of the refractories by molten ash resulting in high furnace maintenance and difficulty in removing the refuse from the furnace. In water-cooled furnaces the limit is generally the deposition of slag on boiler tubes and the clogging of the gas passages through the boiler. Losses from incomplete combustion in many cases are not a serious limitation. With intensive mixing coal could be burned at considerably higher rates before the economic limits due to incomplete combustion would be reached.

Fineness of Coal

Finely pulverized coal burns quicker than coarse coal. Also high-volatile coal ignites and burns quicker than high fixed-carbon coal. There is no need pulverizing coal to a fineness that will give nearly complete combustion at a rate of heat liberation of 40,000 B.t.u. when the construction of the furnace and the fusion of the ash permit a rate of only 15,000 B.t.u. There is no need pulverizing Illinois coal or Texas lignite as fine as the high fixed-carbon Eastern bituminous coals or anthracite. A large part of the combustible of the Illinois coal and Texas lignite burns as gas, which can be burned quickly, whereas most of the combustible in the Eastern coal and anthracite burns as coke or fixed carbon, which burns slowly.

In addition to the relative contents of volatile matter and fixed carbon the various coals behave differently when heated. The particles of anthracite retain their shape and do not stick together when they collide. The Eastern bituminous coals fuse and become sticky. While passing through the stage of fusion, they change their shape, and when two or more particles collide, they may fuse into large pieces. The Illinois coal does not generally change shape and does not become sticky. The individual particles stay separate until completely burned. The lignite and the Western sub-bituminous coals crack and disintegrate. The particles break up into a larger number of smaller pieces, which burn more quickly than the larger particles. When sub-bituminous and lignite coals are burned in pulverized form, it is comparatively easy to reduce the combustible in flue dust to 1 or 2 per cent. On the other hand, it is considered good combustion when the flue dust from burning Eastern high fixed carbon bituminous coal contains 20 per cent combustible. The flue dust from anthracite coal-burning installation often contains 50 per cent combustible.

Therefore the fineness of pulverization should to a large extent be determined by the nature of the coal. Table 1 gives the fineness for the various coals for the best economic results, considering the cost of pulverization as well as the losses from incomplete combustion.

TABLE 1 ECONOMIC FINENESS FOR VARIOUS COALS

	200 mesh	100 mesh	50 mesh
Anthracite	85	97	100
Eastern low volatile	75	92	98
Eastern high volatile	65	85	97
Illinois	55	80	92
Sub-bituminous	45	75	90
Lignites	35	65	88

PROCESS OF COMBUSTION OF PULVERIZED COAL

The early experiments with powdered coal have shown that intensive mixing produced quicker and more complete combustion. Since then designers of pulverized-coal equipment strove to devise methods of firing and to design burners that would produce intensive mixing in the furnace and quick combustion. A closer study of the process of combustion shows the advantage of intensive mixing.

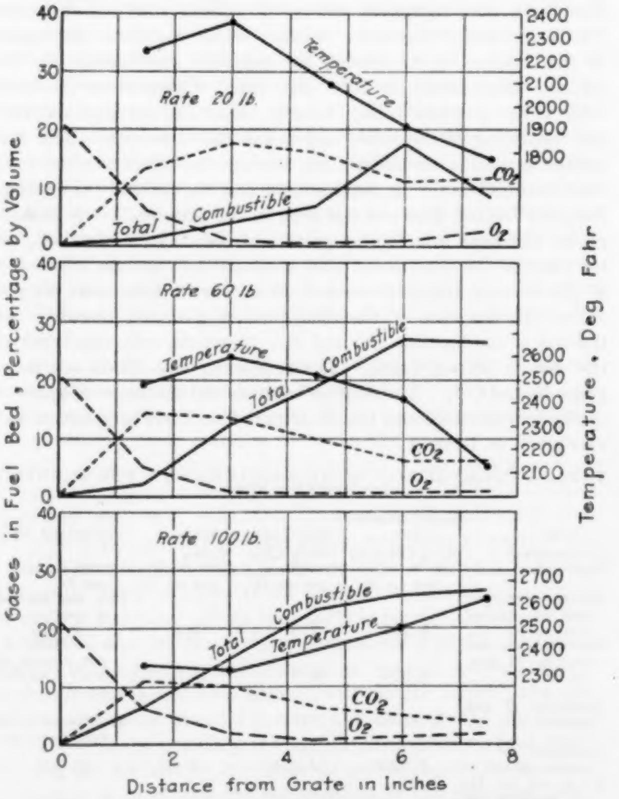

FIG. 1 COMBUSTION OF ANTHRACITE IN FUEL BED

(Composition and temperature of gases in 6-in. fuel bed of anthracite coal. Rates of combustion 20, 60, and 100 lb. per sq. ft. of grate per hour. Oxygen combines with carbon as fast as it is brought in contact with it. Practically all free oxygen combines with carbon in the first 3 in. of the fuel bed.)

Pulverized coal is supplied to the furnace in a mixture with air. The coal particles are heated largely by radiation from the flame of the already burning coal. The heating drives off the volatile matter as gas, and when this gas has been heated to a temperature of about 1100 deg. fahr., it bursts into flame and burns with the oxygen immediately surrounding it. The heat liberated by this combustion further raises the temperature of the coal particles and speeds up the distillation of volatile matter.

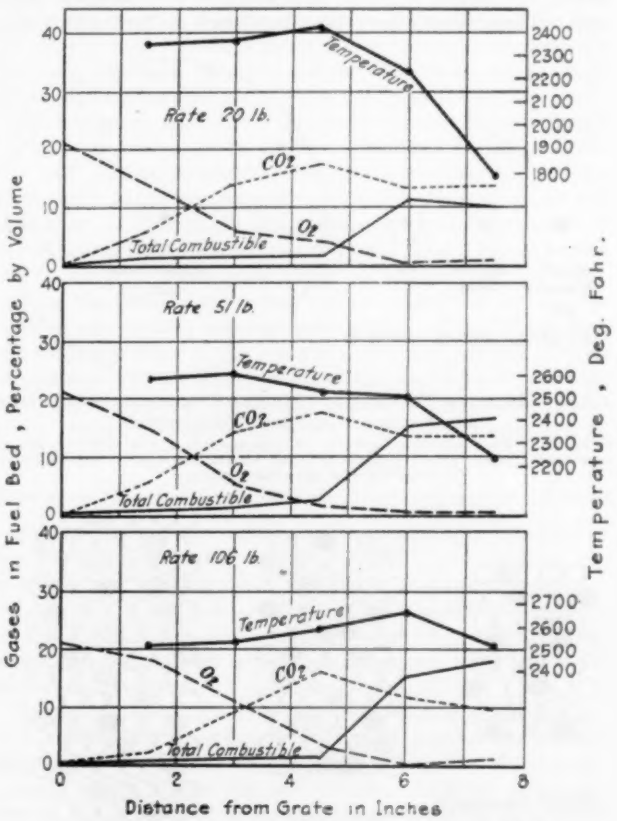

FIG. 2 COMBUSTION OF COKE IN FUEL BED

(Composition and temperature of gases in 6-in. fuel bed of coke from Pittsburgh coal. Rates of combustion 20, 51, and 106 lb. per sq. ft. of grate per hour. Oxygen combines with coke as fast as it is brought in contact with it.)

The distilled volatile matter ignites and burns first; when most of the volatile matter has been distilled and burned, the fixed carbon begins to burn.

Combustion of fuels in boiler furnaces is a chain of two consecutive processes. The first link of this chain is the coming of oxygen and combustible in contact. The second process or link in the chain is the chemical combination of the oxygen with the combustible when they have made contact. The speed of combustion is always controlled by the slower of the two links of the chain. The process of bringing oxygen and combustible in contact is by far the slower of the two links. Time is required for the oxygen and combustible to make contact. Once brought in contact the chemical combination at the ordinary furnace temperature is virtually instantaneous. In other words, the combustible can be burned only as fast as oxygen is brought in contact with it.

This principle is fully utilized in controlling the rate of combustion on grates. The more air that is forced through the fuel bed, the faster the oxygen makes contact with the combustible and the higher is the rate of combustion. During its passage through the spaces between the pieces of fuel, the oxygen comes in contact with the combustible and combines with it as fast as the contacts are made. The limit is reached only when the flow of air through the fuel bed becomes so great that the pieces of fuel are lifted and blown away and holes or craters are formed in the fuel bed. With some fuel it is possible for the rate of combustion or gasification to greatly exceed 100 pounds of fuel per hour per square foot of grate before this limit is reached.

Several years ago the Bureau of Mines made a series of experiments, the results of which demonstrated the foregoing principle. These results have been published in Technical Paper No. 137. Figs. 1 and 2 are reproduced from this publication. They show the composition of the gases at various distances from the grate and how quickly oxygen combines with combustible.[2]

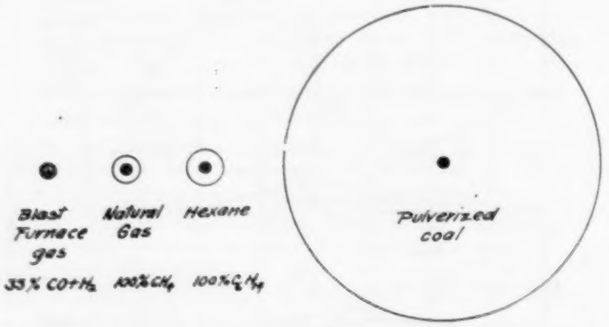

FIG. 3 RELATIVE VOLUMES OF VARIOUS COMBUSTIBLES AND THE AIR NEEDED FOR THEIR COMBUSTION

(The black dots represent spheres of combustible. The outside circles represent spheres whose volume is equal to the air needed for complete combustion of the combustible.)

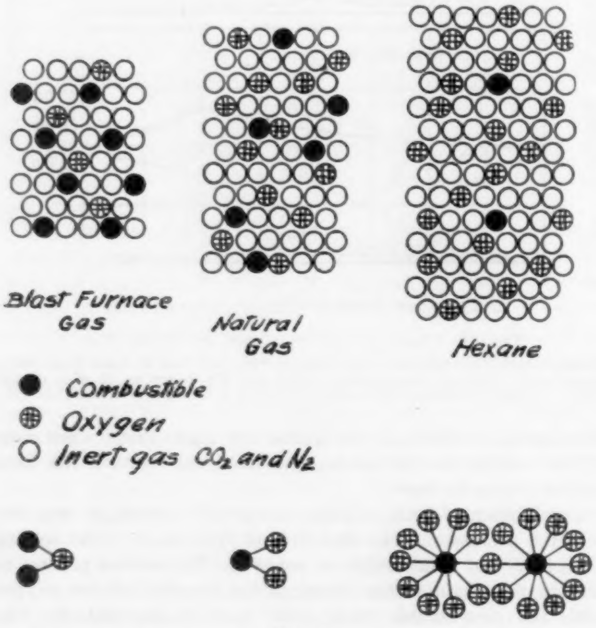

FIG. 4

(At the top are shown cross-sections through three gaseous fuels in a homogeneous mixture with all the air needed for their complete combustion. At the bottom are shown the number of molecules that are to combine with each molecule of the three fuels.)

When fuel is burned in pulverized form, the combustible burns only when it comes in contact with free oxygen, and therefore burns only as fast as it makes contact with oxygen. The distilled volatile combustible being in gaseous state diffuses into the atmosphere immediately surrounding the coal particles, meets the free oxygen, and burns. In other words, it goes halfway to meet the free oxygen and therefore makes contact with it quickly. The fixed carbon on the other hand stays in the coke residue in solid state and must wait until free oxygen works its way to it and makes contact with it.

A particle of pulverized coal is highly concentrated combustible which requires for its complete combustion a large volume of air many times as great as its own volume. Even if the mixture were perfectly uniform—that is, if the particles of coal were so spaced that all the air needed for the complete combustion surrounded each particle in a sphere—a large part of the oxygen molecules would be an appreciable distance from the coal particles, and time would be required to make contact with their surface. In case of gaseous fuels a mixture with air can be obtained in which all the oxygen molecules needed for complete combustion are comparatively near the combustible molecules and contacts between them can be made more quickly than in the case of pulverized coal.

This great concentration of combustible in a particle of pulverized coal and the large volume of air needed for its combustion compared to some of the gaseous fuels is illustrated in Fig. 3. The black dots represent spheres of various combustibles, and the large circles represent spheres whose volumes are equal to the volume of air needed for complete combustion at the furnace temperature of 2000 deg. fahr. Comparison is made with three gaseous fuels; namely, blast-furnace gas, natural gas consisting of methane, and a gas called hexane. The gas hexane is used in the illustration to show the effect of more concentrated fuel on the air requirements and the necessity of mixing. Actually hexane does not last long in the furnace. It is broken up by the heat into lighter gases and soot. It is assumed for the sake of the illustration that methane and hexane are stable at the furnace temperature and do not break into more simple gases. In the case of the blast-furnace gas only one-third of the gas is combustible CO and H_2; therefore, only one-third of the dot is shown black. The remaining two-thirds are inert gases N_2 and CO_2. The relative volumes and diameters of spheres of the combustibles and the air required for their combustion are also given in Table 2.

TABLE 2 COMPARISON OF AIR REQUIREMENTS FOR BURNING DIFFERENT FUELS

Fuel	Blast-furnace gas	Natural gas	Hexane	Pulverized coal
Composition	33% CO + H_2	100% CH_4	C_6H_{14}	....
Heat value	100 B.t.u. per cu. ft.	1000 B.t.u. per cu. ft.	4500 B.t.u. per cu. ft.	13,500 B.t.u. per lb.
Volume of oxygen per cu. ft. of gas, cu. ft.	0.165	2.0	9.5	(Air per pound of coal) 9.8 lb.
Volume of air per cu. ft. of gas, cu. ft.	0.825	10.0	45.6	Air at 2000° F. per pound of coal) 46,000 cu. ft.
Diameter of gas sphere	*D*	*D*	*D*	*D* (diameter of coal particle)
Diameter of sphere of air	1.22*D*	2.225*D*	3.6*D*	35.8*D*
B.t.u. per cu. ft. of mixture at 2000° F.	11.8	19.6	20.8	21.2

It is apparent that in the case of the gaseous fuels, in a nearly homogeneous mixture with all the air needed for combustion, the free oxygen is close to the combustible with which it is to make contact. However, with pulverized coal a large part of the oxygen is a considerable distance from the coal particle and more time is required for all the oxygen to make contact with the combustible in the coal particle than in the case of the gaseous fuels. Furthermore, the gaseous fuels can be easily subdivided into very small volumes which in the limit may become individual molecules, in which case the mixture may become completely homogeneous. In such a mixture the oxygen molecules would be close to the molecules of combustible, and contacts between the two would occur rapidly although not instantaneously. On the other hand, there is a limit to the fineness to which coal can be pulverized. The limits are both physical and economical. There are no available means to tear coal into individual molecules. Even within the limits of practical pulverization, very fine particles tend to cling together to form clusters, and thus the benefit of finer pulverization is partly lost. Besides, fine pulverization is costly. The average-sized particle of pulverized coal is very large compared to the size of a molecule of combustible gas, and much more time is required for all the free oxygen needed for complete combustion to come in contact with the combustible of the coal particle.

---

[2] A more detailed study of this subject is given in a paper, "Burning Characteristics of Different Coals," by the present author and B. J. Cross in Trans. A.S.M.E., paper FSP-50-52 (Sept.-Dec., 1928).

Although contacts between oxygen and gaseous combustible in a mixture occur comparatively easily, they do not take place instantaneously. Even if the mixture is perfectly homogeneous an appreciable length of time is required for all combustible to make contact with the oxygen. The necessity for the time factor is illustrated in Fig. 4, which shows a section through the mixtures and the probable arrangements of the molecules of the three gaseous fuels in nearly homogeneous mixture with all the air needed for combustion. The shaded circles represent the molecules of the combustible, the cross-sectioned circle represents oxygen molecules, and the white circles the inert gases, nitrogen and, in the case of blast-furnace gas, also carbon dioxide. At the furnace temperature the molecules are in rapid motion and collide frequently with one another. In all three mixtures all the oxygen molecules must make contact with the combustible molecules. Some of the oxygen molecules are close to the combustible molecules, and contacts may occur quickly. Other oxygen molecules are farther away, and must work their way around and between the inert molecules toward the combustible molecules, and more time elapses before the contacts are made. As the combustible molecules combine with the oxygen, there are fewer active molecules left, and the contacts become less frequent.

In the heavier combustible gases such as methane and hexane, a number of oxygen molecules must make a contact with each combustible molecule, and many of the molecules must come a comparatively long distance to make the contact. This is especially true of hexane. But even with this heavy gas the number of molecules is small and the distance they have to travel short as compared with the combustion of pulverized coal. So large is the number of combustible molecules in a small particle of coal, and so great is the number of oxygen molecules that must make contact with the coal particle that it is impossible to draw a diagram. If the coal particle consists mostly of fixed carbon, all the oxygen molecules must come to the particle of coal to make contact, and the rate of contact making is slow. If the particle is coal with high volatile matter content, the volatile matter leaves the coal particle and diffuses into the air and the rate of contact making is high. It is well known how slowly burning are anthracite and coke in pulverized form, and how difficult it is to reduce the combustible in the flue dust below even 30 per cent.

MIXING IN FURNACE INCREASES RATE OF CONTACT MAKING

Mixing in the furnace greatly increases the rate of contact making. It brings the unused free oxygen molecules next to the surface of the coal particle. It also carries away the products of combustion and the distilled volatile matter from the coal particle, thus equalizing the distribution or concentration of free oxygen and the unburned combustible in the furnace.

It is the mixing in the furnace that brings combustible and free oxygen nearer together so that they can make contact and combine. Mixing outside of the furnace is ineffective in producing rapid combustion. All the devices that were designed for mixing outside of the furnace failed in producing rapid combustion unless the mixing was carried into the furnace. A uniform mixture of pulverized coal and air is very difficult to obtain, and if it is ever obtained it can not be maintained. The coal is much heavier than air and tends to settle out of the mixture. It is kept in suspension by the movement of the mixture. Even during the flow of the mixture the concentration of the coal particles in various parts of the section of the stream is constantly changing. A slight change in the direction of the stream tends to concentrate the coal at the outside curve of the stream.

With intensive mixing, the coal particle moves faster or slower than the air, or moves in different direction. In other words, the coal particle constantly changes its position with respect to the air, moving out of one location where it made contact and used up all the free oxygen near it, into a new location where there is still uncombined oxygen. At the same time it leaves behind the products of combustion either as CO or CO_2, and H_2O. During the distillation process the particles leave behind also most of the distilled gaseous combustible. A careful observer can easily see some of the larger coal particles moving through the furnace with a comet-like tail of burning volatile matter behind them. Mixing continually equalizes the concentration of free oxygen and combustible in all parts of a cross-section of the stream of burning mixture.

EFFECT OF CONCENTRATION ON THE RATE OF CONTACT MAKING

Even with intensive mixing and the resulting equalization of the concentration of the free oxygen and the combustible, the rate of contact making rapidly decreases as the process of combustion goes on. There are fewer oxygen molecules left; some of the very small particles have burned completely, and the larger ones have smaller surface for the oxygen to make contact with.

In case of a gaseous fuel in a homogeneous mixture with air, each combustible molecule within a given unit volume of this mixture has a chance to make a contact with any of the molecules of oxygen within that unit volume. In other words, the rate at which contacts occur is proportional to the product of the concentrations of the two kinds of molecules. If this concentration is expressed in percentage by volume, then the rate of the contact making is proportional to the products of the percentage of oxygen and the percentage of combustible gas. Thus, if C is the percentage of combustible gas and O the percentage of oxygen, then the rate of contact making $= K(C \times O)$. This is true at any time during the process of combustion as long as the mixture is homogeneous.

If a chemical combination takes place every time a contact between two active molecules occurs, which can be assumed with reasonable certainty, every contact removes one molecule of oxygen and at least part of the molecule of combustible from active participation in the contact making, and also in the process of combustion. The rate of contact making during the process of combustion is then expressed by the equation:

$$-\frac{dC}{dt} = K(C \times O) \dots\dots\dots\dots\dots\dots [1]$$

The oxygen in a furnace consists of two parts; namely, that needed for complete combustion of the combustible, and the excess oxygen that is left after all the combustible has been burned. The first part of oxygen is always proportional to the combustible, and the second part remains constant. We can then write

$$O = aC + b$$

where a and b are constant; b stands for the excess oxygen and a for the number of oxygen molecules required to burn a molecule of combustible. Equation [1] then can be written

$$-\frac{dC}{dt} = KC\ (aC + b)\ \dots\dots\dots\dots\dots\dots [2]$$

On integration and the determination of the constant of integration the equation becomes

$$Kt = \frac{1}{b}\log_e\left(\frac{aC+b}{C}\right) - \frac{1}{b}\log_e\left(\frac{aC_1+b}{C_1}\right)\dots\dots [3]$$

where C_1 = initial concentration of combustible and t = period of time since process of combustion has started.

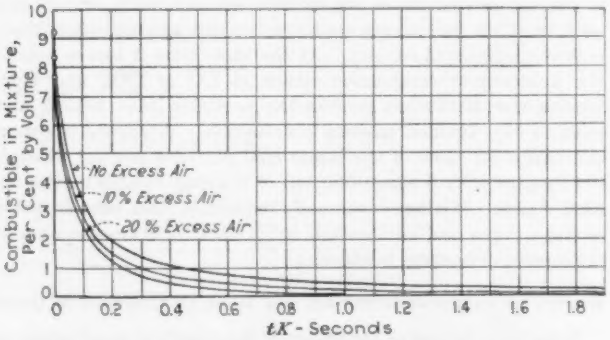

Fig. 5 Process of Combustion of Natural Gas

(This consists of 100 per cent of methane, in a homogeneous mixture with three excesses of air 0, 10, and 20 per cent.)

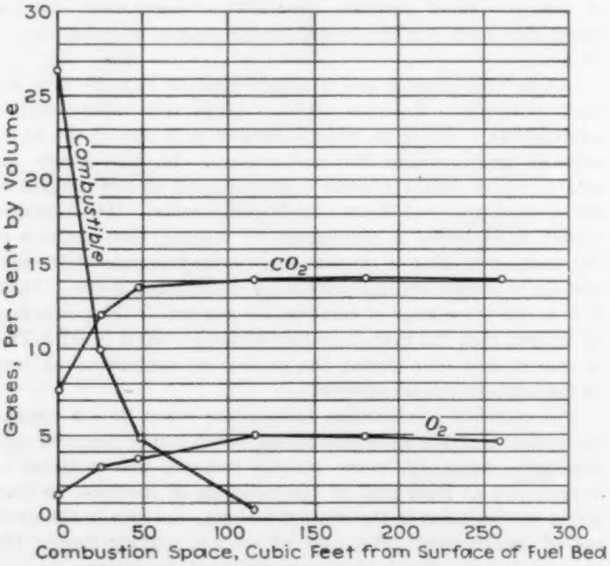

Fig. 6 Process of Combustion of Gaseous Combustible Rising From a Fuel Bed of a Stoker-Fired Fuel Bed

(Air for combustion was supplied through various openings above the fuel bed.)

With no excess air Equation [3] becomes

$$Kt = \frac{1}{ac} - \frac{1}{ac_1}\dots\dots\dots\dots\dots\dots\dots [4]$$

For natural gas containing 100 per cent of methane, and burning with 0, 10, and 20 per cent of excess air, the foregoing equations give the three curves shown in Fig. 5. The curves are plotted with the unburned combustible as ordinates and the time as abscissas.

The curves show two interesting features which are frequently observed in the actual operation of furnaces. The combustible burns at first at high rates, but this rate rapidly decreases as the mixture moves away from the burner, and the rate becomes very low when the combustible has been reduced to 1 per cent. In other words, the first 6 or 7 per cent of the combustible burns much more quickly than the last 1 per cent. It is the burning of the last 1 per cent of combustible that requires time and furnace volume. Within a practical furnace volume the combustible cannot be burned completely, it can be only reduced to economically insignificant quantity. When gaseous fuels are burned it is often difficult to determine the last small traces of combustible in the furnace gases. We know that with pulverized coal we can never reduce the combustible in flue dust to zero.

The rate of heat liberation during the combustion of the first 6 or 7 per cent of combustible is several times as great as the average rate for the entire furnace.

The excess air does not affect materially the initial rate of combustion. It is very useful, however, in burning the last 1 per cent of combustible. The first 10 per cent of excess air is more effective in burning the last 1 per cent of combustible than subsequent additions to the excess air.

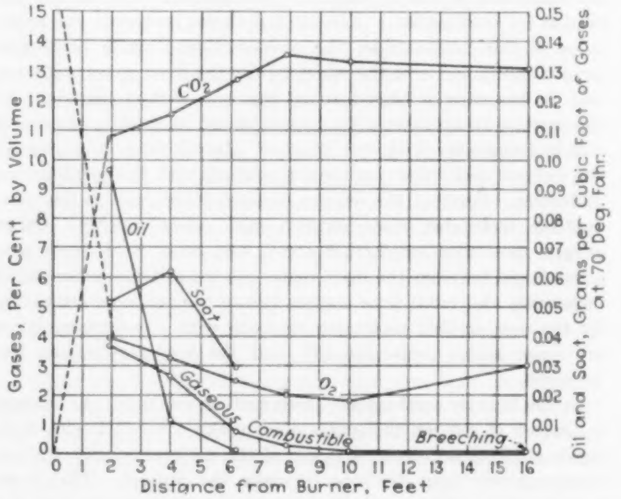

Fig. 7 Process of Combustion of Fuel Oil in a Marine Boiler Furnace

(The atomized oil upon entering the furnace partly burns and partly breaks up into soot and gaseous combustible. About 75 per cent of the combustion occurs within the first 2 ft. distance from the burner.)

Equations [3] and [4] and the curves are applicable to gaseous fuels with which it is possible to express the concentration of combustible in percentage by volume. In oil burning and the burning of pulverized fuel, other factors would have to be substituted for the concentration of combustible. Such factors might be partly proportional to the number of globules of oil or particles of coal and their surfaces per unit volume; that is, the factor should include the fineness of atomization of oil or of pulverization of coal. Most of the oil volatilizes in the furnace and behaves as heavy gas. A large part of high-volatile coal also volatilizes and burns as gas. The curves representing the process of combustion of these two fuels when all the air is supplied through or closely around the burner would be very similar to the curves shown in Fig. 5. With anthracite and other low-volatile fuels the combustion would be slower and the first part of the curves would not be so steep.

For experimental studies in which the air supply could be accurately measured, the sampling of the burning mixture at various distances from the burner and the analytical work could be simplified, if the decrease of the free oxygen were used as the indication of the progress of combustion instead of the unburned combustible. Equation [1] would then become

$$-\frac{dO}{dt} = KC(O + b)$$

where O is the oxygen necessary to burn completely the combustible C, and b the excess of oxygen. The combustible C is then always proportional to O and can be expressed by the equation $C = aO$

Equation [1] in its simplest form then becomes

$$-\frac{dO}{dt} = KaO(O + b)$$

The curves obtained by this equation would be similar to those of Fig. 5, but would be asymptotic to horizontal lines representing the constant excess of oxygen b. Comparison of these curves with those obtained from experimental results would show to what extent the equation would have to be modified.

Experimental data on the process of combustion in furnaces are meager. Obtaining such data requires special apparatus and much careful work. Figs. 6 and 7 show some experimental results from the work of the Bureau of Mines. Fig. 6 shows the progress of combustion of gaseous combustible rising from the fuel bed of a stoker-fired furnace. The oxygen was supplied by air admitted through various openings over the fuel bed and was not therefore mixed with the combustible gases at the point when they were leaving the fuel bed.

Fig. 7 shows experimental data on the progress of combustion in an oil-fired marine-boiler furnace. This figure indicates how difficult it is to determine the total unburned combustible because part of it is in gaseous state, part in liquid, and part in solid state. It is necessary to use two scales to show its amount. The drop in CO_2 and the rise in O_2 in the breeching is due to leakage into the setting.

The curves of these two figures show a strong resemblance to the curves of Fig. 5. Both of these figures indicate very rapid combustion at the beginning of the process. This is especially true of the oil-burning furnace. Two feet from the mouth of the burner a large part of the combustible was burned, as is indicated by 10.7 per cent of CO_2. In the next 6 ft. of the distance the CO_2 increased less than 3 per cent.

CONCLUSIONS

Intensive mixing in the furnace is the most important factor within the control of the designer and operator for producing rapid combustion.

Mixing outside of the furnace is ineffective in producing rapid combustion because a uniform mixture of air and coal cannot be maintained. Without mixing in the furnace, volatile matter distilled from the coal would hang around the coal particles in spheres with only the outside of the surface of these spheres exposed to the contact of the oxygen molecules.

Mixing in the furnace tends to keep the coal particles uniformly distributed across any section of the stream and makes the atmosphere surrounding the coal particles a homogeneous mixture of gases; in other words, mixing in the furnace constantly equalizes the concentration of free oxygen and unburned combustible over any section of the moving stream of burning mixture.

Combustion constantly destroys equalized concentration; mixing reestablishes it. Beyond such constant equalization of concentration, mixing can have no further effect on the rapidity of combustion. With equalized concentration, combustion proceeds at a definite rate depending on the concentration of the combining substances.

Discussion

Ralph A. Sherman.[3] The author has attempted to discuss the problem of the combustion of fuels, particularly of pulverized coal, on a more fundamental basis than has normally been done in the multitude of papers on the subject. He has assumed as his major premise that the rate of combustion is governed only by the rate of contact of combustible and oxygen because this process is much slower than the rate of chemical reaction. This conclusion was reached, apparently, from the results of the experimental work on the combustion of coal in fuel beds which the author conducted when with the Bureau of Mines, where it was definitely shown that the rate of diffusion of oxygen into the film of gas surrounding the particle of fuel governed the rate of formation of CO_2.

Therefore the author sets up the basic differential equation:

$$-\frac{dC}{dt} = K(C \times O) \ldots\ldots\ldots\ldots\ldots\ldots [1]$$

Even for fuel beds, however, this equation does not hold strictly true, for with a given size of a given fuel C is constant, and therefore the rate of combustion is proportional only to the concentration of the oxygen. With a different size of fuel the rate of combustion will also be proportional only to the concentration of the oxygen as before, but will be different from the first by a factor dependent on the relative surfaces of the particles.

Other of the combustion reactions, as

$$\begin{aligned} CO_2 + C &\longrightarrow 2CO \\ 2CO + O_2 &\longrightarrow 2CO_2 \\ 2H_2 + O_2 &\longrightarrow 2H_2O \\ C + H_2O &\longrightarrow CO + H_2 \end{aligned}$$

are relatively slow compared to that of $C + O_2 \longrightarrow CO_2$, and their velocities depend on the specific rate of reaction rather than on the rate of diffusion or of contact making. This assumes, of course, in the combustion of gases good mixing such as would occur in a well-designed burner. With imperfect mixing, such as that of the combustible gases arising from a fuel bed with secondary air, the rate of combustion may well be expected to depend upon the rate of contact making. As the degree of homogeneity is unknown, it can scarcely be hoped to reduce the rate of contact making to a fundamental mathematical expression.

Considering the combustion of coal in pulverized form in its simplest state, that of particles of carbon of uniform size, the rate of combustion at any time should depend only on the concentration of the oxygen, but as the size of the particles decreases, although their number remains constant, a factor for the change in surface should be introduced into the differential equation. When one further considers the combustion of an actual coal in pulverized form where the particles are initially of widely varying size, where they may, as the author points out, coalesce or disintegrate to particles of different size, where the number of particles change as small ones are completely burned, where the evolution of volatile matter gives as intermediate products

---

[3] Fuel Engineer, Battelle Memorial Institute, Columbus, Ohio. Mem. A.S.M.E.

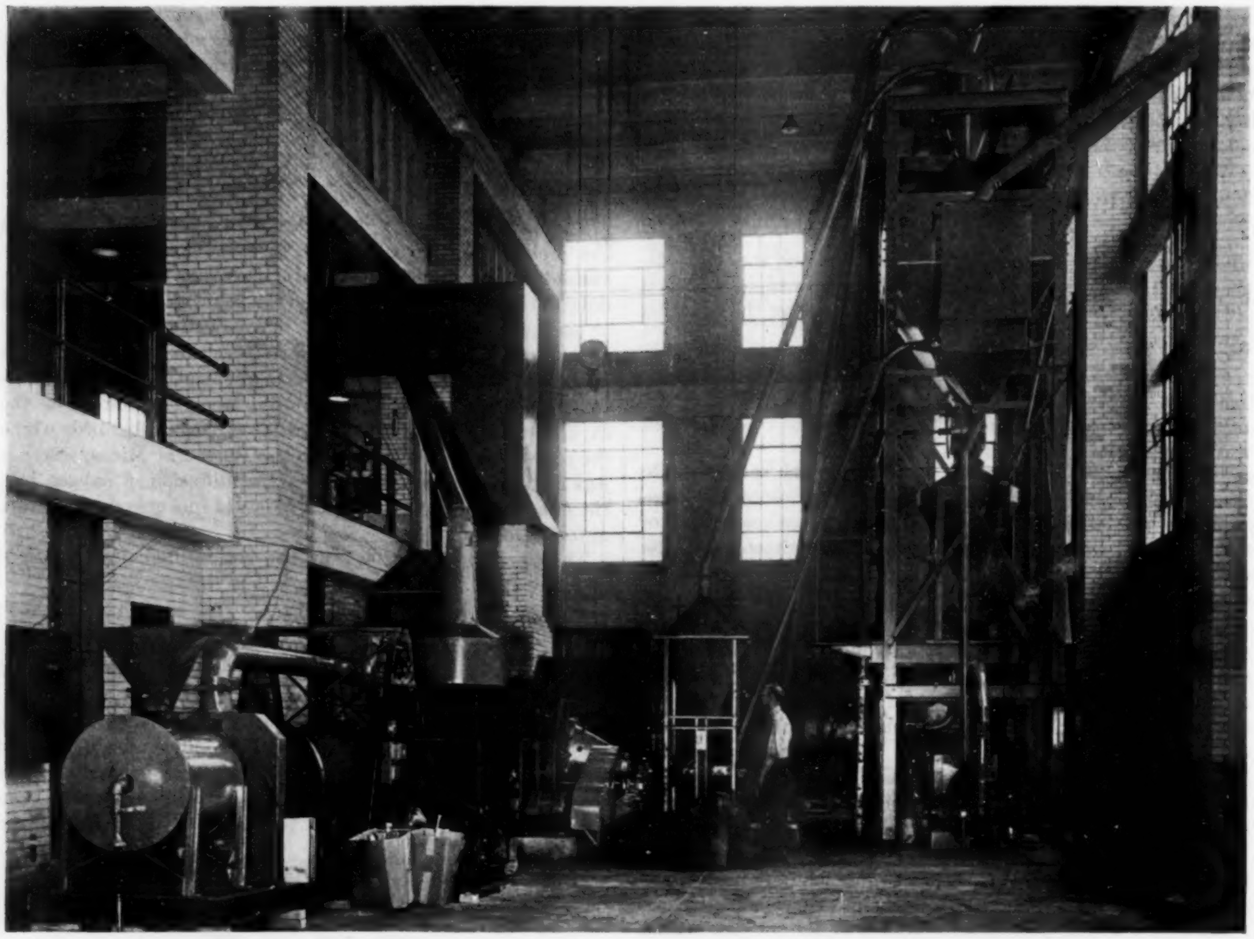

FIG. 8 EQUIPMENT FOR THE STUDY OF COMBUSTION OF PULVERIZED COAL AT BATTELLE MEMORIAL INSTITUTE

gaseous hydrocarbons, hydrogen, and soot, and where the reactions $CO_2 + C \longrightarrow 2CO$ and $H_2O + C \longrightarrow CO + H_2$ may and do occur, the possibility of expressing the rate of reaction in as simple a form as the author suggests is remote.

Experimental data on the process of combustion of pulverized fuels are extremely meager. Audibert[4] made a small-scale study of the process, using a number of fuels, two different sizes, and different amounts of excess air. At the Bureau of Mines two studies have been made by Griffin, Adams, and Smith[5] and Smith and Gudmundsen[6] on the rate of burning of individual particles. These studies are valuable, but are not directly applicable to the present problem.

Realizing the lack of data, the Battelle Memorial Institute felt that as great a contribution as it could make to the advance of the science of fuel utilization would be the undertaking on its own endowment of a study of the process of the combustion of pulverized fuel. Fig. 8 shows the equipment which has been installed for the study. In the left foreground is a rotary drier, from which the coal is handled to the hopper at the rear through a constant-weight feeder into a ball mill. The coal is discharged through the conical superfine classifier, by adjustment of which the size may be controlled, and is collected in the cyclone collector at the top of the 2-ton storage bin. The coal is discharged into a 500-lb. weighing bin mounted with the screw feeder on Toledo scales, so that the rate of feeding at any time is accurately shown. The coal is picked up by the entire amount of air, which is measured by an orifice, and fired through a simple burner into a horizontal, refractory-lined furnace, $3^1/_2$ ft. in diameter and 18 ft. long. The steel shell is welded or cemented at joints to insure against infiltration. A series of sampling holes and observation doors on the sides of the furnace are provided for the sampling of gases and solids and measurement of the temperature. The temperature of the wall is determined by a series of thermocouples embedded in the refractories at four points along the furnace.

The present program includes the study of the process of combustion with different degrees of fineness, with different amounts of excess air, and with different coals. The effect of air temperature, wall temperature, and burner design will be studied later.

Although, as the author states, the quantitative sampling of solids from the gases is difficult, yet we are attempting to determine the completeness of combustion in that way and have developed a method which is not too difficult. The installation has only recently been completed, and some details of the apparatus are not yet working smoothly, but some results have been obtained which may supplement the author's paper.

[5] Griffin, H. K., Adams, J. R., Smith, D. F., "Rate of Burning of Individual Particles of Solid Fuel," *Ind. and Eng. Chem.*, vol. 21, 1929, pp. 808–829.

[6] Smith, D. F., and Gudmundsen, A., "Mechanism of Combustion of Individual Particles of Solid Fuels," *Ind. and Eng. Chem.*, vol. 23, 1931, p. 277.

Fig. 9 shows typical results, gas composition, and gas temperature as determined by a shielded velocity-type thermocouple, wall-surface temperature, percentage combustible in dust, and the carbon in the dust as a percentage of the total carbon in the gas, plotted against the distance from the burner. These results were obtained when burning at a rate of 200 lb. per hr., with approximately 30 per cent excess air, a semi-bituminous coal from the Sewell bed, Fayette County, West Virginia, with 0.7 per cent moisture and 3.6 per cent ash. The screen size of the coal was:

Screen size of coal	Per cent
On 20 mesh	0.0
Through 20 mesh, on 50 mesh	0.2
Through 50 mesh, on 100 mesh	1.0
Through 100 mesh, on 200 mesh	11.0
Through 200 mesh	87.8
	100.0

The distance from the burner is not a good scale for the abscissas, as the gases, because of temperature change and expansion from the burner mouth, do not move at uniform velocity. From readings of the velocity with a water-cooled pitot tube the time to each sampling point has been approximately determined and used in the following calculations and figures.

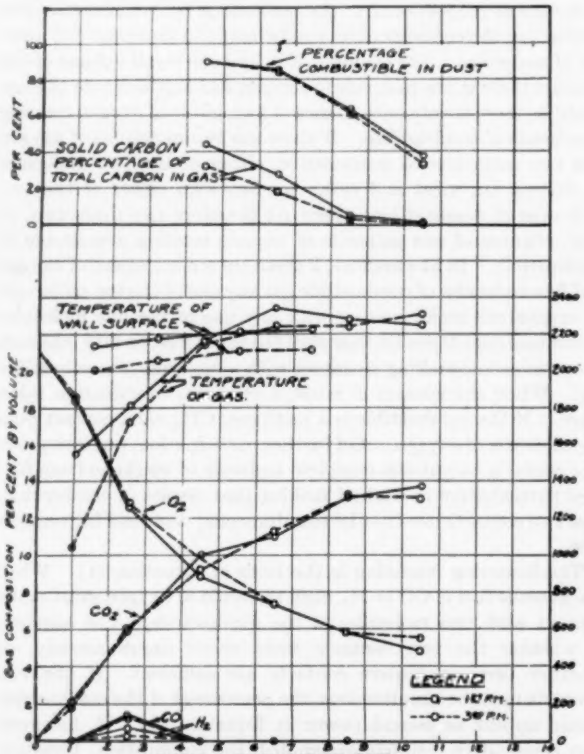

Fig. 9 Typical Data From Experimental Furnace Burning Pulverized Coal

Fig. 10 shows the concentration of O_2 remaining in the gases as calculated from the gas composition shown in Fig. 9 and the air-combustible ratio known from the firing conditions. The type of the curves is similar to those shown in the author's paper with the oxygen concentration becoming asymptotic to the constant excess air lines.

Fig. 11 shows the percentage of the total combustible unburned (1) as calculated from the oxygen remaining and (2) as determined by the quantitative sampling of the solids. The first method is in error, as the calculation is based on the oxygen necessary for the entire combustible, whereas in the later part of the burning time only carbon is being burned. The two methods of calculation do not check, and further careful work is necessary to determine whether the difficult sampling of the solids can be abandoned for the simpler sampling of the gases only.

To determine how closely the rate of combustion might be governed by the rate of contact making as suggested by the author or by the concentration of the oxygen, only values of K have been calculated from the expression

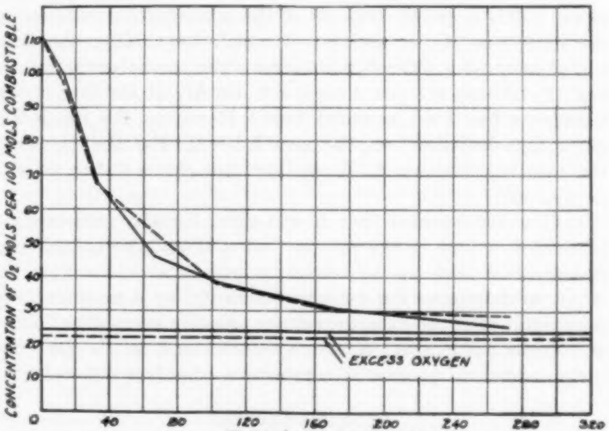

Fig. 10 Rate of Change of Concentration of Oxygen in Experimental Furnace Burning Pulverized Coal

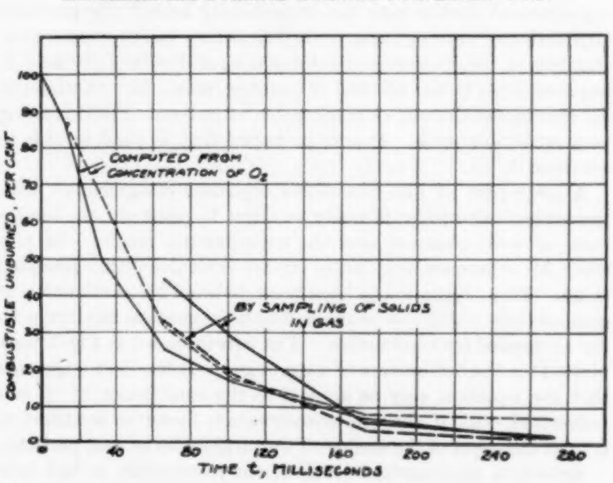

Fig. 11 Percentage of Combustible Unburned in Experimental Furnace Burning Pulverized Coal

$$K_1 = \frac{1}{t} \cdot \frac{1}{ab} \log_e \frac{(O + b)\,O_1}{(O_1 + b)\,O}$$

which is the integrated form of the final equation given on the last page of the paper, and from

$$K_2 = \frac{1}{t} \log_e \frac{O_1 + b}{O + b}$$

which is the integrated form of the differential equation $-\frac{dO}{dt} = K(O + b)$; t is the time in milliseconds, a the initial ratio of oxygen to combustible, b the constant excess of combustible,

O the concentration of oxygen at time t, and O_1 is the initial concentration of the oxygen. Following are the results:

	t, milliseconds					
	13	33	66	103	173	283
$K_1 \times 10^{-6}$..........	1.3	2.9	2.5	3.4	3.7	6.4
$K_2 \times 10^{-3}$..........	9.0	10.1	12.5	10.4	7.6	5.0

Neither of the "constants" is, as was to be expected, a constant. This is partly because of the admitted inaccuracies in the data, one of the greatest of which is probably the time t, (1) because it is difficult to determine the velocities accurately, and (2) because the zero time is not directly at the face of the burner as has been assumed here. However, the maximum percentage deviation from the mean is less for K_2; that is, where the rate is calculated to depend on the concentration of the oxygen only.

It is to be expected that K will differ for the various complicated reactions in the process, but a thorough experimental investigation such as we intend to pursue should enable us, if not to determine the velocity constants, by a mathematical interpretation of the data, to evaluate properly some of the factors and throw some light on this successful and much used but little understood process of combustion of pulverized coal.

Author's Closure

Mr. Sherman's discussion is a valuable contribution to the study of combustion of fuels. Although such theoretical and experimental studies may not immediately benefit the practical application of burning fuels, nevertheless they increase our understanding of the processes of combustion, and eventually lead to improvements in our method of burning fuels. Mr. Sherman in his experimental study of combustion of pulverized coal is doing very creditable work. It is to be hoped that he shall be able to continue it.

A large part of Mr. Sherman's apparent disagreement with the author's deduction is really an effort to point out the limitations of such equation and the experimental results. In this effort Mr. Sherman went really farther than the author intended to go. Thus, Equation [1] has been deduced for combustion of gaseous fuels which can be made into homogeneous mixture with the air needed for combustion. The curves shown in Fig. 5 were plotted for the combustion of natural gas. It has been suggested that the equation may be applied to the combustion of oil and pulverized coal, if the fuel-concentration factor is modified to include the effect of the surface of the oil globules or coal particles.

Results of experimental study of the combustion in fuel beds were used to show that combustion takes place as fast as oxygen can be brought in contact with the combustible. The rate of combustion can be increased tenfold by increasing the weight of air passing through the fuel bed tenfold. This can be done within certain practical limits regardless of the extent of surface. We can bring 10 lb. of air in contact with 1 sq. ft. of surface and burn a definite amount of coal, or we can bring 100 lb. of air in contact with the same foot of surface and burn 10 times the amount of coal. In the same manner we can take 2, 3, or more square feet of surface and bring 10 and 100 lb. of air in contact with the surface. The amounts of coal burned are the same as when the air comes in contact with only 1 sq. ft. It is a matter of the amount of oxygen coming in contact with the surface.

The practical limit to increasing the rate of combustion by increasing the air flow through the fuel bed is reached when the velocity of the air becomes so high that it lifts the coal and holes are formed in the fuel bed. The air then passes through these holes without making contact with the coal. The fusion of the ash into clinker may also affect the flow of air and its contact with the surface of coal. If the size of coal is too large, the spaces between the lumps may be too wide, so that the air may flow through the large passages without making contact with the surface of the coal.

After establishing with reasonable certainty the fact that combustion takes place as fast as oxygen can be brought in contact with combustible, the next move was to find how fast contacts between oxygen and combustible occur in the burning of various fuels. The simplest case is the combustion of gaseous fuels such as natural gas, because the fuel is as finely subdivided as the oxygen in air, and the combustible mixture can be made completely homogeneous. A homogeneous mixture is one having the same concentration of free oxygen, as well as combustible, in every part of the volume of the mixture. Applying this to a stream of burning mixture, if we take a sample of the gases from every square inch of the entire cross-section of the stream of mixture and find the percentage of free oxygen the same, and also the percentage of combustible the same in all the samples, the mixture could be called homogeneous. In such a mixture the rate of contacts of oxygen with combustible would be in proportion to the number of molecules of free oxygen times the number of molecules of the combustible gas. Inasmuch as the number of molecules is proportional to the percentage by volume, this percentage, or the concentration, can be made to represent the number of molecules. For example, if in any one small volume of the mixture there is one molecule of oxygen and one molecule of combustible, there is only once chance of a molecule of oxygen meeting a molecule of combustible. If there are two molecules of oxygen and two molecules of combustible, either of the two molecules of oxygen can meet and make contact with either of the two molecules of combustible; there are therefore two times two, or four, chances of one molecule of oxygen meeting a molecule of combustible. In like manner, if there are ten molecules of oxygen and five molecules of combustible gas any one of the ten molecules of oxygen can make contact with any one of the five molecules of combustible; there are therefore ten times five, or fifty, chances of one molecule making a contact with a molecule of combustible gas. When the contact is made, a chemical combination takes place. If the combustible is a methane, CH_4, each contact puts one molecule of oxygen out of further participation, but it requires two contacts to put one complete molecule of methane from further participation in contact making that results in combustion. The two contacts need not be simultaneous; they can be consecutive.

The foregoing reasoning is the basis of Equation [1]. When the gaseous fuel is CO or H_2, each molecule of oxygen must make contact with two molecules of the combustible. The question is whether the two contacts must occur simultaneously, or whether two consecutive contacts are sufficient. If the two contacts must be simultaneous, the percentage of the combustible would appear as second power in Equation [1]. If, however, two consecutive contacts accomplish the combustion, Equation [1] remains as it stands.

It has been suggested in the paper that the equation can be made to apply to the combustion of pulverized coal if the factor representing the concentration of combustible is modified to take care of the variation of the surface of the coal particles. This surface varies with the fineness and also with the progress of the combustion process. We know that very finely pulverized coal burns quicker than coarsely pulverized coal. Also for any uniform fineness the surface varies approximately as $^2/_3$ power of the volume or mass of the coal particle. This volume, however, does not approach zero volume as the combustible burns, but the volume of the ash residue. In cases of coal with very uniform distribution of ash, it may not be possible to burn out the combustible in the center of the larger coal particles because the ash residue may form a protective layer on the surface and prevent contacts of oxygen with the combustible inside of the ash shell. This and other similar factors make it very difficult if not impossible to formulate an exact mathematical law applicable to all coals and all degrees of fineness. Attempts to formulate such law may indicate the direction of the influence of these factors, which is about all the practical value we can hope to deduce from such formulas. Nevertheless a study of these factors is not devoid of benefit; it increases our understanding of the process of combustion of pulverized coal.

Mr. Sherman has done considerable work in his attempt to test Equation [1] with the results of his experiments. The curves given in his Figs. 10 and 11 show a remarkable similarity to the curves of Fig. 5. That his constants *K* did not come out as constants is not at all surprising. Equation [1] applies to a homogeneous mixture of gaseous fuel with oxygen. With pulverized coal a homogeneous mixture cannot be made. The mixture can be only uniform; that is, in the limit a stream of burning mixture could be made to contain the same number of the same size, evenly spaced coal particles with the same percentage of free oxygen in every square inch of the entire cross-section of the stream of the burning mixture. This condition was far from fulfilled in Mr. Sherman's experiments. At a cross-section 2 ft. from the burner, the percentage of CO_2 varied from 8 to 16 per cent. The percentage of oxygen and the concentration of combustible probably varied in similar manner. The velocities varied from about 70 ft. per sec. in the forward direction to 5 ft. in the rearward direction. The weighted averages of the concentrations of combustible and oxygen when substituted in the equation give results greatly different from the average of the individual results that would be obtained if the concentration values of each small area of the cross-section of the furnace having nearly uniform concentration were substituted in the equation. The errors introduced in such computations are far too great to prove or disprove the validity of any equation. Such errors have the tendency to flatten the first part of the curve and make it less steep.

Lack of uniformity of concentration is a hindrance to rapid combustion. Some parts of the section of the stream of burning mixture contain too much oxygen and too little combustible. Other parts, again, contain too much combustible and too little oxygen. In either case the combustion is slower than it would be if the concentration were equalized over the entire section of the stream of burning mixture. It is the intensive mixing that constantly tends to equalize the concentration and thereby causes rapid combustion. A furnace in which the mixing has been carried to the limit and has continuously produced equal concentration has not as yet been put in operation.

Improvements in Missouri-Kansas Coals and Their Burning Equipment

By E. L. McDONALD,[1] KANSAS CITY, MO.

In the producing of Missouri-Kansas steam coals, there always have been certain undesirable qualities, the reduction of which would materially improve the quality of the coal; namely, high ash, high sulphur, low fusion temperature, excessive moisture, and inconsistent quality. While these undesirable qualities exist in most coals, the character of the local coals and the mining method (mostly strip pitting) make them more evident in these fields. The effort put forth in recent years to improve the quality and the results obtained are briefly covered in this paper. During the past 25 years improvements have been made to reduce various operating problems and to increase boiler-room efficiency. The major improvements made in this field and the actual results obtained are also covered.

IN ORDER to discuss the improvements in Missouri-Kansas coals and their burning equipment, particularly the latter, it is necessary to go back over a number of years, as these improvements were not made in a single step, but rather in a series of steps extending over a long period of time.

A period of 25 years has been adopted as it includes a period with which most people are generally familiar and it includes equipment of which both extremes still exist in some of the plants of today.

It is the intention of this paper to bring out the operating problems existing during this period, the changes or improvements made to overcome these problems, and the results of these improvements.

It is realized that many of the operating problems existing in this field are those common to other fields and have been solved in the same or in some equally efficient manner.

It also is realized that some of the improvements in operating conditions and efficiencies have been derived by the installation of the same equipment that has been generally adopted in other fields, and in order to link together the various steps that have gradually brought the boiler-room operation and efficiency in this field up to its present standard, it will be necessary to include, at least briefly, some facts that are already known. However, generalities will be avoided and the paper will be confined to showing how these developments have improved conditions in a specific field. The data shown are those obtained from equipment actually installed and from tests actually run on this equipment.

The paper has been confined to chain-grate stoker equipment, as the marked improvement made in underfeed stokers and pulverized-coal equipment has been ably covered by two previous papers.[2]

The object in combining the improvements in Missouri-Kansas coals with improvements in their burning equipment is twofold; first, to show that all of the improved operating conditions in this field cannot be credited to improvements in equipment and, second, to show what has been accomplished in improvement of coal by more careful mining.

Improvements in Coal

Of all the boiler-room operating problems, that created by slag and clinkers predominated. For years high percentages of ash or impurities were considered inherent in the coals. Means were devised to combat their effects, but little was done to reduce their existence.

The extent to which impurities can exist in these coals is more evident when it is realized that practically all are from strip-pit mines, which necessitates the use of large steam or electric shovels for the removal of 15 to 40 ft. of overburden before the thin seam (18 to 36 in.) can be reached. Unlike the deep shaft seam, this seldom has a shale cover or floor which permits the easier separation of the coal and impurities.

The incentive for better mining methods, better drainage of pits, and more careful picking of coal, which have created the improvements in Missouri-Kansas coals, has been the selling of coal on a B.t.u. basis, an idea instilled by the consumer, whereby the coal operator is rewarded for better coal and penalized for poorer coal.

With coal purchased in this manner, delivered at the station, the coal operator pays the freight on all of the moisture and impurities and receives nothing in return.

There is of course a limit to which a reduction of ash is desirable in chain-grate stokers, as a very low ash offers little protection to the rear of the stoker, resulting in increased maintenance. There is a physical limit to which moisture and impurities can be removed, and also there is, what is perhaps of most importance to the shipper, a commercial limit, governed by the increased cost of production and the increased sale value of the coal. However, the fact that it is economically practical to reduce moisture and impurities is evident from the gradual increase in the heat value caused by these reductions during the past several years.

Fig. 1 shows the yearly composite average B.t.u. of coal "as received" from several of the larger shippers during the past several years and indicates clearly the gradual improvement in quality, in some cases as much as 1000 B.t.u. per lb.

The various curves represent different yearly tonnages, the minimum being about 25,000 tons and the maximum about 125,000 tons a year. Each curve represents coal from a specific shipping point.

---

[1] Efficiency Engineer, Kansas City Power and Light Company. Mem. A.S.M.E. From 1904 to 1919 Mr. McDonald was with the Commonwealth Edison Company, in plant operation and betterment work. Received technical education during this period at Armour Institute. Wrote "Burning of Mid-West Coals" for April, 1927, Fuels Meeting and several other papers on power-plant subjects. Has conducted about 400 8- to 24-hour evaporation tests on Illinois, Kansas, Missouri, Oklahoma, and Arkansas coals.

Presented at the Fourth National Fuels Meeting, Chicago, Ill., Feb. 11 to 13, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

[2] "Development and Recent Design of Stoker-Fired Equipment for Steam," by F. G. Worker and F. S. Bennett. "Progress in Central-Station Use of Pulverized Coal," by E. H. Tenney.

The reliability of the curves will be better appreciated when it is stated that each car of coal is sampled by an automatic sampler and analysis is made on composite samples of not over ten cars and usually less; hence, it is evident the points represent not a few, but hundreds of samples and analyses.

A knowledge of the mine improvements made and a check on the moisture, ash, and ashless B.t.u. show that the increased heat value is not due to a change in the inherent qualities of the coal, but rather to better mining methods, reducing impurities, and better drainage of strip pits, reducing surface moisture.

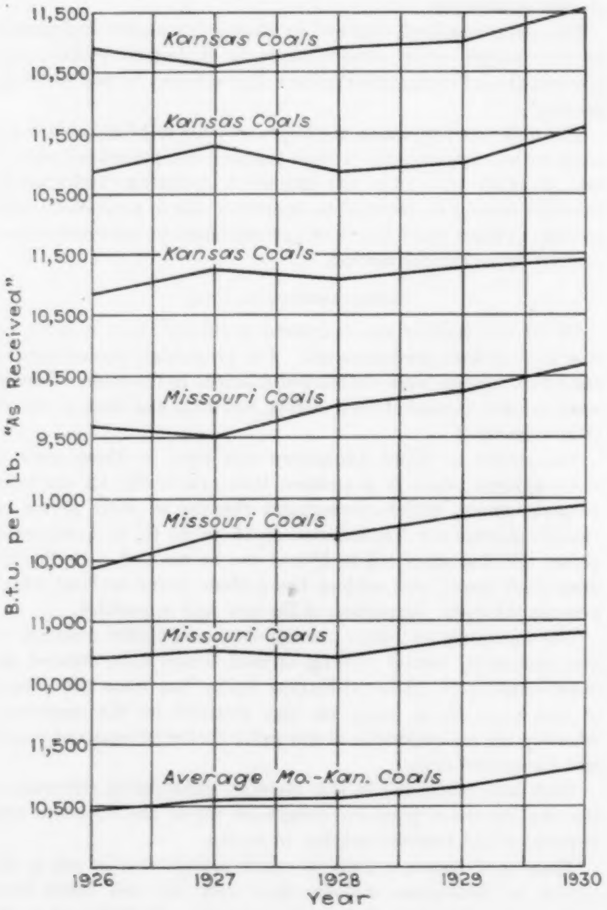

Fig. 1 Improvement in Quality of Missouri-Kansas Coals Due to More Careful Mining

This has gradually resulted in not only a better, but a more consistent quality of coal. Moistures of 20 to 22 per cent have been practically eliminated. An observation of the fuel bed seldom discloses the partly burned islands of coal and impurities found so frequently in the past. Ignition is better, lower ashpit losses exist, and more dependable ratings are available.

It should not be construed from the foregoing that the quality of this coal is without fault or that all Missouri-Kansas coals have so improved, for such is not the case; however, where an improvement has not taken place it usually is due to the lack of an incentive such as selling on a B.t.u. basis. The possibility of improvement in the quality of any of these coals should be evident from the data submitted, and the benefits derived from such must be given consideration when comparing the present-day operation with the past, for surely some of the improvements covered in this paper can be credited to the improved quality of the coal and not all to the improvements in equipment.

Improvements in Equipment

The most predominant boiler-room equipment in the modern central station of 25 years ago in this field was the natural-draft chain-grate stoker, set under a 300 to 500 hp. boiler, underfeed stokers coming into more general use a little later.

While a cross-section of such a furnace (Fig. 2, 1905) may help to visualize the operating problems of that period, they can only be fully appreciated by those who have burned the low B.t.u. Middle West coals with their high percentage of moisture, sulphur, and low-fusion ash.

The effort of the old loosely constructed chain-grate stoker, with about 20 per cent air space, through which 6 to 8 per cent of the coal sifted, trying to liberate 45,000 to 70,000 B.t.u. per cu. ft. of furnace volume with 8 to 10 ft. of flame travel, was met with slag, clinkers, smoke, high maintenance, low efficiencies, and short periods of operation—simple words, but by no means simple problems. It is the gradual improvements made to reduce these specific problems and the results accomplished that form the basis for the remainder of this paper.

First Improvement

The first real improvement came from the realization that these problems were greatly the result of overworked furnace capacities and short flame travel, and the answer, obviously, was higher set boilers.

In accomplishing this, two thoughts occurred; first, the increasing of boiler height only and, second, the reversal of the boiler and gas flow (Fig. 2, 1908-*A*). The first increased the furnace volume and lengthened the flame vertically; the second, more horizontally, resulting in longer flame travel and the utilization for more space directly below the boiler. This became the more generally adopted header-type boiler for some years to come.

The first installations of this type were built with a bridgewall extending 4 to 5 ft. above the grate, in back of which was a so-called soot hopper, which in actual operation developed into a slag hopper, collecting an almost molten mass of slag that fused into a solid body, which took hours to cool and more hours to remove.

The operating difficulties attending this form of construction were somewhat reduced by the next improvement that soon followed, which consisted of a bridgewall sloping from a short distance above the water box to a short distance below the rear boiler header, as shown by Fig. 2, 1908-*B*. This reclining bridgewall reflected heat to the passing gases. It also permitted some of the molten slag to drip back to the rear of the stoker and hence into the ashpit, although furnace temperatures permitting this were usually undesirable from a maintenance standpoint.

While this form of construction improved conditions a little, it still possessed many deficiencies, one in particular being the accumulation of slag on the low sloping wall, which gradually built up, cutting down the furnace volume and obstructing the first pass opening. No means of removal while in service was available. Hand-lancing of the boiler tubes permitted holding the boiler on the line about 20 days at gradually reduced ratings. The work of removing the slag deposit from the bridgewall was not only hot and dirty, but also hazardous.

Surprising as it now seems, this type of boiler unit remained for over 10 years, with little effort being made to overcome its many deficiencies. Slag and clinkers were accepted as operating problems, and while means were devised to facilitate their removal, little was done to prevent their formation, and it is questionable how long this unit would have remained had not the increase in turbine capacities demanded an increase in boiler capacities.

Boiler Size Doubled and Economizers Added

This demand came rather abruptly, and boilers more than doubled in size in almost a single jump, resulting in higher settings, longer flame travel, steeper bridgewalls, and of course larger combustion chambers. The advantages that might have been gained from the latter in slag reduction were lost, however, in the tendencies for higher boiler ratings, and normal operation found this unit running at an even higher B.t.u. liberation per cubic foot of furnace volume than the boiler of 10 years previous. However, there remained two points gained, longer flame travel and a steeper bridgewall, both of which permitted higher ratings for longer periods of time.

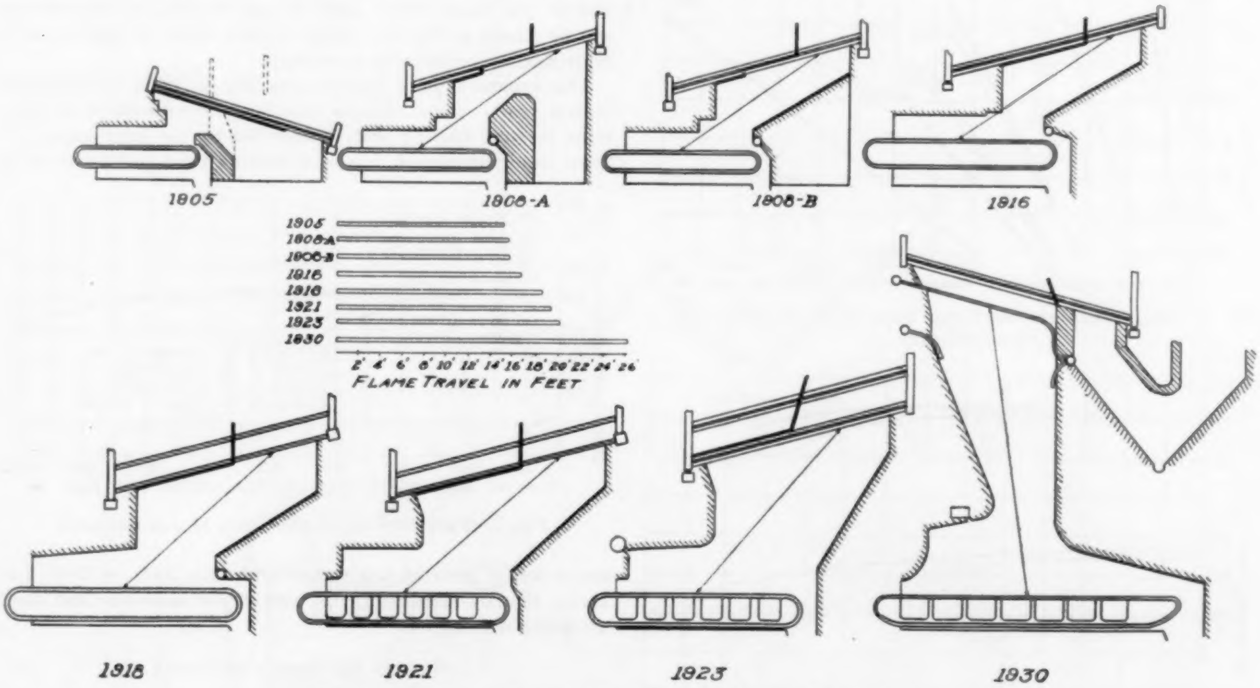

Fig. 2 Changes in Furnace Design for Missouri-Kansas Coals

This larger boiler unit (1200 to 1400 hp.) brought with it the installation of two stokers under a single boiler, and, more important, the installation of an economizer, which was the first real step in improving boiler-room economy.

The old cast-iron economizer, operating under full boiler-feed pressure, reduced the stack-gas temperatures, increased the efficiencies, and likewise increased the boiler-room maintenance, which accounts for its replacements in subsequent installations by the steel tube economizer. Incidentally, the oxygen problems encountered with the first steel-tube economizers threatened for a while to parallel the maintenance of the cast-iron economizer.

Forced-Draft Stokers

The next and perhaps the most important improvement in the actual burning equipment for this grade of coal was the introduction of the forced-draft chain-grate stoker. This not only permitted quicker pick-up, greater capacities, and higher economies, but it also permitted the burning of a greater variety of coals, ranging from the low grade of strip-pit Missouri to the semi-anthracite and anthracite of Oklahoma and Arkansas. It also brought an added step in the improvement of rear-wall construction. By eliminating the old water box, a steeper bridgewall was possible, less slag accumulated, and again longer periods of operation resulted. It is safe to say that the elimination of the old water box caused no grief among the maintenance men, particularly in plants with poor feedwater.

Air Preheaters

The continued advance of turbine bleeding for feedwater heating and the economies gained soon made evident the lack of place for large boiler and economizer surface. The reduction in economizer area in turn made room for the next step or improvement in fuel-burning equipment, namely, the air preheater.

The first large air preheater purchased for central station use in this country was installed in the Northeast Station at Kansas City in 1923. It was a plate-type heater containing 9600 sq. ft. of surface and was installed in conjunction with 12,700 sq. ft. of boiler and 8100 sq. ft. of economizer surface.

On this installation, air was heated from room temperature up to about 175 deg. Tests on the unit showed the overall gain to be in excess of that calculated, due to heat absorbed from the exit gases, and was accounted for by more rapid ignition, lower stack loss (less excess air), and lower combustible losses.

The quicker ignition created by preheated air permitted the utilization of a greater portion of the grate for fuel burning, resulting in higher combustion rates and higher capacities. This was particularly evident with the low-grade Missouri coals containing a high percentage of moisture and ash.

Contrary to the original belief that the air preheaters would be of short life, due to the high sulphur content of Missouri-Kansas coals, this first installation is still in daily use after seven years of service, and many air-heater installations have since followed, some preheating air up to 600 deg. with 350 to 400 deg. as a safe operating limit.

Along with the improvements due to the air-preheater installation came the improvements due to wider tube spacing in the first few rows of boiler tubes, and once again flame travel and furnace volumes were increased through higher-set boilers, all of which were steps in the right direction to help reduce the still-existing slag problem.

OVERFIRE AIR THE NEXT IMPROVEMENT

For several years considerable experimenting had been carried on (particularly by the Commonwealth Edison Company) with overfired air as an aid to the better combustion of Middle Western coals and as a means of reducing smoke. This can possibly be inserted here as the next step in the progress of improvements in Missouri-Kansas fuel-burning equipment, as anything that assists in reducing smoke surely deserves a place in the line of progress.

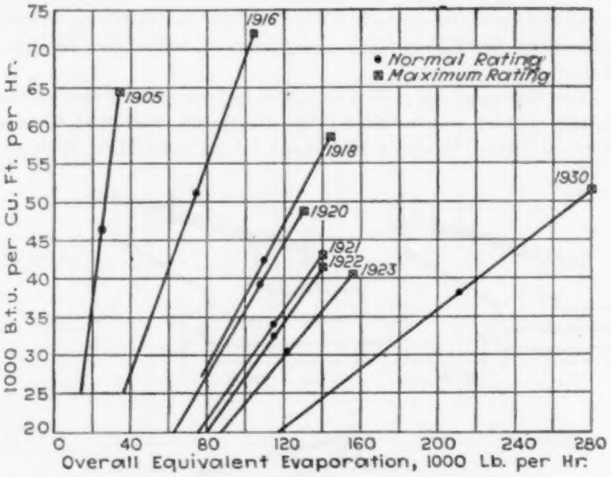

FIG. 3 B.T.U. LIBERATED PER CUBIC FOOT OF FURNACE VOLUME ON VARIOUS UNITS

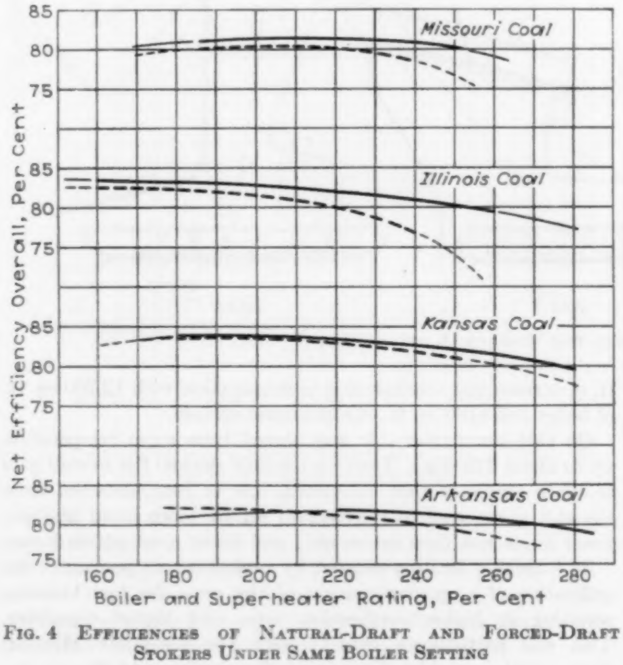

FIG. 4 EFFICIENCIES OF NATURAL-DRAFT AND FORCED-DRAFT STOKERS UNDER SAME BOILER SETTING

Application was first made in this section principally as a means of smoke reduction, and its value when burning some of the long-flamed, high-volatile Missouri coals was particularly evident; however, subsequent tests showed a gain in excess of that anticipated.

WATER-TUBE SIDEWALLS

Throughout these years various means had been tried to reduce two of the most annoying of operating problems, sidewall clinkers and sidewall maintenance, perhaps more serious in the Middle Western field than in others because of the high percentage of low-fusion ash in these coals.

Numerous kinds of refractory materials, air-cooled tile, and waterwall boxes were tried with various degrees of success, but it remained for the water-cooled sidewall to make the greatest improvement in this direction. This form of construction, together with the radiant-heat superheater, which made its appearance shortly afterward, has done much toward the reduction of furnace maintenance, and the latter has played its part in improving the plant economy of many of the older plants; and so the water-cooled sidewall and the radiant superheater can be placed as the next major improvement, at least in Missouri-Kansas fuel-burning equipment.

This general type of construction (Fig. 2, 1923) remained for several years. Some changes were made in subsequent installations in tube spacing and furnace height, the most important being the improvement in stoker design, which permitted using one stoker in place of two stokers under the 20-ft. to 24-ft. furnaces, thereby eliminating the two center sidewalls and their attending deficiencies.

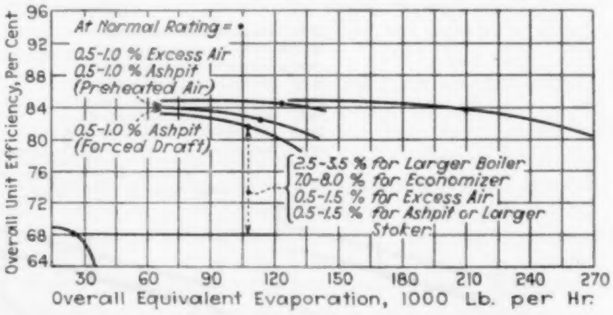

FIG. 5 TEST EFFICIENCIES ON FIVE MAJOR CHANGES

MODERN EQUIPMENT OF TODAY

With the adoption of forced-draft stokers, economizers, air preheaters, waterwalls, etc., there appeared to be little room for increased efficiency in the present modern unit.

Steam rates had increased, but furnace volume increased in greater proportion, resulting in a gradual reduction of B.t.u. liberated per cu. ft. This, together with the gradually increasing flame travel and better tube spacing, permitted longer periods of operation, but not long enough, as slag and maintenance still controlled.

The answer was obviously to again increase flame travel, and this time a very material increase was made in the height of the boiler setting (Fig. 2, 1930).

In this unit, improvements in stoker construction permitted increasing the preheated-air temperature to 350 or 400 deg. for normal operation, and the water-wall surface has been extended to include the front and rear walls. No longer is the refractory surface of the arch exposed to the full blast of furnace temperature or flame, the brunt of the force being taken by the water tubes placed in front and in some places entirely replacing the refractory surface. But the value of this water wall extends beyond its ability to prolong the life of firebrick. Its high rate of heat absorption has permitted an upward trend in the B.t.u. liberated per cu. ft. of furnace volume, and the normal rate of today is close to the maximum rate of the unit previously shown.

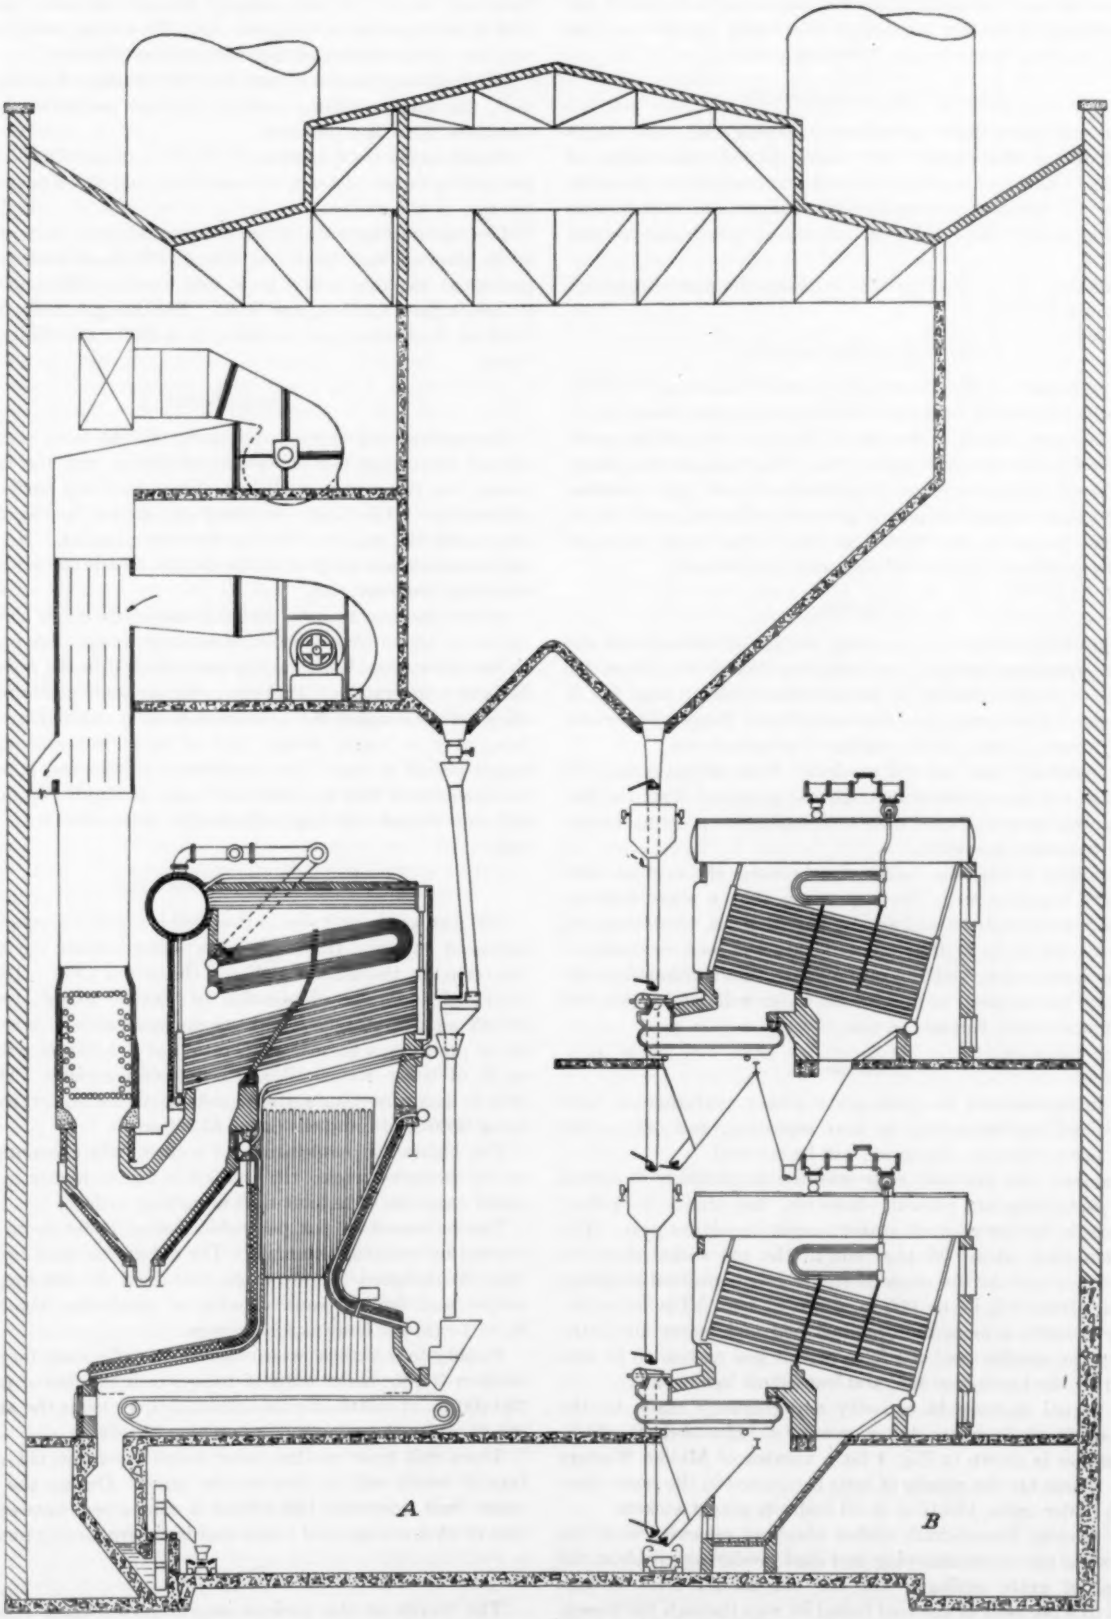

FIG. 6 EQUIPMENT OF 1930 (*A*) AND OF 1905 (*B*) IN SAME STATION
(Grand Avenue Station, Kansas City Power & Light Co.)

It has permitted increasing boiler capacities far in excess of the same amount of surface applied to the boiler proper and has aided in securing much longer operating periods.

RESULTS OF IMPROVEMENTS

Time and space have permitted covering only the major changes during this period. The more rugged construction of equipment, the many improvements in mechanical features, the value of soot-removal equipment, boiler-room instruments, etc., all of which have aided in improving conditions, remain untouched.

A summary of the results obtained from the more important changes will be made.

EVOLUTION OF BRIDGEWALL

The evolution of the rear wall or bridgewall is of interest. The gradual change in contour of this wall is evident from Fig. 2. During the past 25 years, the rear of the original wall has gradually described an arc, until today it has turned almost completely over. Each change was an improvement over the previous wall, and each change brought a gradual reduction, and finally an almost complete elimination of two of the most vexing of operating problems, bridgewall slag and maintenance.

FURNACES

The gradual tendency to prolong the life of refractories and increase operating periods by reducing the B.t.u. liberation previous to the installation of water walls is evident from Fig. 3, which shows the average and maximum B.t.u. liberated per cubic foot of furnace volume in the various furnaces shown.

As typical of most curves produced from actual data, the points are not as consistent as might be produced from the frequently used manufactured data or imaginative powers; nevertheless, the trend is evident.

The radical increase in boiler size between the unit of 1905 and 1926, together with the impression that a short increase in flame travel alone would permit higher B.t.u. liberation, accounts for the jump at that point. This was soon corrected in the next installation, and the rate of liberation continued downward until the modern unit, with its water walls and arches and longer flame travel, turned the tide.

STOKERS

The improvements in chain-grate stoker performance have been voiced too frequently to bear repeating, and only a few points, not commonly discussed, will be covered.

Of course, the greatest step was the application of forced draft, permitting air control; however, the ability to reduce air spaces in the forced-draft stoker was an important gain. The reduction from about 20 per cent in the old stoker down to about 9 per cent in the modern stoker has permitted reducing coal sizes from $1^1/_2$ in. or $1^3/_4$ in. down to 1 in. The latter obviously permits a more uniform fuel bed and better air distribution; the smaller coal particles permit less carbon to be embedded by the low-fusion ash, and less ashpit loss results.

The actual increase in capacity and economy made by the forced-draft chain-grate stoker over the induced-draft chain-grate stoker is shown in Fig. 4 for a number of Middle Western fuels. These are the results of tests conducted in the same plant on two boiler units, identical in all respects except stokers.

The modern forced-draft stoker also has removed from the boiler room one more annoying and dust-producing problem, the disposal of grate siftings. On the old natural-draft stokers from 6 to 8 per cent of the coal found its way through the loosely constructed grates in the form of fine dry siftings, the dust and disposal of which were usually a problem. Containing 90 to 95 per cent of the heat value of the coal, economy demanded that it be returned to the grate, and the mixing with fresh coal was not always accomplished with full satisfaction.

While siftings have not been entirely eliminated in the present unit, the small quantity and the modern methods of disposal eliminate them as a problem.

Stoker speeds have increased from 20 to 65 and 70 ft. per hour, permitting faster pick-up, thinner fires, and more protection to the rear of the stoker.

The fuel-burning rate of the old natural-draft unit was about 40 lb. average and 55 lb. maximum. Without forced draft or preheated air, this was a little high, and on the unit of 1916 it was dropped to 35 lb. and 50 lb. This has gradually increased until on the modern unit of today it is 48 lb. and 65 lb., respectively.

EFFICIENCIES

Throughout all these years many things have contributed toward increasing the boiler-unit efficiency, but the major increase has come from additional heat-absorbing surface. The efficiencies of the units discussed are shown in Fig. 5, which also shows the major causes for the various gains. No attempt will be made here to go into the details, which are evident from what has been covered.

It is of interest to note that the test efficiency of the modern unit is no higher than the unit of seven years ago, due principally to the commerical limit having been reached in the reduction of flue-gas temperature. However, the present unit obtains its efficiency at a higher B.t.u. liberation, at a much higher steam flow, over a longer range, and of most importance, over a longer period of time. In considering efficiencies, it must also be remembered that the inherent losses in Middle Western coals will not permit the high efficiencies obtainable with Eastern coal.

INCREASED CAPACITIES

The increase in unit size in this field is not as impressive as the increased capacity from the same water-heating surface, best illustrated by the units of 1923 and the unit of 1930. The former produced a normal evaporation of 100,000 lb. of steam with 20,843 sq. ft. of boiler and economizer surface, whereas the latter produces a normal evaporation of 175,000 lb. with 20,900 sq. ft. of boiler, waterwall, and economizer surface. The difference in heat-absorbing surface exists in the air heater, the former being 9600 sq. ft. and the latter 23,750 sq. ft.

The higher air temperature, of course, only accounts for part of the increased work; the balance is due to higher m.t.d. and larger amounts of radiant-heat absorbing surface.

The increased output per cubic feet of boiler room is made evident by an actual example. The old double-deck boiler room (Fig. 6) designed 28 years ago contained 40 500-hp., 185-lb. stoker-fired boilers, each capable of producing about 30,000 lb. of steam per hour as a maximum.

Twenty-four of these were removed to make room for six of the modern 700-lb. boiler units of today, each capable of producing 250,000 lb. of steam as a maximum, or over twice the amount of steam under the same roof as previously existed.

There still exist in this boiler room 16 of the old units the fate of which will in time be the same. During the last few years their operation has offered a comparison between operation of 25 years ago and today that is not frequently available.

SUMMARY

The merits of the various improvements have been shown throughout the paper. The increased capacities and efficiencies are of course quite evident; however, the most impressive comparison and perhaps the most logical proof of the vast improvements in operating conditions is the ability to keep the modern unit in continuous operation for long periods of time.

Operating periods of 20 to 25 days, considered good in the old units, have been lengthened to over 100 days.

Slag, clinkers, smoke, high maintenance, and low efficiencies, representing problems in the old boilers, have gradually been reduced, until today, while by no means eliminated, they are but a shadow of their former selves.

The greatest single stride in all of this progress has come with the modern unit of today, where flame travel was increased from 20 to 26 ft. at a single step and water-cooled front and rear arches were installed. This water-cooled rear arch has not only aided in reducing the ashpit loss, but also in protecting the rear of the stoker from the intense furnace heat.

Such protection, together with the rugged construction of this modern stoker with its heavy framework and drive and its water-cooled rear shaft, has brought the maintenance cost down and the reliability of the stoker up to a place previously unknown.

The handling of ash has been so simplified by the modern installation that only three men now are required to handle ash from the same coal tonnage that formerly required eighteen men. Ash can be removed at any time without admitting excess air. High maintenance, dirt, dust, and the hazards of handling hot ash are no longer problems.

It has not been intended for this paper to convey the idea that the improvements made have eliminated all of the operating problems and that the boiler room of today is a playhouse, for such is not the case.

Many of these improvements have brought with them new problems, but the prolonged periods of operation make evident that they also have reduced other more serious problems, and only those who have operated both extremes can fully appreciate the value of improvements in Missouri-Kansas coals and their burning equipment.

Discussion

J. G. Worker.[3] The author's experiences certainly should interest users of chain-grate stokers, particularly for Missouri and Kansas coals.

A recent survey of the coal consumed by public-utility plants during 1928 shows that out of a total consumption of 42,000,000 tons of coal, there was about 20,000,000 tons burned on underfeed stokers, 12,000,000 tons on chain-grate stokers, 7,000,000 tons as pulverized coal, and 2,000,000 tons on overfeed stokers and by hand firing. This report also showed that there was a little over 1,000,000 tons of Missouri and Kansas coal burned by public utilities during 1928; so that if the author has shown a way to save even 5 per cent of this by better application of stokers and boilers it seems that this work has been worth while.

As to the author's curve, shown in Fig. 3, indicating a gradual lowering of the heat-release rate in chain-grate furnaces, it is pleasing to see that the author in his 1930 installation has shown a higher heat-release rate than the 1923 installation. Would it not be possible in the next installation to even increase this heat-release rate up to 70,000 B.t.u. per hour? It seems that 25 ft. from the grate to the tubes is a somewhat expensive design. Have we not gone too far in the building of large combustion furnaces when we consider the effect that modern furnace elements such as water walls, slag drips, and preheated air have in overcoming the difficulties that directed us toward decreasing the heat-release rate and building these larger furnaces? Would it not be possible to use the 1923 application with all of the present modern furnace elements of construction and still obtain as good results as the 1930 installation?

A few years ago a prominent engineer in the Middle West declared that the limit of chain-grate development was 125,000 lb. of steam per hour in a boiler. It is noted that the author has shown that there will be chain-grate installations of 250,000 lb. of steam per hour. This surely shows a marked development in coal-burning capacity of chain-grate stokers. The writer would like to ask the author what is the possibility of developing chain-grate stokers for 500,000 lb. of steam per hour. This would probably mean a burning of 80 lb. of coal per square foot per hour.

The author did not bring out any of the developments in the design of the stoker structure itself. It would be interesting if the author would mention some of the major designs in modern forced-draft chain-grate stokers compared with the natural-draft chain-grate stokers of 20 years ago. There must have been many important improvements in chain-grate link design or air-control compartments and arch construction. Surely some of the stoker structure designs have helped to bring about the results that the author has so ably mentioned.

F. H. Rosencrants.[4] In view of Mr. Worker's remarks concerning the limitations in the size of traveling-grate stokers, it will perhaps be of interest to known that in England a traveling-grate stoker 32 ft. wide by 22 ft. long is now in successful operation at the Central Electric Station in Liverpool. It is believed that this is the largest traveling-grate stoker thus far built.

John Van Brunt.[5] The author has contributed a concise and valuable summary of the development of the chain-grate stoker and furnaces for Mid-Western fuels. This development has been paralleled in other plants, but this is the first attempt to knowledge to bring the data together and present them in such excellent form.

Mr. Worker referred to Fig. 3 and to the form of curve drawn through the maximum and normal points of the lines showing the relation between overall evaporation or B.t.u. released per cubic feet per hour. This curve shows very clearly the influence of the water-cooled furnaces on the possible maximum combustion rates, but it is not probable that the maximum combustion rates reached in 1930 will be materially increased. The limit is the rate at which the slag accumulation in the boiler tubes will prevent continuous operation of boilers at the designed ratings.

Mr. Worker's question as to why stokers of this type could not be built in larger size than those referred to in the paper can be easily answered. At the present time standard designs are available for widths up to 24 ft. to 25 ft. Wider furnaces can be equipped by installing two stokers in a furnace, and with other designs it would be possible to extend the widths to 28 ft. or 30 ft. The cost of designing special machines of this type is high, and it is largely a question of dollars and cents to the buyer. Manufacturers can design and build these extremely large stokers, but unless the purchaser is willing to pay for the cost of design, it is not likely that the manufacturers will urge larger sizes.

Author's Closure

Mr. Worker suggests the possibility of 70,000 B.t.u. heat release in future stoker furnaces and also suggests that 25 ft. from the grate to the lower row of tubes may be expensive furnace construction.

[3] General Sales Manager, American Engineering Company, Philadelphia, Pa. Mem. A.S.M.E.

[4] International Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

[5] Vice-President for Engineering, Combustion Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

The author believes that with some modification of the present furnace design, a figure of 70,000 B.t.u. could be reached as a peak. However, higher combustion rates and lower settings mean more maintenance and more slag problems, and it is simply a matter of what conditions one is content to operate under. Each succeeding step in longer flame travel has brought a reduction in slag problems, and the present length is not deemed excessive. Also, when it is considered that the 1930 unit in question occupies the same space formerly occupied by four smaller units and produces over twice the capacity, the higher setting will not appear so out of proportion.

Mr. Worker is quite correct in his statement that it would be of interest to know some of the detailed mechanical improvements in the design of the modern stoker, but this is a subject by itself, on which a lengthy paper could easily be written, and it was deemed best not to include it.

Mr. Van Brunt has covered the inquiry regarding the possibilities of a stoker for 500,000 lb. evaporation per hour.

FSP-54-11

Comparative Performance of a Large Boiler Using Oil and Natural-Gas Fuels

By F. G. PHILO,[1] LOS ANGELES, CALIF.

Tests were made with utmost care by well-trained and experienced observers, and the data presented are comparable in accuracy with carefully conducted tests burning coal. The boiler tested was a Babcock & Wilcox cross-drum, straight-tube type with interdeck superheater. The furnace was completely inclosed by Bailey-type water-cooled walls. The Babcock & Wilcox air heater was of tubular construction. Peabody combination oil and gas burners were used. The highest rate of output at which the boiler was tested was 450,751 lb. of steam per hour, which represented operation of the 3416-hp. boiler at 413.2 per cent of rating. Efficiency-capacity characteristics are straight lines between 100 per cent and 400 per cent rating. Efficiency with oil fuel is approximately 4 per cent higher than with gas due to higher "hydrogen losses" with gas fuel. Superheated-steam temperatures are considerably higher when burning gas than when burning oil fuel, due jointly to lower water-wall heat absorption and larger flue-gas volume while burning gas fuel. Maximum heat liberation was 27,300 B.t.u. per cu. ft. of furnace volume, although it is felt heat-liberation rates as high as 60,000 B.t.u. per cu. ft. might be satisfactorily maintained in this furnace.

PERFORMANCE data showing the operating characteristics of a large boiler burning oil and natural-gas fuels were obtained by a series of 14 tests made between June and November of 1929. Boiler 50 was tested. This is one of the three boilers serving unit 10 in the Long Beach Steam Station of the Southern California Edison Company, Ltd. These tests were made with utmost care by experienced men under the direction of the efficiency engineer of the Long Beach Steam Station. The A.S.M.E. Boiler Test Code was followed and results were computed in accordance with the code.

Because of widespread extension of natural-gas transmission pipe lines and increasing consumption of oil and natural gas for central-station and industrial power, it is felt that the data presented will be of value and timely interest. Considerable related data on forced- and induced-draft fan, water-wall, superheater, and air-heater performance were obtained, but are largely omitted as irrelevant to the purpose of this paper. For the sake of brevity actual test readings and calculations are omitted.

It is felt that, although a calibrated venturi meter was used for measuring the boiler feedwater in these tests, the data obtained are comparable in accuracy with carefully conducted tests burning coal. While using oil or gas fuel such difficulties as obtaining representative fuel samples, indeterminate quantities of unburned fuel in solids discharged from the stack, and unburned fuel in the ashpit refuse are not encountered. Once steady temperature conditions are obtained throughout the boiler and furnace, boiler tests, using liquid and gaseous fuels, can be obtained with a high degree of accuracy within periods of possibly not over two to three hours. In this series of tests trial runs were of four hours' duration at constant steam flow and excess air. Observations were taken every half hour during the test run. Approximately one hour before each test run, the boiler was

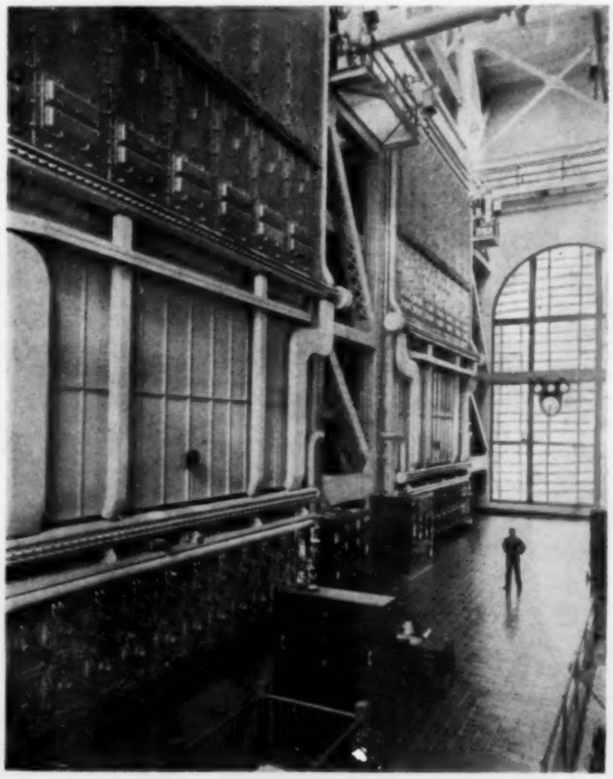

FIG. 1 BOILER-ROOM, UNIT 10 BOILERS, LONG BEACH STEAM STATION

---

[1] Superintendent of Steam Generation, Southern California Edison Company, Ltd. Mem. A.S.M.E. Mr. Philo was educated at Ohio State University and in 1911 participated in the Delray tests of large boilers of the Detroit Edison Co. From 1912 to 1914 he was boiler-room engineer for the Corn Products Refining Co., Edgewater, N. J., and later was efficiency engineer for the Harwood and Hauto power stations of the Lehigh Navigation Electric Co. During 1918–1919 he placed in operation the Burling Slip Station "A" of the New York Steam Corporation, and was appointed chief operating engineer of its downtown New York district. From 1919 to 1924, Mr. Philo was connected with Stone & Webster, Inc., as engineer in the power-station betterment division. Most of his time was spent in power-station betterment and initial operation of new power stations. In 1924, after placing the Long Beach steam plant of the Southern California Edison Co., Ltd., in operation for Stone & Webster, Inc., he was appointed to his present position.

Contributed by the Power Division and presented at the Semi-Annual Meeting, Detroit, Mich., June 9 to 12, 1930, of THE AMERICAN SOCIETY OF MECHANICAL ENGINEERS.

NOTE: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

brought to the desired steaming rate and steady operation ascertained before readings were taken.

The highest rate of output at which the boiler was tested was 450,751 lb. of steam per hour. This output represented operation of the boiler at 413.2 per cent of the boiler rating of 3416 boiler hp. The relations at various boiler ratings of the more important characteristics of the equipment under test are shown in Figs. 4 and 5. The efficiencies obtained with oil fuel parallel closely the efficiencies obtained with gas, but are about 4 per cent higher. The ratings given are the heat output of the boiler, superheater, and water walls expressed as percentages based on the 34,162 sq. ft. of heating surface in the boiler.

Comparative Efficiencies With Oil and Gas Fuels

Within close limits of accuracy the efficiency-capacity characteristics of the combination of furnace, boiler, superheater, and air heater burning both fuels may be assumed to be straight lines between 100 per cent and 400 per cent of rating. These are shown in Fig. 6. It is interesting to note that the unaccounted-for losses in both oil- and gas-fuel tests are approximately 1 per cent in each case. No surprise at this should be expected, however, as such indeterminate losses as carbon in stack gases and ash refuse are not a factor in the burning of liquid and gaseous fuels.

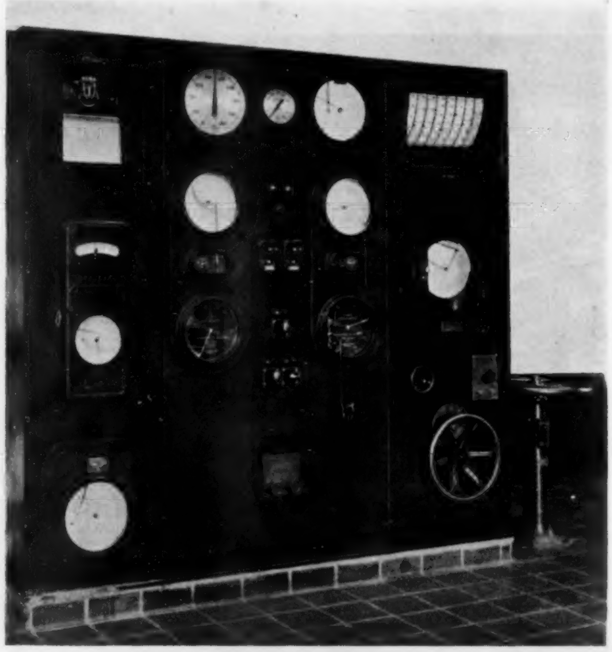

Fig. 2 Boiler Instrument and Combustion Control Board

In the series of tests using gas fuel the heat-balance calculations assisted very materially in establishing what is considered the correct shape and slope of the efficiency-capacity curve. For some undetermined reason the efficiency as shown in tests using gas fuel at the two lowest ratings did not fall in line with the efficiencies shown in the tests at higher capacities. This deviation, however, was only approximately 1 per cent, and was probably caused by the usual difficulties in gas measurement at the lower rates of gas flow. The corresponding heat-balance efficiencies indicate this error plainly.

The difference in heat loss due to the amounts of water formed by combustion of the hydrogen in the two fuels accounts for the difference in efficiencies obtained with oil and gas fuels. The "hydrogen losses" at 400 per cent boiler rating are theoretically 10.3 per cent for gas fuel and 6.1 per cent for oil fuel.

This theoretical difference, 4.2 per cent, checks closely with the difference of 4.15 per cent as shown in the tests. It is interesting to note that, for each pound of gas burned, approximately 2 lb. of water are formed in combustion, and for each pound of oil burned 1 lb. of water is formed. This water of combustion passes up the stack as superheated steam. On a cold, still day this steam is observed as a cloud of vapor above the stacks.

Combustion is normally controlled by complete Bailey automatic control, but during test periods control was by push button, with the fuel control set for constant flow and only such changes in fan speed as were necessary to maintain constant excess air. Peabody combination oil and gas burners were used. The oil burners are of the Peabody return type, but the return feature was not used during the tests.

All instruments were calibrated carefully before and after each series of tests. Water to the boiler was metered through a $3^1/_4$-in. by 8-in. Builders Iron Foundry venturi tube in the boiler-feed lines, the flow being recorded and integrated on a standard recorder which was calibrated by means of a water column against builders specifications for the tube. Previous checks on similar equipment against weighed quantities indicate an accuracy by this method within 0.3 of 1 per cent at ranges above 20 per cent of full-meter capacity.

Gas fuel was metered by a standard orifice in general use for this purpose, the orifice being located in a specially constructed 68-ft. straight section of 12-in. pipe. Pressure and differential connections were taken at four equally spaced points around the circumference of the pipe. The differential drop across the orifice was measured by a U-tube manometer at the higher rates of flow and with an Ellison inclined-tube manometer at the lower rates of gas flow. Orifice-meter calculations include determinations of the gravity, temperature, and absolute pressure of the gas taken with standard equipment, and the proper coefficients applied. With a given orifice the accuracy of this method of metering is greatest at the higher flow differentials, but the maximum error at all points taken should not exceed 0.5 of 1 per cent. The heating value of the gas was determined continuously by a Thomas recording gas calorimeter which was checked against hydrogen. This record was also checked by periodic determinations with a Junkers calorimeter. The specific gravity of the gas was determined with a standard Edwards density balance. The oil was weighed cold and fed to the boiler through heaters maintaining by thermostatic control approximately 250 deg. fahr. temperature at the oil-burner supply header. The heating value and specific gravity of the oil were determined independently by Smith-Emery Company of Los Angeles and in the station laboratory. Chemical analyses were made of a sample of oil taken from Oil Test No. 6 and a sample of gas taken from Gas Test No. 1. Since all oil used was from the same supply tank and all gas was received from the same sources, these were taken as representative for all tests.

The temperature of the superheated steam leaving the boiler, the feedwater entering the boiler, and flue gases leaving the induced-draft fan were taken with calibrated industrial glass thermometers. Other important measurements were made with a potentiometer-type Leeds and Northrup recorder. Flue-gas analyses were made with two sets of Orsat apparatus, and samples of gas were taken alternately from the east and west sides of the boiler. Pressures of the air and flue gases were measured with water in glass manometers.

The maximum overall pressure drop in the air and gas system was 16.2 in. water with oil fuel, and the boiler operating at 413.2 per cent of rating. The resistance of the oil-burner diffuser plates increases the pressure drop between the forced-draft fans and the furnace when burning oil. The greater volume of flue gases makes the drop from furnace to stack greatest when burning gas. The maximum heat liberation per cubic foot of furnace volume during these tests was approximately 27,300 B.t.u. per cu. ft. at 413.2 per cent rating. The relation of heat liberation to boiler rating is shown in Fig. 7. Based on observation of the combustion characteristics of the fuels used in these tests it is felt that heat-liberation rates of at least 60,000 B.t.u. per cu. ft. of furnace volume might be satisfactorily maintained with oil or gas fuel with this furnace and the combustion equipment used.

Hydrogen and Dry-Gas Losses Compared

It is interesting to note the relative magnitudes of the hydrogen and dry-gas losses. At 300 per cent rating, burning oil fuel, the hydrogen loss was 1.44 times the dry-gas loss. At the same rating, burning gas fuel, the hydrogen loss was 2.47 times that of the dry-gas loss. It is interesting also to note that the total boiler losses with gas fuel are 1.35 times those of oil fuel at 300 per cent boiler rating. The dry-gas losses of both fuels decrease uniformly with the rating, while the losses due to hydrogen are approximately uniform within the range of capacities shown. These relations are shown in Figs. 8 and 9.

Fig. 3 Cross-Section of Boiler 50 and Related Equipment, Long Beach Steam Station

Since the total volume of products of combustion with gas fuel is considerably greater than with oil fuel it might be expected that the total pressure drop in the air and flue-gas system with gas fuel would be greater than that with oil fuel. This is not the case on account of the additional restriction to air flow caused by introduction of the oil-burner diffuser plates which increase materially the resistance of the burners to air flow while burning oil fuel. The comparative total pressure drops in the air and gas system using both fuels and the effect of damper regulation are shown in Fig. 10.

When segregated, as shown in Fig. 11, it will be noticed that

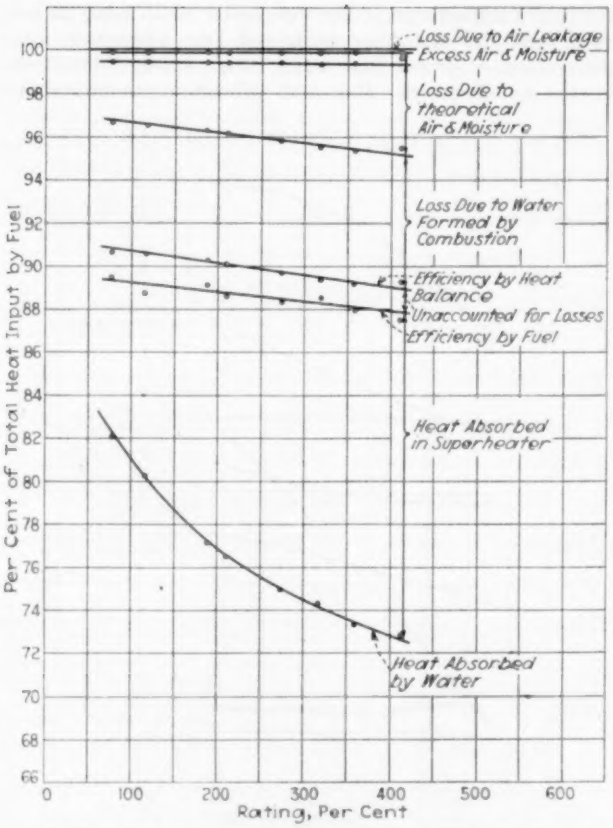

FIG. 8 HEAT BALANCE VS. BOILER RATING WITH OIL FUEL

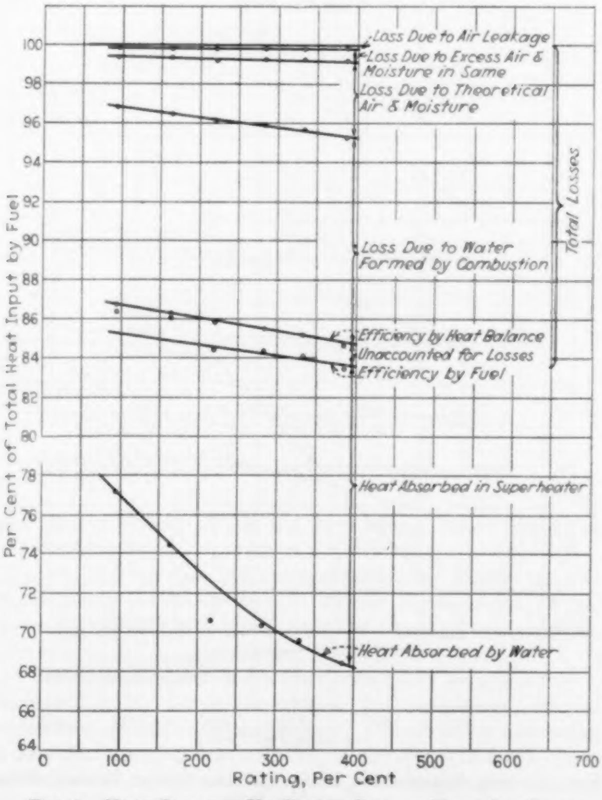

FIG. 9 HEAT BALANCE VS. BOILER RATING WITH GAS FUEL

the oil-fuel air pressures are considerably higher than those for gas, but the induced-draft requirements are greater for gas than those for oil fuel, due principally to the decreased boiler efficiency while using gas fuel and increased volume of combustion products per pound of gas fuel, caused mainly by the larger volume of water vapor formed in the combustion of the natural gas.

Curves of the more important temperatures observed are shown in Figs. 12 and 13. These curves agree very closely with the exception of the temperature of the superheated steam. Fig. 14 illustrates to a larger scale the superheater characteristics. As might be expected the superheated-steam temperatures are considerably higher when burning gas than when burning oil fuel due, jointly, to lower water-wall heat absorption with gas fuel and larger flue-gas volumes while burning gas fuel.

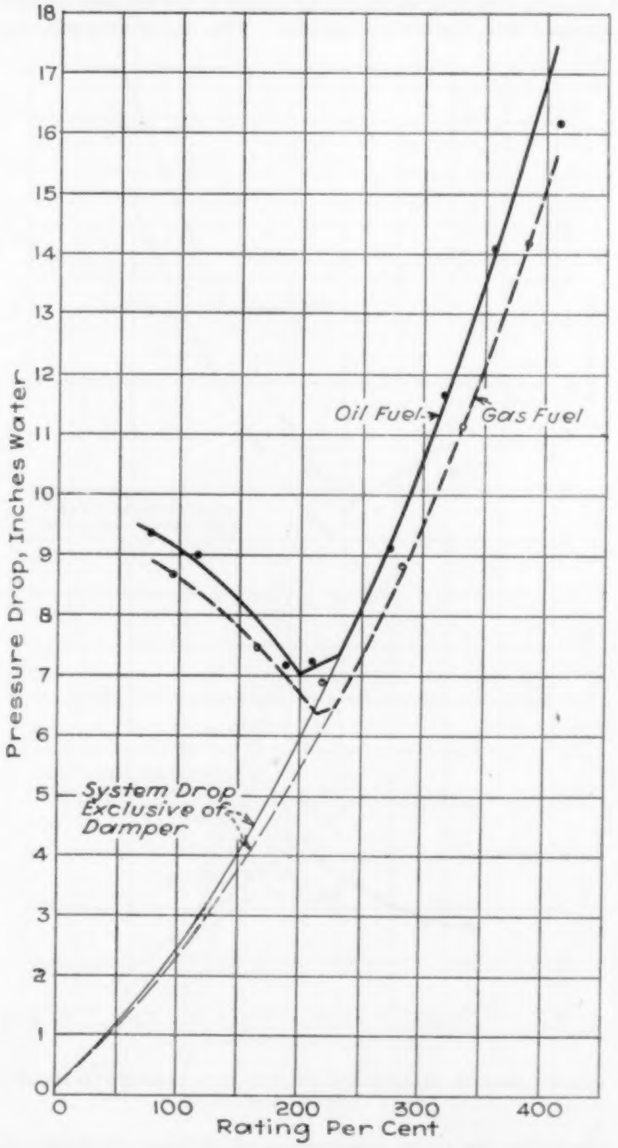

FIG. 10 TOTAL PRESSURE DROP IN FORCED AND INDUCED-DRAFT SYSTEMS

SUPERHEATED-STEAM TEMPERATURE HIGHER WITH GAS THAN WITH OIL

In the installation reported superheated-steam temperatures in all cases fell below the manufacturer's guarantee, especially at the lower capacities. It is felt that the reason for this is largely chargeable to abnormally high heat absorption by the water-cooled furnace walls, since no slag or other accumulations occur on these walls as is the case when burning coal. By burning oil and gas fuel with the equipment provided, it is possible to run with 15 per cent excess air within all ordinary limits of capacity. The characteristics of most coal-burning installations have been such that the excess air supply to the furnaces usually increased with the lower capacities. This had a compensating effect upon the steam temperatures which tended to flatten the steam-temperature curve. With low exit-gas temperatures and low values of excess air it has been found, by practice, that the overall plant efficiency might be raised in some instances by deliberately admitting increased amounts of air to the fires, especially at the lower capacities, which cause higher steam temperatures with a beneficial effect upon the turbine greater than that caused by the loss of the boiler efficiency.

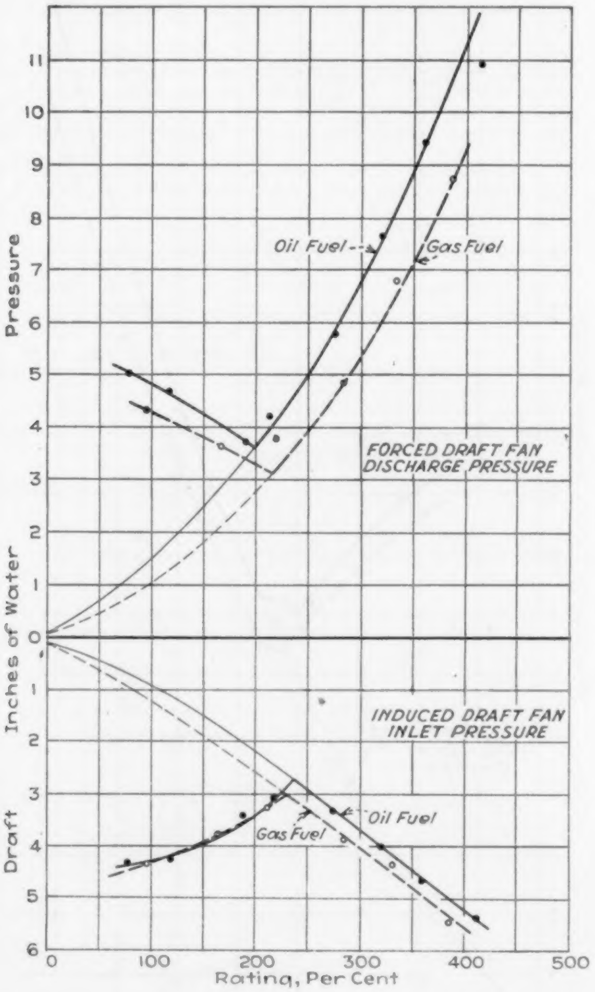

Fig. 11 Boiler Rating Vs. Forced and Induced-Draft Fan Pressures

From the observed performance of the water-cooled furnace walls with both fuels, shown in Figs. 19 and 20, it will be noted that the total heat absorption of the water-cooled furnace walls at 400 per cent rating is approximately 35 per cent greater with oil fuel than with gas fuel. This difference largely accounts for the poorer performance of the superheater while using oil fuel. Such variations in furnace water-wall heat adsorption make the problem of proper superheater design a very difficult one for the manufacturers. It is very difficult to obtain accurate

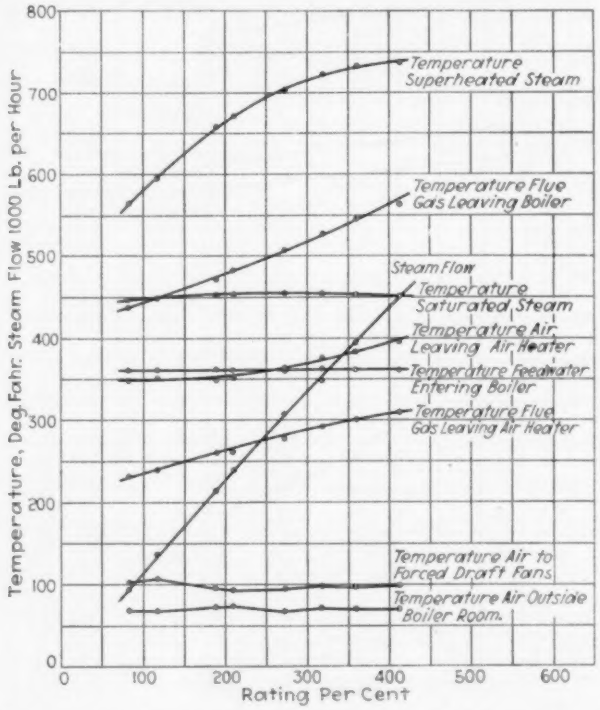

Fig. 12 Air, Feedwater, Flue Gas and Steam Temperatures With Oil Fuel

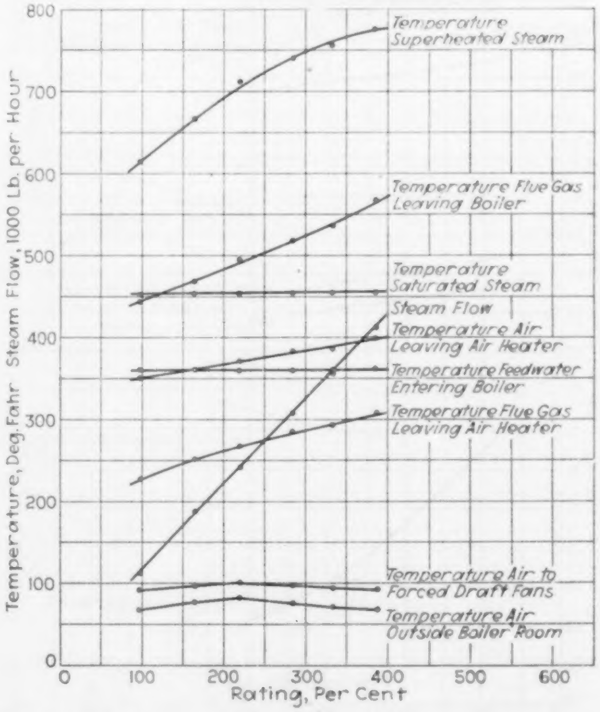

Fig. 13 Air, Feedwater, Flue Gas and Steam Temperatures With Gas Fuel

data on water-cooled furnace-wall absorption by using accepted methods; however, the data shown, it is felt, indicates fairly closely the heat absorption of the water-cooled furnace walls. It is interesting to note that in the case with oil fuel the water-cooled furnace walls with but 3.4 per cent of the total heating surface apparently absorbed approximately 50 per cent of the total heat absorbed at 250 per cent rating and 67 per cent of the total heat absorbed at 100 per cent rating. This relation is shown in Fig. 20.

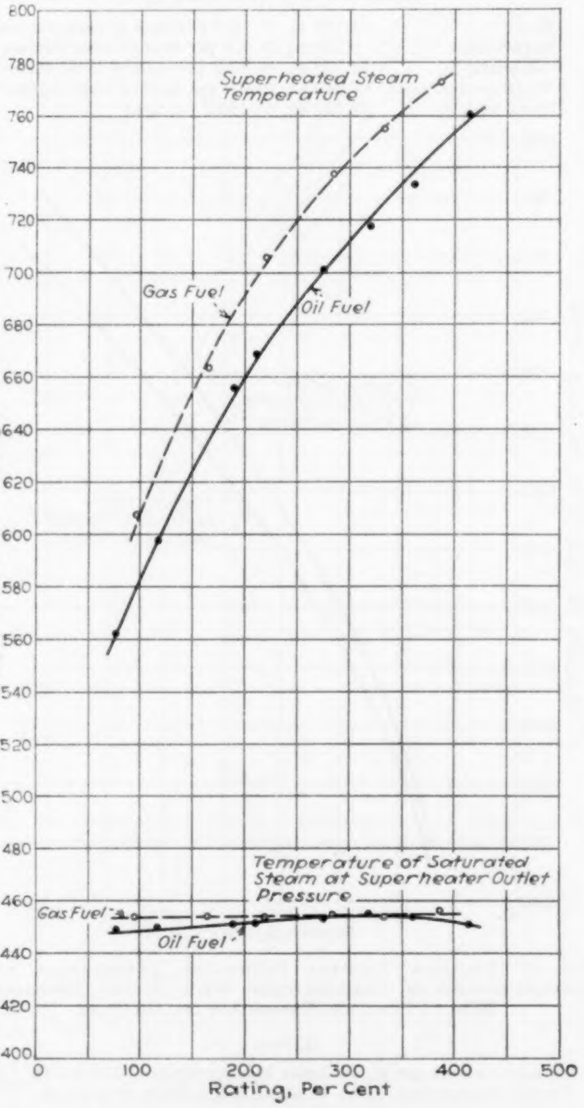

Fig. 14 Superheated-Steam Temperatures

Curves showing observed temperatures, heat absorption, and specific heats are shown in Figs. 22 and 31, inclusive. These curves are selected from the original test report as being of sufficient interest for inclusion in this paper.

A heat-balance diagram for this boiler while using gas fuel is shown in Fig. 21. Again the ratio of "hydrogen losses" to total stack losses appears quite prominently. Also it is very interesting to note that the total heat delivered in the steam from the boiler is 109.5 of the heat input of the fuel. This apparent enigma is due almost entirely to the amount of heat in the feedwater returned from extraction headers being greater than the total boiler losses.

Appendix 1

Boiler Data

Water tube, cross-drum type manufactured by Babcock & Wilcox Co. Heating surface 34,162 sq. ft. Drum 60 in. dia. Tubes 4 in. O.D. Length 24 ft. 0 in. No. 6 B.w.g. thickness. Number of tubes 1326, including three rows of circulating tubes. Arrangement: 51 tubes wide, 23 tubes high in three decks. Lower deck 5 tubes high. Two upper decks are 9 tubes high each.

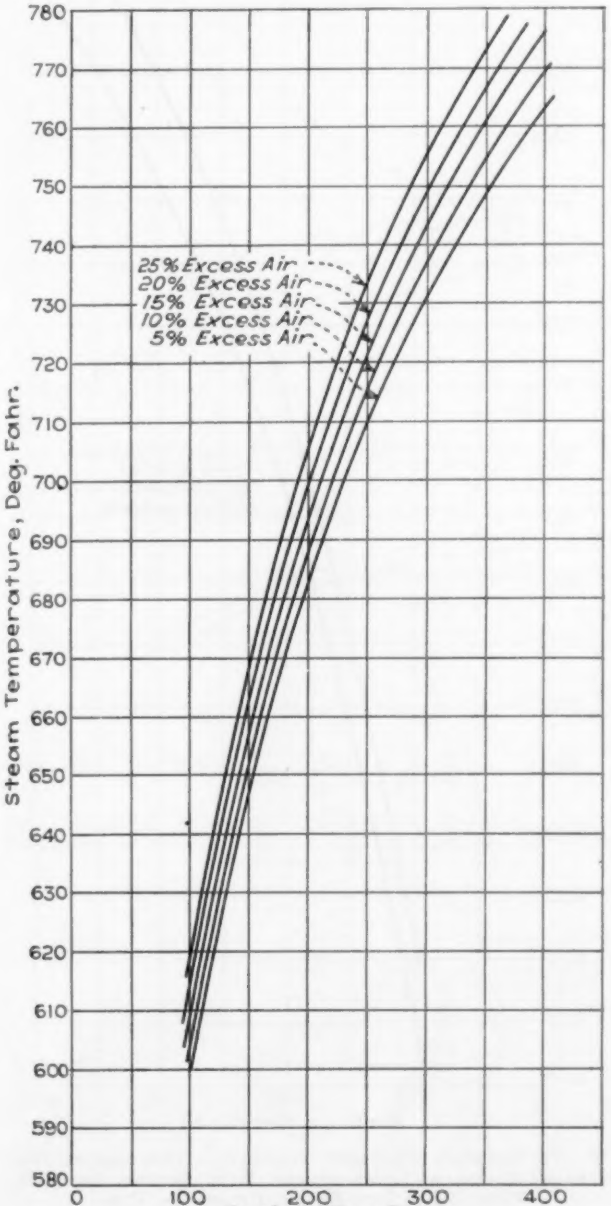

Fig. 15 Superheated-Steam Temperatures as Affected by Variations in Amount of Excess Air With Gas Fuel

Superheater Data

Convection type, quadruple deck, three pass, manufactured by Babcock & Wilcox Co. Superheater located interdeck, immediately above lower deck of boiler tubes. Heating surface 6553 sq. ft. Total number of tubes 462. Passes have equal number of tubes and equal surface. Tubes 2 in. O.D., No. 10 B.w.g. thickness.

AIR-HEATER DATA

Tubular type manufactured by Babcock & Wilcox Co. Heating surface air-touched 51,232 sq. ft. Internal gas-touched surface 46,350 sq. ft. Air-passage area 54.5 sq. ft. Gas-passage area 60.6 sq. ft. Number of tubes 2176. Tubes $2^1/_2$ in O.D., No. 11 B.w.g. thickness. Length 36 ft.

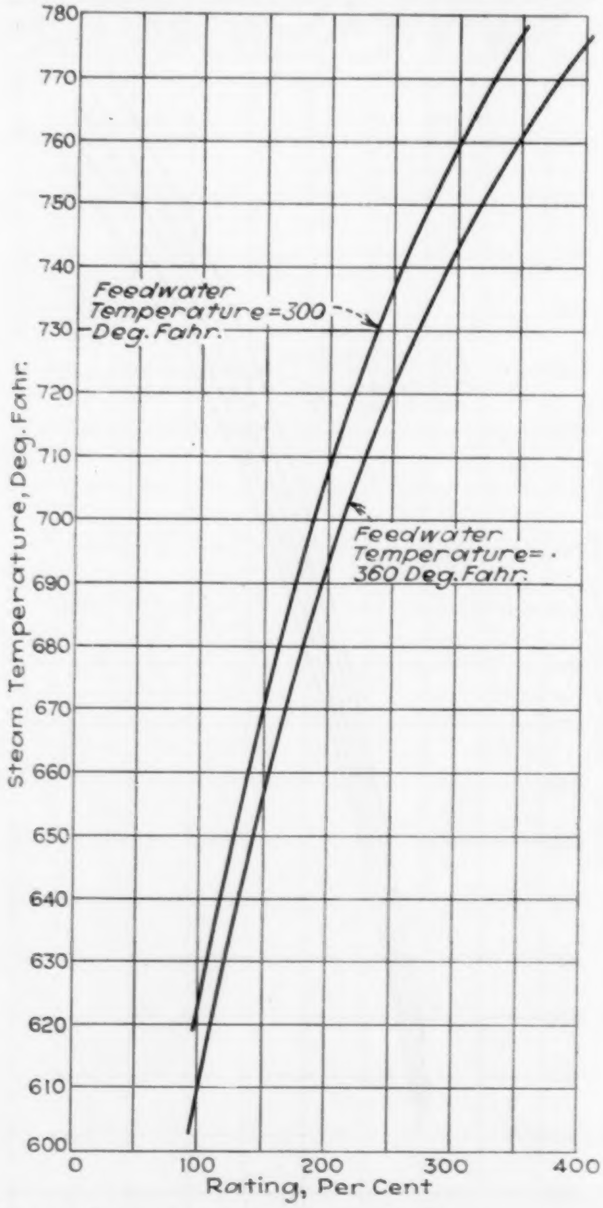

FIG. 16 RELATION BETWEEN FEEDWATER TEMPERATURE AND SUPERHEATED-STEAM TEMPERATURES WITH BOILER OPERATING WITH 15 PER CENT EXCESS AIR AND GAS FUEL

WATER-COOLED FURNACE WALLS

Bailey, refractory-faced iron-block type. Manufactured by Fuller-Lehigh Co. Heating surface 3240 sq. ft. The side walls have 42 water-cooling tubes each. The front wall, front-ashpit wall and rear wall have 60 cooling tubes each. Tubes $3^1/_4$ in. O.D. No. 6 B.w.g. thickness. Wall blocks type BAG with $^3/_4$-in. thick "carbosite" refractory face. Block is cast around molded refractory material. Corners are made with type WAC and WAJ blocks with $1^1/_4$-in. and $2^1/_2$-in. thick No. 80 B. & W. fire-brick refractory cemented in.

Furnace width 30 ft. $2^1/_2$ in. Depth 20 ft. $10^3/_4$ in.

Furnace Volume:

Above firing aisle floor	15,920 cu. ft.

[a] Fuel analysis from one representative sample, applied to all tests.

[b] The heat value of fuel gas was determined for each test with a Thomas calorimeter. The heat value of fuel oil was determined once, from the supply that was used on all tests.

Discussion

D. S. Jacobus.[2] This is a most valuable paper. The accuracy of the results is shown by cross-checking and is also evidenced through the pains employed in securing exact experimental data. The paper should serve as a model for the making of tests of the sort.

The comparative results for the oil and gas fuel are of great interest, as well as those showing the amounts of heat absorbed by the boiler and furnace wall cooling tubes.

Fig. 7 shows the relation between heat liberated in the furnace and the boiler rating, and if drawn to different scales would also show the relation between the heat absorbed and the heat available for absorption. This relationship is shown to be a straight line passing through the origin for both oil and gas fuel, the only difference being in the slope of the lines, that for the gas being a little steeper than the other. This is a fundamental relationship and one not always reported. In the present case it is especially interesting to find that the lines pass through zero.

In view of the fact that tests of such accuracy on equipment of such a large size are very costly, the results which are herein given to the public are rare and should be appreciated in proportion thereto.

It was the writer's privilege to work with Mr. Philo in the Delray tests. It is indeed gratifying to note the success of those with whom one has striven in the past, and the writer wishes to extend his congratulations for the masterly way in which the author has conducted the tests and in which he has presented the results.

It would be well to add the data, which are referred to in the paper as being largely omitted, on forced- and induced-draft fans, water walls, etc. It is seldom that one finds as accurate test results as those given in the paper, and any supplementary matter of the sort would still further increase its value.

E. B. Powell.[3] The author presents much valuable data, which have been greatly needed, on the comparative characteristics of oil and gas as steam-boiler fuels. We have had impressions of performance and theoretical deductions upon which we have based expectations, but the author, by eliminating all elements of difference except those of the fuel consumed and by securing complete and equally efficient combustion of each, definitely measures the differences inherent in the two fuels. The care and thoroughness with which the observations have been taken are clearly evidenced by the exceptionally high degree of consistency shown by his results.

The data of the paper are, however, of even greater value in their contribution to the analysis of heat transfer in the steam-generating unit, particularly in the comparison which they afford of radiation from luminous and from non-luminous flame. These latter data will be of material assistance in furthering steam-boiler and furnace design. It will be noted that, for the same net heat liberation, for the arrangement and proportions of heat-absorbing surface of the steam-generating unit here represented, the two fuels show practically identical efficiencies. Data for the boiler and superheater, considered independently from the air heater, suggest very slightly higher efficiency for the oil-fuel condition. Doubtless a unit having a considerably smaller proportion of convection surface would show an appreciable loss in absorptive efficiency when burning gas fuel as compared with that obtainable with oil, but it is most interesting to note that, in this instance, the absorptive capacity of the convection surface handling the somewhat greater mass of combustion products was sufficient to compensate for a very marked deficiency in absorption on the part of the radiant surface.

[3] Consulting Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Mem. A.S.M.E.

E. H. Peabody.[4] This paper does not at first sight give an intimation of its really stupendous importance in the field of modern steam-engineering practice. Of its dozen pages (half of which constitute the appendix), scarcely more than two are devoted to written statements. These few pages describe in simple language the basic facts concerning the charts and tables which record the results of weeks and months of careful and laborious observation, but which form a veritable treasure box of up-to-the-minute fact and information.

It is a commentary on the spirit of service which permeates our great public-utility companies and leading engineering organizations that such tests as these reported by the author can be carried out with such accuracy and the results published to the world. Information of this kind can be obtained only under exceptionable conditions; it is accessible to few, and its compilation requires a lavish expenditure of time, enthusiasm, and money. The writer welcomes the opportunity to express his feeling of indebtedness for the gift of actual operating data of such great helpfulness. It must be a satisfaction also, to every one concerned with the design, to find in this report confirmation of expectations entertained before the plant was built.

The comparative performances of the various elements making up the steam-generating unit when burning oil and natural gas are of particular interest to operating engineers and equipment designers, because of the increasing availability of natural gas in new territories throughout the country, and because of its use under highly forced conditions. By segregating the component parts of the unit and thoroughly analyzing the data applying to each part, the author has presented a clear picture of the function of each piece of equipment and its operating characteristics under varied conditions of fuel and load. He also has demonstrated that natural gas, a comparatively new fuel to many engineers, can be successfully applied to steam generation under most exacting conditions. It should be remembered that but a year or two has elapsed since it was generally considered the height of folly to burn gas other than by means of natural draft. This fact alone demonstrates how rapid has been the progress.

The writer's attention has been particularly attracted to one point in the paper. In Fig. 19 the curves on heat absorbed per square foot of heating surface indicate that there is apparently a limit to the absorption rate in the furnace walls when burning gas, while with oil the rate continues to increase. This is also shown in Fig. 20, in which the percentage of total heat absorbed in the furnace walls and boiler section closely approach each other when burning oil and tend to maintain equality, while corresponding curves on gas attain equality at approximately 230 per cent of rating and become widely separated at higher capacities. Combustion gas temperatures and furnace temperatures do not indicate the reason for this apparent limit to the heat-absorption rate in the radiant section when burning gas. It is possible that the rate of combustion per unit of furnace volume determines the point at which "saturation" of the radiant heating surface occurs. This brings up the question of proper furnace shape and proportioning of radiant surface to convection surface in connection with gas-fired furnaces, and it is hoped that the author will find time to further discuss this point.

It is interesting to note that the water-cooled furnace walls absorbed approximately 35 per cent more heat with oil fuel than with gas fuel at 400 per cent of boiler rating. This has of late been a somewhat controversial matter. It will be very helpful if similar data are obtained on other types of furnaces, such as bare tubes and tubes covered with bare cast-iron blocks.

In spite of the radically different distribution of absorbed heat by boiler and furnace as shown by Fig. 20, the temperatures of the gases leaving the boiler are practically the same as indicated by Figs. 4 and 5.

One assumption made by the author—namely, that the capacity-efficiency characteristics fall on a straight line between 100 and 400 per cent of rating—jars a bit on the sensibilities of the writer. We know that it must be a curve even if a very slight one within these limits, and so why not favor the appearance of the true conditions rather than use the "simplified spelling" of a straight edge. Anyhow, the latest trend of theory is that there are no such things as straight lines.

The writer must take exception also to the author's use of the word "rating" in the sense of "capacity." It is a somewhat lamentable thought that the usage he is adopting is a very common one with the younger generation, but why should a perfectly good word like "capacity" be thrown into the discard and a word substituted which already has a very definite and a very different meaning. In doing this we are weakening the language. It is perhaps a small point to bring up in connection with a paper of such outstanding importance, and the writer does so only by way of emphasizing the fact that a bad practice is rapidly springing up among us.

It is the writer's impression that the Society has looked askance on tests of only four hours' duration. This is an academic attitude which this paper should go far to prove to be antiquated and ridiculous. A continuation of any of these tests longer than four hours would have served no useful purpose whatever and resulted only in the necessity of increased vigilance to prevent observational errors.

E. G. Bailey.[5] The paper is of very timely interest to many engineers, even though today they are burning neither oil nor gas. The furnaces used in conducting the tests by Mr. Philo were designed for the use of pulverized coal should that later be found desirable.

With the extension of high-pressure gas lines to the North and East from the Texas and Louisiana gas fields, it seems likely that more power stations now burning pulverized coal may be interested in burning a certain amount of gas as a surplus fuel. It is believed that when the time comes to do this it can be quite readily applied to existing pulverized-coal-fired furnaces, at which time the very valuable data collected by Mr. Philo will be of much benefit.

It is interesting to note that this type of furnace-wall construction gave an average absorption rate in excess of 60,000 B.t.u. per sq. ft. per hour through furnace walls using a refractory-faced cast-iron block lining, even at the relatively low heat liberation in the furnace of approximately 27,000 B.t.u. per cu. ft. per hour. This high rate of absorption may be accounted for by several factors, among which are extremely high furnace temperatures with low excess air used in burning oil and gas and the relatively clean condition of the heat-absorbing surface.

---

[4] President, Peabody Engineering Corporation, New York, N. Y. Mem. A.S.M.E.

[5] President, Fuller Lehigh Co., New York, N. Y. Mem. A.S.M.E.

The radiant-heat-absorbing surfaces in the boiler and furnace walls are not subject to accumulations of ash and slag on the surface and are therefore in a much better position to absorb radiant heat than they would be in a coal-fired furnace.

In Fig. 24 the author shows the difference between calculated and observed temperatures taken under the first tube bank. This differential is apparently due to the radiation absorption to the boiler tubes, which evidently has not been included in the author's calculations.

Considering the difference in temperature between the calculated and observed results for gas firing, and assuming that the total effective boiler-tube surface exposed to radiant heat is 140 per cent of the total area of the first row of boiler tubes, the rate of heat absorption to these tubes would be 60,000 B.t.u. per sq. ft. per hour. Using the same absorption rate per square foot of boiler-tube surface with oil firing, a gas temperature entering the front bank of boiler tubes of 1900 deg. fahr. is obtained. The difference between this temperature and the actual observed temperature may perhaps be accounted for by the effect of direct radiation to the thermocouple with oil firing.

The type of construction installed on these furnaces lends itself to determining rates of heat absorption to furnace walls very readily. In order to make such determinations, certain of the refractory-faced cast-iron blocks are provided with thermocouples at definite points in the cast-iron backing of the block so that the temperature gradient across this iron can be measured, from which the corresponding rate of heat transfer may be calculated. These blocks are made up very accurately with welded junction chromel-alumel thermocouples staked into the cast iron of the block at locations which are very accurately maintained. The calibration constants for determining the rate of heat transfer from any given temperature gradient were accurately determined from a laboratory furnace set up using full-size blocks and tubes and a furnace of sufficient size to give results comparable to those obtained in actual practice.

In making these calibration tests a large number of readings were taken determining the gradient curves corresponding to certain conditions, and the rate of heat transfer was determined through individual blocks by accurately weighing the water evaporated. With the precautions taken to insure accurate results it is felt that the calibration constants used are of a high degree of accuracy and that the rates of heat absorption obtained from the thermocouple blocks in actual practice are accurate within the limits of practical test work.

The accuracy of this method is even greater in connection with oil and gas firing than with coal firing, since there are no ash and slag deposits on certain portions of the walls which might give unequal rates of transfer on adjacent portions of the wall surface.

It is very interesting to note that the radiation and unaccounted-for losses for this series of tests are less than 2 per cent for all tests and are in the neighborhood of 1 per cent for quite a few of the tests. This would indicate very low loss of unburned gaseous fuel. By calculations from the gradient curves used for calculating the absorptions to the furnace walls it appears that the surface temperature of the blocks will range from 1800 to 2500 deg. fahr. This is borne out by wall temperatures of 2000 to 2300 deg. fahr. given in Fig. 27. It is evident that under such conditions there is much less chance of unburned fuel escaping from the furnace than in the case of water-cooled walls having a surface temperature of the order of 500 deg. fahr. This is an important consideration as the usual control of furnace operation does not give an indication of the possible losses due to unburned fuel, so that unless complete tests such as those reported by the author are made such a loss may exist without being suspected.

The author points out that while these furnaces are operated at a maximum rate of heat liberation of only 27,000 B.t.u. per cu. ft. per hour, rates as high as 60,000 B.t.u per cu. ft. per hour could probably be maintained satisfactorily. Other installations with similar furnace and wall construction have exceeded 50,000 B.t.u. per cu. ft. The relatively low heat release of the present furnaces is in line with current practice when these furnaces were designed for possible conversion to burn pulverized coal.

Ralph A. Sherman.[6] The paper will be used often and long as a source of experimental data by designing engineers. Because of this, it is felt that certain of the data given in the curves should have more explanation than is given in the test. The authority for the specific heats of the gases as given in Fig. 22 and of the oil as given in Fig. 23 should be quoted.

It would also be of interest and value to know how the gas temperatures were measured. The writer has been personally guilty of making many measurements of temperatures of furnace gases with an exposed thermocouple. Most of these were made in coal-fired furnaces where the presence of suspended ash made the use of any other type impractical. However, the author had an excellent opportunity to use the shielded velocity type of thermocouple with his ashless fuels, and if this type was used his data are of much greater value than otherwise. It is doubtful that this type was used, however, from the discrepancy shown in Fig. 24 between the calculated and observed temperatures below the first tube bank. The observed temperatures were lower than the calculated temperatures and the observed temperatures when burning gas were lower than those when burning oil, which is not as it should be because of the demonstrated greater rate of transfer of heat from the oil flame in the furnace.

Author's Closure

The author is grateful to those who prepared written discussions of this paper and is pleased by the remarks, which are interpreted as indicating the rapidly spreading interest in liquid and gaseous fuels, particularly for central-station use.

Dr. Jacobus suggests that data on related equipment referred to as being omitted from the paper be included. It was felt that the inclusion of too much of the data accumulated in the tests would make the paper unnecessarily bulky. As an appendix, data obtained in four of the eight oil-fuel tests and three of the six gas-fuel tests are included. The tests selected to report are at low, intermediate, and high ratings, thereby covering the full range investigated, without making the appendix burdensome.

The primary purpose in presenting this paper, as defined by the Power Committee, was a comparison of the characteristics of the two fuels as burned in one boiler. It is felt that inclusion of data on fans and other auxiliary boiler equipment is irrelevant to this purpose.

As Mr. Peabody states, natural gas is now easily burned under modern steam-generating units with standard equipment. The use of forced and induced draft causes no difficulty in the use of gas as fuel, and the ease with which it can be handled and its cleanliness make gas a highly desirable fuel.

The variations in heat absorption for the two fuels, as noted by Mr. Peabody, and shown in Fig. 19 and Fig. 20, have been a source of considerable discussion. Perhaps the result of this variation is most noticeable in the curves showing superheated-steam temperatures, Fig. 14. The author's experience has shown that superheated steam temperatures are usually higher with gas fuel than when oil fuel is used. The variations encountered depend largely on the type of furnace, refractory settings giving smaller variations than water walls, the variation increasing as the water-wall surface and water-wall absorption rate is increased.

Oil fires have higher temperatures than gas fires and are highly luminous. Combustion with oil fuel is delayed to a certain extent, so that a considerable proportion of the furnace is filled with luminous flame, varying of course with the rating, amount of excess air, temperature of the air and oil temperature, and pressure. These conditions tend to increase the heat absorption of the furnace walls and tubes facing the furnace, when oil fuel is used, but the resultant furnace temperature is still higher than it is with gas. With oil fuel and at a given rate of steam flow, the temperature, volume, and specific heat of flue gases entering the superheater are less than with gas fuel. These factors predominantly influence the final steam temperature. With gas fuel, combustion is extremely rapid. There is no visual evidence of luminous flame, and in all probability the combustion "area" is much reduced.

---

[6] Fuel Engineer, Battelle Memorial Institute, Columbus, Ohio. Mem. A.S.M.E.

With the special test blocks installed in the water-cooled walls, reliable comparative measurements of heat transfer are secured, and these results were used as the basis for the water-wall data given in Figs. 19 and 20.

Perhaps Mr. Peabody is correct in his statement that the efficiency graphs should, theoretically, be curved lines. At extremely low ratings there would undoubtedly be a break in the curve, since increased efficiency, with decreased rating, will only hold to a point where combustion efficiency falls off and heat losses from the boiler become proportionally large enough to be a governing factor. In the case of the tests reported, it was thought that the straight lines shown more nearly indicated the trend of results of the tests than any curve which could have been drawn through the test points.

Mr. Bailey has pointed out the discrepancy between the temperatures observed under the first tube bank shown in Fig. 24 and the curve of calculated temperatures at this point. The designation of the curves for "calculated" temperature is unfortunate, since no deduction was made for radiant heat absorbed by the lower rows of boiler tubes. Notation of this is made in Fig. 24 for final printing. The difficulty of correctly measuring flue-gas temperatures in this location, which has been quite thoroughly discussed by Kreisinger, Barkley, and others, is well recognized. In the tests presented, it was found that these temperatures were by no means uniform, and after some rather unsuccessful attempts to secure more uniform results with shielded couples, the tests were run with exposed couples. Some couples used were made of No. 22 chromel-alumel wire and others of No. 16 iron-constantan wire, the results being reported as showing "approximate" rather than true temperatures. If it were possible to calculate accurately the average gas temperature at this point, it would undoubtedly be more nearly in agreement with the observed values, which, admittedly, are probably too low.

The comments on measurement of temperatures below the first tube bank given in reply to Mr. Bailey's discussion will be of interest to Mr. Sherman.

The data for the mean specific heats of the flue gases given in Fig. 22 of the paper were taken from "Principles of Combustion in the Steam Boiler Furnace," by Arthur D. Pratt, published in 1920 by the Babcock & Wilcox Co. Values for each constituent of the flue gases were taken from Fig. 1, page 32, of this text and combined in the proportions indicated by the average flue-gas analysis as given, to secure the composite curve presented. The curve of specific heat of fuel oil was derived from experimental data obtained from the Union Oil Company of California.

Load-Deflection Relations for Large Plain, Corrugated, and Creased Pipe Bends

By E. T. COPE[1] and E. A. WERT,[2] DETROIT, MICH.

E. T. Cope

This paper presents the results of tests made on 10-in. and 14-in. seamless steel pipe loaded in the same manner as the simple cases shown on pages 526 to 529, "Piping Handbook,"[3] by Walker and Crocker. Comparison has been made between calculated deflections and the results of tests in the six cases for a plain pipe bend. The relation between the results of tests on corrugated and creased pipe bends and the calculated results for plain pipe bends of the same dimensions are shown. Such calculations are included as are necessary to show the method of analysis by which the load-deflection relations of a plain quarter-bend and its tangents are determined.

E. A. Wert

INTRODUCTION

THE limitations placed on the design of main steam piping for unit No. 6, Marysville Power Plant, made desirable the use of piping made up of elements having much more than customary flexibility. The installation of a 50,000-kw. turbo-generator in the space originally provided for a 30,000-kw. unit called for main steam piping of greater diameter. Large pipe in close quarters required unusual means to obtain sufficient flexibility and it was decided to resort to corrugated[4] pipe. Accordingly nine pieces in all corrugated quarter-bends and tangents were secured.

There did not appear to be available test data on the relative flexibility of corrugated bends and plain bends of the same dimensions. The desirability of accurate test data showing load-deflection relations for these bends was most evident. These data and the conclusions drawn from them should be especially valuable for future design. At the same time it was thought worth while to compare the load-deflection relations of a large plain pipe bend, as secured by actual test and as calculated. The investigation was further extended to include the creased[5] pipe bend and a bend made up of a short-radius forged elbow having a tangent welded to each end.

This paper presents the results of the tests made in checking the flexibility formulas for loadings of a 10-in. quarter-bend made of 400-lb. A.S.A. seamless steel pipe having a ratio of bend radius to pipe diameter of 6 to 1. The loadings were similar to those illustrated in Cases V to X, inclusive, of "Piping Handbook."[3] The results are shown for similar loadings on each of two 14-in. corrugated bends made of 400-lb. A.S.A. seamless steel pipe, two 14-in. creased bends made of 400-lb. A.S.A. seamless steel pipe, and one 10-in. bend made up of a forged seamless steel elbow having a tangent corresponding to dimensions of 250-lb. A.S.A. pipe welded to each end. The results of tests on a 14-in. corrugated expansion U-bend and on a 10-in. corrugated U-bend borrowed from the 10,000-kw. British Thomson-Houston Company high-temperature turbine installed in Delray P. H. 3 are also included. Load-deflection relations for pipe bends made of plain pipe having the same dimensions as the corrugated and creased bend tested have been calculated and are compared with the results of the tests.

A 14-in. corrugated tangent made of 400-lb. A.S.A. seamless steel pipe was also loaded as in Cases II, III, and IV. The flexibility of this tangent is compared with that of a plain tangent of the same dimensions. Fig. 1 shows the schemes of loading. The drawings of the pipe bends and the tangent tested are shown in Figs. 2 to 8, inclusive.

I—TEST PROCEDURE APPLIED TO 90-DEG. PIPE BENDS

Loadings of each 90-deg. bend according to the schedule shown in Fig. 1 were carried out by bolting one flange of the bend to the top of the turbine casing of a partly dismantled vertical shaft turbo-generator. The generator had been removed. This heavy casting proved to be a satisfactory bending table. The turbine top, the framework of the building, adjacent abandoned

FIG. 1 SCHEDULE OF TESTS MADE ON THE VARIOUS SPECIMENS OF PIPE

steam turbines, and the traveling crane hoist were used as points of attachment for chains or cables used in applying load. Load was applied by the use of chain falls or turnbuckles or both. In the cases where a single pull was applied to the end of the pipe, the chain fall was satisfactory. In the cases where a moment was applied to the end of the pipe, a chain fall and a turnbuckle were used in series. Load was measured by Chatillon traction dynamometers which were calibrated in the Universal testing machine before and at intervals during the tests. When a moment was applied, the two dynamometers were calibrated, one against the other. This proved to be a worth-while added precaution.

Measurements of deformation were made between fixed points on the pipe and fixed points attached either to the bending table or the building. A micrometer having, when necessary, a filler piece of fixed but unknown length was used in making the readings.

Contact points for the micrometer, on the pipe and on the fixed points, consisted of short brass pins driven tightly into small drill holes in the pipe and the fixed points. The outer ends of the brass pins were filed round.

The movement of the free end of the bend was measured in three directions at each load. Measurement of movement of the pipe a few inches above the fixed end was also made. This measurement had no direct bearing on the problem, but immediately revealed unexpected displacement of the fixed end during the progress of the test.

Experience in calibrating helical springs has shown that the spring must be loaded heavily two or three times before consistent load-deflection readings can be secured. This same treatment was found to be necessary with new pipe bends. The load on the pipe was rapidly increased. At each step in the loading, readings of the major deflection were obtained and a load-deflection curve plotted. When the proportional limit was slightly exceeded, the load was removed and the no-load readings were repeated. The load necessary to stress the pipe to the proportional limit was reapplied and released two or three times until the no-load readings before and after successive loadings became consistent. Then the formal loading of the pipe was carried out. In most instances this procedure made possible the securing of successive deformation readings that agreed within a few thousandths of an inch. The test assemblies of the various kinds of 90-deg. bends are shown in Figs. 9 to 15, inclusive.

II—MATHEMATICAL ANALYSIS OF A 10-IN. PLAIN PIPE BEND

The mathematical determination of deflections of pipe bends lying in one plane is based on the grapho-analytical method, using area-moment diagrams and the principles of superposition.

The condition in which only a single force or moment acts at the free end is assumed. These solutions are not of direct application to the problem of determining flexibility of piping subjected to thermal expansion. When piping is subjected to thermal expansion, both ends are considered as anchored and the remaining forces and restraining moments are considered as acting at hypothetical "free" ends. The principles of superposition are used, whereby the load-deflection characteristics

of the pipe bend are solved by first transposing the thrusts and bending moments which exist at the anchor points, applying them to each component part of the pipe bend, and then making an algebraic summation of, first, the deflections of the parts due to such transposed forces and moments and, second, the deflection of the parts due to the cumulative rotations of the parts between each component part and the anchored end of the bend.

Ten elementary cases are required to determine completely the relations between the possible forces and moments which may act on these elements and the resulting rotations and deflections.

These ten cases are treated in "Piping Handbook," pages 526 to 529, inclusive. The applications of the elementary cases to specific pipe bends are taken up one at a time.

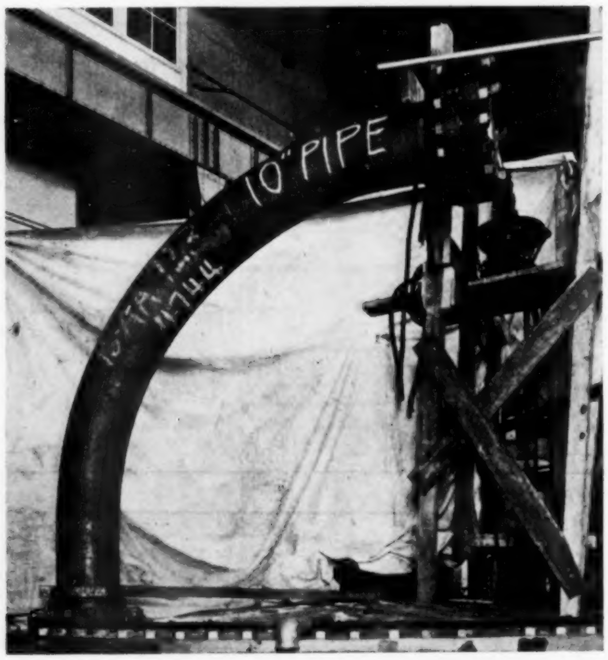

FIG. 12 10-IN. PLAIN PIPE BEND

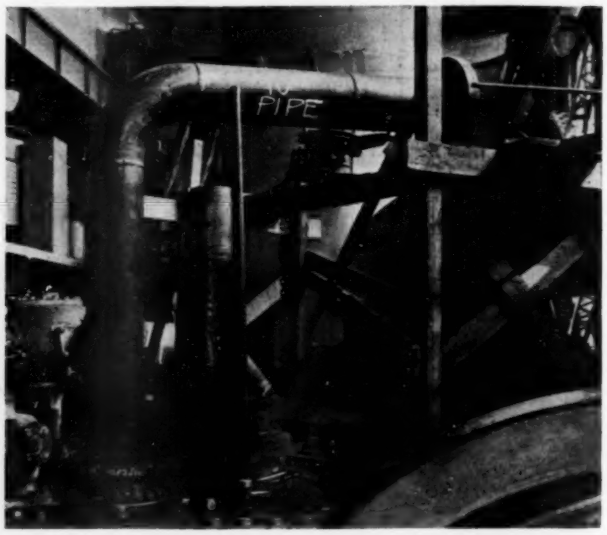

FIG. 14 10-IN. TUBE TURN WITH TANGENTS

PIPE BEND LOADED WITH A TRANSVERSE FORCE ACTING AT THE FREE END IN THE PLANE OF THE BEND

The manner in which forces and moments are transposed and deflections combined for a 10-in. plain pipe bend, Fig. 2, having a transverse force F acting at its free end in the plane of the bend, is explained as follows [Fig. 16 (*a*) shows the bend as a line drawing]: The component parts of the bend are shown with the transposed forces and moments in Fig. 16 (*b*). The component part *ce* is a straight cantilever with a transverse force F applied at its free end as in Case II. The abscissa of the moment diagram is the true length of this part. *bc* is a quarter-bend having a radial force F (called F_r) and a moment Fl, both acting in the plane of the bend, applied at its free end. The value of l in the moment Fl is the length of *ce*. These two loadings are, respectively, Case V*a* and Case VII*a*. The abscissa of the moment diagram is the developed length of this quarter bend, $\pi R/2K$ or $\pi \times 60/2K$, where K is the rigidity multiplication factor.[6] This is called the virtual length of the bend and equals 188.5 in. *ab* is a cantilever having the moment $Fl + F_rR$ which equals $13.81F + 60F$ or $73.81F$ acting at its free end *b*. The abscissa of its moment diagram is its true length. This loading is Case III. The force F is transmitted axially through *ab* to the anchor point.

In addition to the deflections at the free ends of these cantilevers, due to bending within themselves, rotations of the component parts between their hypothetical fixed ends and the anchored end of the pipe bend, represented by ψ_b and ψ_c, produce deflections at the ends of the cantilevers. These are added algebraically to the individual deflections of the parts.

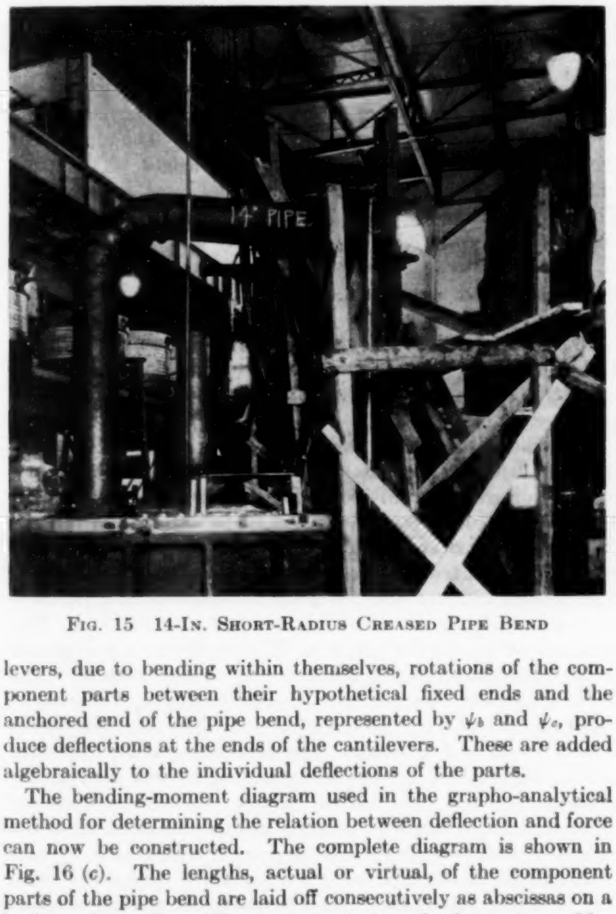

FIG. 15 14-IN. SHORT-RADIUS CREASED PIPE BEND

The bending-moment diagram used in the grapho-analytical method for determining the relation between deflection and force can now be constructed. The complete diagram is shown in Fig. 16 (*c*). The lengths, actual or virtual, of the component parts of the pipe bend are laid off consecutively as abscissas on a horizontal base line. The moment at any point is represented by the ordinate at that point. The moment diagram for the part *ce* is a triangle, the value of whose ordinate is zero at *e* and Fl, which equals $13.81F$, at point *c*. The moment Fl carries through the section of piping to *b*, hence a horizontal line is drawn from the top of the ordinate at *c* toward the left and ends at the ordinate at *b*. The quarter bend *bc* is subjected to an additional bending moment due to the transposed radial force F. This diagram takes the form of a half-segment of a parabola. The value of its ordinate is zero at *c* and FR, represented by and equal to $60F$, at *b*. The moment at *b* is the sum of the ordinates at this point which equals $13.81F + 60F$ or $73.81F$. This moment is carried through to the left and ends at the ordinate at *a*. The difference in the flexural rigidity of the component part *bc* and the other component parts, caused by flattening of the cross-section due to flexure in the plane of the bend, is taken into account by the use of the virtual length of the part *bc* for the abscissa in the bending-moment diagram. The bending moment acting on each component part corresponds to the transposed forces and moments as shown in Fig. 16 (*b*). In the computations, all rotations above the abscissa have been considered as clockwise, those below as counterclockwise. The direction of rotation of the resulting moments is then apparent from an inspection of the free-body diagram in Fig. 16 (*b*).

From the bending-moment diagrams described above, deflections at the free end of each component part can now be obtained. The deflection at the free end of each component part is the algebraic sum of all the deflections which may be due to all or part of the following:

a Rotation caused by deflection of preceding component parts
b Force acting at free end of component parts
c Moment acting at free end of component parts.

Deflections due to rotations are equal to the length of a component part multiplied by the algebraic sum of all the areas of the bending-moment diagram preceding the fixed end of the part, divided by EI.

Deflection due to forces and moments is the result of successive rotations of the elementary length comprising the component part. The total deflection at any point equals the algebraic sum of all the deflections preceding the part in question.

FIG. 16

The total downward deflection at the point *d* (the point at which downward deflections were measured in the tests on this pipe bend), Fig. 16 (*a*), is obtained by the summation of all the increment downward deflections from the fixed end of the pipe bend up to the point *d*. The total deflection to the right at the point *c* of the pipe bend is the summation of all the increment deflections to the right.

The values of deflection obtained by the above method of calculation and from tests made on this bend are shown both tabulated and graphically in Fig. 17. No allowance has been

made for changes in the value of moment of inertia because of flattening of the quarter-bend or other parts of the pipe during fabrication. The value of I for the cross-section at the middle of the quarter-bend was computed, using actual measurements and using nominal dimensions. In each case the nominal thickness of metal was assumed. The results are:

Using measured dimensions, $I = 160.4$ in.⁴
Using nominal dimensions, $I = 160.7$ in.⁴

PIPE BEND LOADED WITH AN AXIAL FORCE ACTING AT THE FREE END IN THE PLANE OF THE BEND

The solution of the 10-in. pipe bend already described, when subjected to an axial load at its free end, is shown in Fig. 18. The component parts of the pipe bend are shown with transposed forces and moments in Fig. 18 (*b*). The component part *ce* is a straight cantilever acted on by an axial force. The abscissa of the bending-moment diagram is the true length of the part. *bc* is a quarter-bend acted on by the axial force *F*, called F_a. The abscissa of the bending-moment diagram is the developed length of the bend divided by the rigidity multiplication factor *K*. The length used as abscissa is known as the virtual length of the quarter-bend and equals $\pi R/2K$ or 188.5 in. This loading of the quarter-bend is Case VI. *ab* is a cantilever acted on by the force *F* and the moment F_rR in the plane of the bend. F_rR equals 60*F*. The abscissa of the bending-moment diagram is the true length of this cantilever. These loadings are Case II and Case III, respectively

Rotations of the elements are added algebraically to the individual deflections of the component parts. The bending-moment diagram is constructed in the following manner [Fig. 18(*c*)]: Component part *ce* is acted on by an axial force, consequently there is no bending. The ordinate of the diagram is zero. The quarter-bend *bc* is acted on by an axial force *F*. The bending-moment diagram is the half-segment of a parabola having an ordinate of value zero at *c* and *FR* (60*F*) at *b*. The ordinate 60*F* carries through to *a*. The cantilever *ab* is subjected to an additional bending moment due to the force *F*. The bending-moment diagram is a triangle having an ordinate of value zero at *b* and *F* × *ab* or 18.56*F* at *a*. The total ordinate at *a* is *RF* + *ab* × *F* or 78.56*F*. The summations of the respective deflections obtained by the same method as was used in the previous problem gives values for the relations between the downward displacement at points *d* and the displacement to the right at *e*, and the force *F*. *d* is the point at which the downward displacement of the pipe bend was measured during the tests. The values of deflections obtained by the above method of calculation and from actual tests are shown tabulated and graphically in Fig. 19.

PIPE BEND LOADED WITH A MOMENT ACTING AT THE FREE END IN THE PLANE OF THE BEND

The relation of force to deflection of the 10-in. plain pipe bend under discussion when subjected to a bending moment at its free end in the plane of the bend is next determined. Fig. 20 shows the plan of the bend and the analysis of this loading. The component parts of the bend with transposed moments are shown in Fig. 20 (*b*). The component part *ce* is a straight cantilever having a moment 72*F*, acting at its free end. This is Case III. The abscissa of the bending moment diagram is the true length of *ce*. The quarter-bend *bc* is acted on by a moment in the plane of the bend as in Case VII. The abscissa of the bending-moment diagram is the virtual length of the developed quarter bend and equals 188.5 in. *ab* is a straight cantilever acted on by a moment at its free end as in Case III. The abscissa of its bending-moment diagram is its true length. Rotations of the parts are added algebraically to the individual deflections as previously described. The complete bending-moment diagram is shown in Fig. 20 (*c*). The bending moment *M*, which equals 72*F*, carries through the entire length of the pipe bend. The summation of increment deflections to the right at point *e* and downward at point *d* per unit value of *F* are shown. Fig. 21 shows the values of deflections for different values of *F* both in a table and graphically.

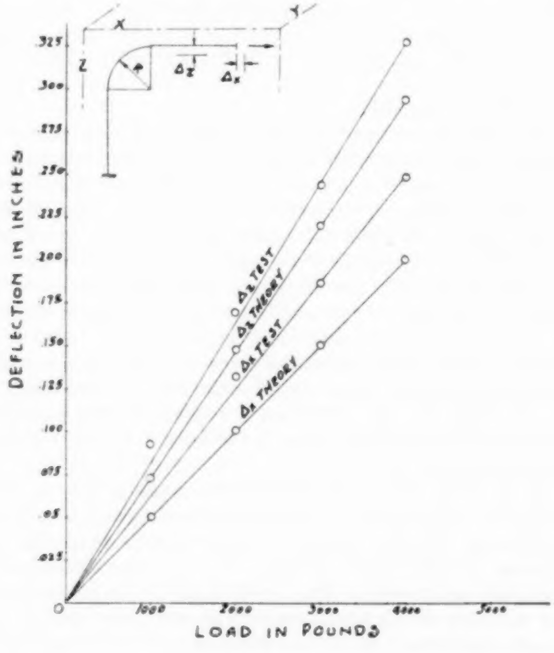

FIG. 19

PIPE BEND LOADED WITH A FORCE ACTING AT FREE END IN PLANE PERPENDICULAR TO PLANE OF BEND

The force applied in this manner causes rotation of the elements of the section of the piping in two planes, namely, the *XY* and *YZ* planes. This is shown in Fig. 22 (*a*). The resultant deflection along the *Y*-axis is determined as follows: The displacement is determined for each component part, caused by the action of the force *F* in the *XY*-plane. To this displacement is added the displacement of each component part caused by the action of the force *F* in the *YZ*-plane.

The manner in which forces and moments are transposed and deflections combined in the *XY*-plane is explained as follows: The component parts of the pipe bend with the transposed forces and moments acting upon them are shown in Fig. 22 (*b*). The component part *ce* is a straight cantilever with a transverse force *F* acting at its free end (Case II). *bc* is a quarter-bend acted upon by a moment equal to *F* × *ce* or 13.93*F* and a force *F*, both of which are in a plane perpendicular to the plane of bend and tangent to its free end. (Cases VIII*b* and IX, respectively.) *ab* is a straight cantilever acted upon by a torsional moment caused by the force acting in the *XY*-plane. This tor-

FIG. 23

sional moment is equal to $F \times ce + FR$ = ($13.93F + 60F$ or $73.93F$). In addition to the deflections at the free ends of these component parts due to bending within themselves, rotations of the elements between the hypothetical fixed end and free end of each component part are represented by ψ_b and ψ_c which produce deflections at the free ends of the component parts. These deflections are added algebraically to the individual deflections of the component parts (Case I). To determine the sign of ψ_b and ψ_c, see Appendix II. The bending-moment diagram for the force in the XY-plane is constructed as follows [Fig. 22(*c*)]: The lengths, either actual or virtual, of the component parts of the pipe are laid off consecutively as abscissas on a horizontal base line, and the moment at any point is represented by the ordinate at that point. Part *ce* is in bending and is represented by its actual length, 13.93 in. Quarter-bend *bc* is both in bending and torsion. Its abscissa is represented by a virtual length of $1.806R$, which equals 108.36 in. (Cases VIII, IX, and X). *ab* is in torsion and the abscissa is represented by[7] $1.3 \times l$ which equals 24.13 in. The moment diagram for part *ce* is a triangle, the ordinate of which is zero at point *e* and Fl (represented by $13.93F$) at point *c*. This moment Fl carries through the section of the piping to point *b*, hence a horizontal line is drawn to end at *b*. The quarter-bend is subjected to an additional bending moment due to the transposed force. This diagram is represented by the half-segment of a parabola, the value of the ordinate of which is zero at point *c*, and $60F$ at point *b*. The total moment at *b* equals $13.93F + 60F$ or $73.93F$. The moment at point *b* is carried through as a torque moment to point *a* and hence a horizontal line is drawn from *b* to *a*. The force as applied causes all the parts to be rotated in a counterclockwise direction, with respect to the XY-plane. Thus all of the bending-moment diagrams shown in Fig. 22 (*c*) are drawn below the horizontal base line.

The deflection at the free end of each component part is obtained by the same method as previously explained. In addition to these deflections, the moment acting at the free end of quarter-bend *bc* also produces a rotation of the part *bc* in the YZ-plane (Case IX*a*). The total rotation ψM_{ys} of this part multiplied by $0.695R$ gives the value of the additional deflection caused by the moment acting in the XY-plane. This deflection in the YZ-plane is at all times of opposite sign to the deflection in the XY-plane (this refers only to the deflections on part *bc* caused by the moment acting at the free end of this part). For the determination of the direction of the rotation in the YZ-plane, see Appendix No. 2. Values of the deflections of each component part along the Y-axis, due to the actions of the force F in the XY-plane, are now determined.

As previously stated this force F also causes a bending in the YZ-plane. The manner in which forces and moments are transposed in the YZ-plane and the deflection of each component part obtained, is explained as follows: The component parts of the pipe bend are shown in Fig. 23 (*b*), with the transposed forces and moments acting upon them. The component part *bc* is a straight cantilever with a force F acting at its free end. *bc* is a quarter-bend acted on by a force F in a plane perpendicular to plane of the bend and perpendicular to the free end of the pipe. *ab* is a straight cantilever acted upon by a moment which equals $60F$ and a transverse force F. Deflections due to rotations of the elements are added algebraically to the individual deflections of the component parts. The only rotation to cause a lateral displacement is represented by ψ_b.

The same method as previously stated is used to construct the bending-moment diagram. Part *ce* is not laterally displaced by the action of the force in the YZ-plane, and thus its length may be neglected. Quarter-bend *bc* is both in bending and in torsion and its abscissa is represented by $1.806R$ which equals 108.36 in., a virtual length (Case VIII). *ab* is a straight cantilever acted on by a moment and a force at its free end, hence its abscissa is represented by its true length, 18.56 in.

The bending-moment diagram for the entire pipe bend, due to the action of the force in the YZ-plane, is drawn as follows [Fig. 23(*c*)]: The ordinate of the moment diagram for part *ce* is zero throughout. The moment diagram for quarter-bend *bc* is in the form of the half-segment of a parabola, the value of the ordinate is zero at point *c* and $60F$ at point *b*. This moment, $60F$, carries through the section of the piping to the point *a*, hence a horizontal line is drawn to end at *a*. The straight cantilever *ab* is subjected to an additional bending moment due to the transposed force *F*. This diagram is represented by a triangle, the ordinate of which is zero at point *b*, and *Fl*, represented by 18.56*F*, at point *a*. The force as applied causes all the parts to be rotated in a clockwise direction with respect to the *YZ*-plane. Thus all of the bending-moment diagrams are drawn above the horizontal base line. By applying these areas to the elementary cases to which they correspond, the deflection at the free end of each component part is calculated.

---

[7] Reference 1, p. 529.

The total deflection along the *Y*-axis is equal to the summation of the deflections of the component parts due to the actions of the force *F* in both the *XY*- and *YZ*-planes. This total summation for the point *d* is shown in Fig. 23 and is represented by $EI\,\Delta y = 594.980F$ *right;* $\Delta y = 0.0001234\ F$ in., *right.*

The tables and curves shown in Fig. 24 show the deflections determined by theory and by tests.

PIPE BEND LOADED WITH A BENDING MOMENT ACTING AT ITS FREE END IN A PLANE PERPENDICULAR TO THE PLANE OF THE BEND AND PERPENDICULAR TO ITS FREE END

Fig. 25 (*a*) shows this pipe bend with the load applied. The component parts of the pipe bend with the transposed moments acting on them are shown in Fig. 25 (*b*). *ce* is a cantilever acted on by the bending moment, which equals 72*F*, at its free end (Case III). *bc* is a quarter-bend acted on by same moment in a plane perpendicular to the plane of the bend and tangent to its free end (Case IX). This moment is transposed to the cantilever *ab* as a torque moment and carries through to the anchor point *a*. Rotations of the component parts are represented by ψ_b and ψ_c.

The same procedure as in the other loadings is used in the construction of the bending-moment diagram which is shown in Fig. 25(*c*). The abscissa of the bending moment diagram *ce* is its actual length 13.93 in. The abscissa of the bending-moment diagram of the quarter-bend is a virtual length which equals 1.806 × *R* or 108.36 in. (Case IX). *ab* is a straight cantilever in torsion. The abscissa of its bending-moment diagram is represented by a virtual length equal to 1.3 times its actual length. This is 24.13 in. The bending moment which is 72*F* at *e* carries through from point *e* to point *a*, hence a horizontal line is drawn from *e* to end at *a*. The couple as applied causes all the parts to be rotated in a counterclockwise direction with respect to the *XY*-plane, hence all of the bending-moment diagrams are drawn below the horizontal base line.

The computation of deflections at the free end of each component part is carried out in the same manner as previously described. The additional deflections of the quarter-bend *bc* caused by the moment in the *XY*-plane producing a rotation in the *YZ*-plane are determined in the same way as discussed in the eighth preceding paragraph. The summation of all the increment deflections preceding any point determines the total deflection at that point. Fig. 25 shows the calculated deflections of the component parts and the total deflection of pipe bend along the *Y*-axis at point *d*, which is the point at which deflections were measured in the test. The table and curves of Fig. 26 show the calculated deflection for different loads as compared with the deflections obtained by test at the same loads.

PIPE BEND LOADED WITH A TORQUE MOMENT ACTING AT ITS FREE END IN A PLANE PERPENDICULAR TO ITS FREE END

The pipe bend with load applied is shown as a line drawing in Fig. 27 (*a*). The component parts of the bend with transposed moments are shown in Fig. 27 (*b*). Part *ce* is a straight cantilever having a torque moment 72*F* at its free end. *bc* is a quarter-bend acted on by the same torque moment at its free end. Part *ab* is a straight cantilever having a bending moment acting at its

free end. Rotations of the component parts are represented by ψ_b and ψ_c.

The bending-moment diagram, Fig. 27 (*c*), is constructed as follows: The moment acting on part *ce* produces no lateral displacement. This is Case IV. The abscissa of the bending-moment diagram is a virtual length of the part *ce* equal to 1.3 times its length. This is represented by 16.55 in. The quarter-bend *bc* is subjected to both bending and torsion, consequently the abscissa of its bending-moment diagram is a virtual length equal to 1.806R, which equals 108.36 in. (Case X). *ab* is acted on by the bending moment 72F at its free end (Case III). The abscissa of its bending-moment diagram is equal to its true length. The ordinate of the moment diagram of *ce* is the torsion moment 72F. This ordinate carries through the bend from *e* to *a*, hence a horizontal line is drawn from *e* to end at *a*. The couple as applied causes all the parts to be rotated in a counterclockwise direction with respect to the YZ-plane. All of the bending-moment diagrams are, in consequence, drawn below the horizontal base line.

The deflections of the component parts are determined by the same method as has been described before. In addition to these deflections, the moment acting at the free end of the quarter-bend *bc* also produces a rotation of *bc* in the XY-plane (Case X*b*). The total rotation, ψM_{xy} of the part *bc* multiplied by 0.306R gives an additional deflection along the Y-axis caused by the moment acting as shown in Fig. 27 (*b*). Due to the bending of the quarter-bend *bc* in the XY-plane, there is a deflection produced on the component part *ce* at *d*. This deflection at *d* is equal to the rotation of the bend *bc* in the XY-plane multiplied by the distance *cd*. This is called $\psi c_{xy}l$. For the value of this

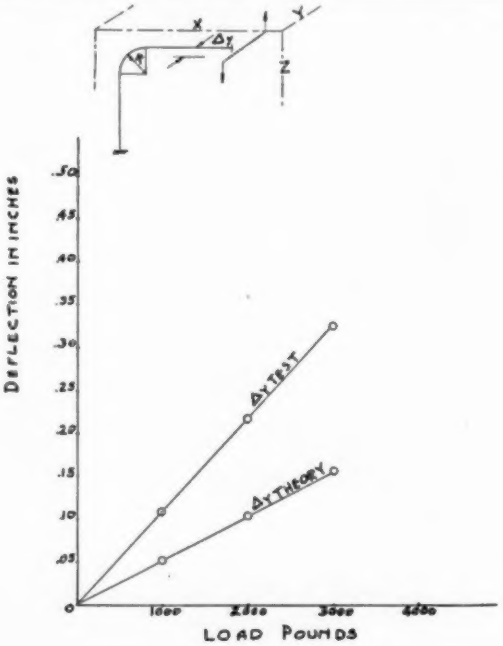

FIG. 34

rotation see Case X. To determine its direction in the XY-plane see Appendix No. 2. All increment deflections preceding point d are combined to determine the total deflection along the Y-axis. The determination of the calculated deflection of each component part and the summation of the deflections are shown in Fig. 27. The tables and curves in Fig. 28 show the relation between the calculated deflection and the deflection obtained by the tests. In the calculations, no allowance is made for the reduction in I because of flattening of the cross-section of the pipe.

III—TUBE TURN WITH TANGENTS

The "tube turn" with tangents was tested and the grapho-analytical solution of the six loadings was carried out, as has just been explained for the plain bend. Figs. 29 to 34, inclusive, show the load-deflection curves both calculated and by test for these six loadings. In calculating the deflections, the value for I was determined by the use of the measured thicknesses of the walls of the quarter-bend and of the tangents. These thicknesses were obtainable when this pipe bend was cut open and measured after the test had been completed. It was found that the use of correct values for wall thickness made a difference of about 10 per cent as compared with the results obtained by the use of nominal thicknesses.

IV—CORRUGATED PIPE BENDS

The grapho-analytical method of solution of bends made of plain pipe of the same major dimensions[8] as the two corrugated bends tested have been carried out for all the six cases of loading. Figs. 35 to 46, inclusive, show the load-deflection relations obtained by tests of the corrugated bends and by calculation for plain pipe bends having the same major dimensions.

V—CREASED BENDS

Figs. 47 to 58, inclusive, show the load-deflection curves obtained by tests of the two creased bends and the calculated load-deflection curves for plain bends of the same major dimensions.[8]

In the study of corrugated and creased pipe bends, no effort was made to arrive at a factor by which I and S of a plain pipe bend might be multiplied to satisfy the load-deflection relations of a corrugated or creased pipe bend of the same dimensions. The possibility of arriving at such a factor was discussed with Prof. S. Timoshenko, but he advised that at present such a factor could not be obtained by calculations as there were too many variables involved. He further called attention to the fact that such a factor obtained for one corrugated bend would not necessarily apply to another bend unless the physical proportions of pitch and depth of corrugations, thickness of pipe wall, etc., were identical. In this study the relations of load to deflection of the pipe bends in question and of a plain pipe bend of the same major dimensions,[8] alone, have been considered.

VI—14-IN. CORRUGATED EXPANSION U-BEND

Because of its shape and size this expansion U-bend could not be conveniently erected on the turbine-top bending table

---

[8] By "plain pipe of the same major dimensions" is meant a smooth pipe having the same diameter and wall thickness as that used in making the bend under test. The center-to-face dimensions of the plain pipe bend and the bend under test are assumed to be the same.

used in testing all the other pipe specimens. It was suspended by rope slings from the frame of the building. Fig. 6 shows the drawing of this bend. Fig. 59 shows this bend prepared for compression loading, which was the only loading applied. Load was applied by a turnbuckle attached by cables to the top and the bottom of a yoke at each end of the bend. This is clearly shown in Fig. 59. The two traction dynamometers, one of which was in series with each turnbuckle, had been calibrated just preceding the test. It was planned that readings, from which deflections were to be obtained, were to be made between short iron posts welded to the pipe at each end of the bend, both on the top and the bottom of the pipe. Change of distance between these posts with change in load were measured with a micrometer having an iron-pipe filler piece of fixed length. The deflections shown by the top and bottom readings were in such close agreement that it was evident that the pipe was deflecting as perfectly as could be desired. This, together with the fact that the amount of deflection probable, when the pipe was loaded to the proportional limit, would exceed the adjustable length of the micrometer, led to the substitution of a steel tape for the micrometer and a chisel mark at the top of each end flange for a reference point. This arrangement provided ample flexibility and was quite satisfactory.

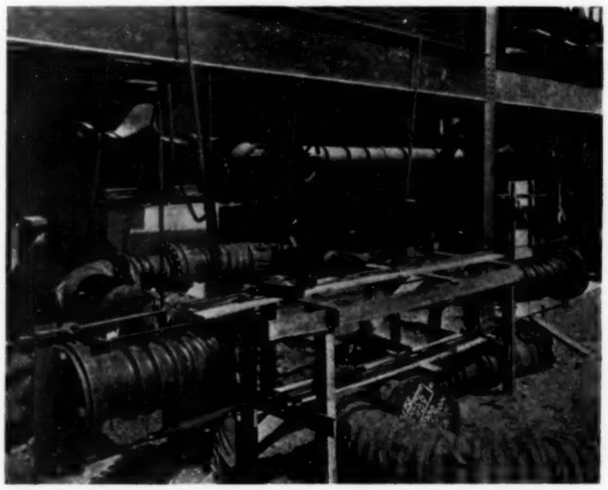

FIG. 59 14-IN. CORRUGATED EXPANSION U-BEND

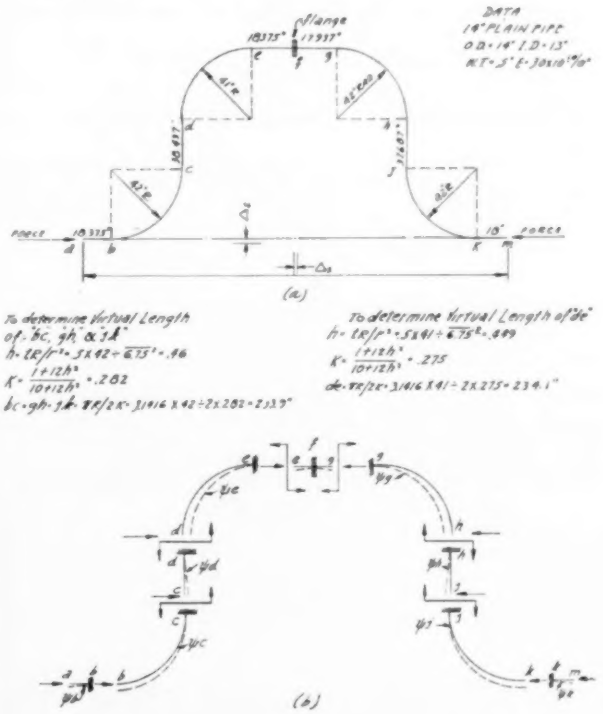
The grapho-analytical solution by which the load-deflection relations of a plain pipe having major[8] dimensions identical with those of the corrugated pipe is as follows: The expansion U-bend [Fig. 60 (*a*)] is divided into two S-bends, each of which is considered anchored at the flange *f*. In Fig. 60 (*b*), the component parts of the expansion U-bend are shown with the transposed forces and moments acting upon them. Rotations of the elements, as discussed in the previous analyses, are also indicated. The bending-moment diagrams corresponding to these forces and moments for S-bend *a–f* are shown in Fig. 61 (*c*). Those for S-bend *f–m* are shown in Fig. 62 (*c*). The total deflections at point *a* of S-bend *a–f* and point *m* of S-bend *f–m* are determined as follows: From Fig. 61 (*c*) and Fig. 62 (*c*) are obtained the rotations and "moments of areas" due to the force and moment on each component part. The deflections on each component part are the result of the actions of these rotations, forces, and moments; hence the application of these to the elementary cases to which they correspond determines the deflections of each part. The summation of these increment deflections gives the total deflections at points *a* and *m*. The addition of the Δ*x* deflection, Fig. 60 (*a*) at points *a* and *m*, determines the total Δ*x* deflection. The Δ*z* deflections, Fig. 60 (*a*) at points *a* and *m*, are equal to each other and represent the total Δ*z* deflection.

GRAPHO-ANALYTIC SOLUTION FOR DEFLECTIONS OF A PLAIN EXPANSION "U" BEND HAVING THE SAME MAJOR DIMENSIONS AS A CORRUGATED EXPANSION "U" BEND. AXIAL FORCE ACTING AT THE FREE ENDS.



To determine Virtual Length of "bc", "gh" & "jk"
$h = tR/r^2 = .5 \times 42 \div \overline{6.75}^2 = .46$
$K = \frac{1+12h^2}{10+12h^2} = .282$
$bc = gh = jk = \pi R/2K = 3.1416 \times 42 \div 2 \times .282 = 233.9"$

To determine Virtual Length of "de"
$h = tR/r^2 = .5 \times 41 \div \overline{6.75}^2 = .449$
$K = \frac{1+12h^2}{10+12h^2} = .275$
$de = \pi R/2K = 3.1416 \times 41 \div 2 \times .275 = 234.1"$

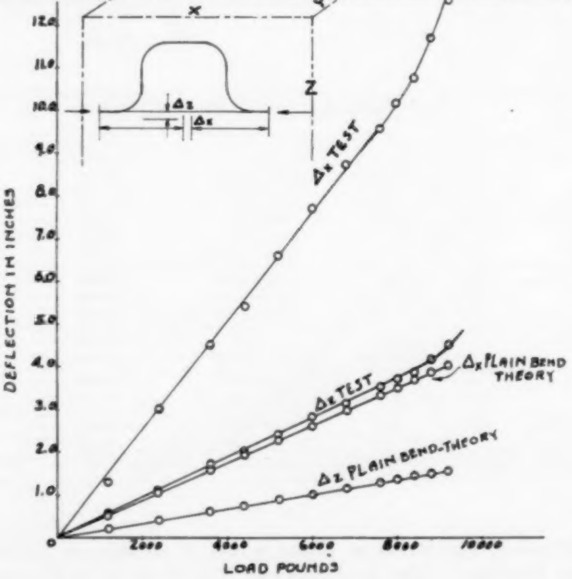

Fig. 63

The calculations of these deflections are shown in Fig. 60 for S-bend *a–f* and Fig. 61 for S-bend *f–m*.

The table and curves of Fig. 63 show the load-deflection relations for the corrugated expansion U-bend as found by the test and the load-deflection relations for a plain expansion U-bend of identical major dimensions.[8] The ratio between the deflections of the two pipes at any load is shown by the value of *R*.

VII—10-IN. CORRUGATED U-BEND

The high-temperature British Thomson-Houston turbo-generator, which, at the time of the tests, was being assembled in Delray P. H. 3, has two corrugated U-bends between the high-pressure and low-pressure cylinders. One of these bends was borrowed for test. The drawing of this bend is shown in Fig. 7 and the bend in one test assembly in Fig. 64. In carrying out the three loadings, one flange of this bend was bolted to the turbine-top bending table, the other flange extended clear of the table. The bend was so flexible that it was decided to load it by the use of standard 50-lb. weights. 600 lb. was the maximum load. Before the bend was erected on the bending table, the faces of the flanges were tested to see how nearly they lay in the same plane. They were found to be so nearly in the same plane that no correction was thought necessary. When the pipe was bolted to the bending table, the free end deflected so much at no load that an adjustable attachment was made to this end. By this attachment an upward pull was applied just sufficient to bring the face of the free flange into the same plane as the face of the fixed flange. Throughout each loading this upward pull was maintained constant. In two of the three loadings of this bend, a horizontal load was applied. This was accomplished by attaching a light rope to the free flange, passing it over a pulley properly placed in relation to the bend, and attaching the weights at its free end. During readings the pulley was tapped lightly. Displacement of the free end of the bend was measured in three directions, using a micrometer.

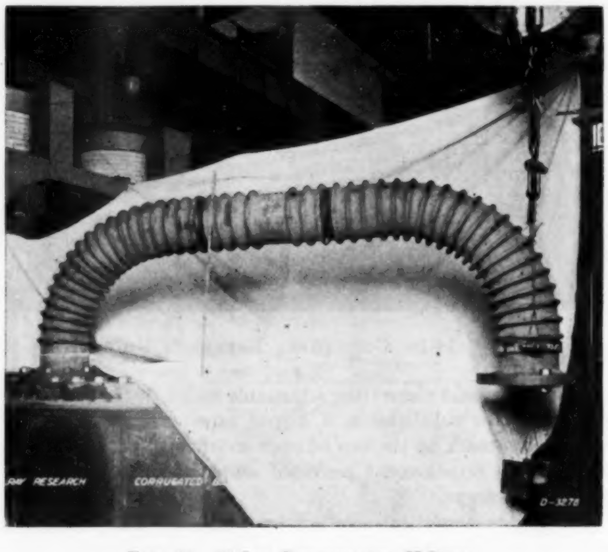

Fig. 64 10-In. Corrugated U-Bend

Grapho-analytical solutions for the determination of deflections of a 10-in. plain U-bend having the same dimensions[8] as the 10-in. corrugated U-bend were carried out. The loadings were identical with those used in the tests on the corrugated bend. From the results of the tests and of the mathematical solutions, comparisons of flexibility were obtained. Figs. 65, 68, and 71

to the hypothetical free end. (*c*) of each figure is the bending-moment diagram for moments and forces in the plane of the bend. Fig. 71(*c*-1) is the bending-moment diagram for moments and forces in the plane perpendicular to the plane of the bend. The abscissa of each of these bending-moment diagrams is laid out in exactly the same manner as is described in the study of the plain bend. The directions of rotation of the component parts are determined in the manner already described. The determination of deflection, with the calculation of each increment shown in detail, is shown in Figs. 66, 69, and 72. These are shown in sufficient detail that further explanation is thought unnecessary.

VIII—CORRUGATED TANGENT

Four loadings were applied to the 14-in. corrugated tangent made of 400-lb. A.S.A. seamless pipe. These were Cases II, III, and IV, and an axial load. The same method of loading was used and the same precautions taken as with the pipe bends. Fig. 8 is a drawing of the tangent. Figs. 74, 75, and 76 show the test assemblies for the three numbered cases. Figs. 77, 78, and 79 show the load-deflection relations obtained by tests on the corrugated tangent and the calculated load-deflection relations for a plain tangent of the same major dimensions.[8]

CONCLUSIONS

This paper shows the results of tests made to compare the flexibility of a plain 10-in. pipe bend having a ratio of radius of bend to pipe diameter of 6:1 with the results obtained by calculation in all the elementary forms of loading. In all cases the flexibility of the pipe as shown by tests was greater than the calculated flexibility. Use was not made of the amended formula for the determination of K, the rigidity multiplication factor, as proposed by Mr. H. E. Jenks in his discussion of A.S.M.E. FSP-51-52.[9] The plain pipe bend made up of a forged quarter-bend having a tangent welded to each end showed the same characteristics as the bend of larger radius. While the ratios of flexibility of these two bends obtained by test and by calculation did not agree in all cases, they were, nevertheless, of the same order. Both pipe bends showed excessive flexibility when subjected to a torsional moment at the free end. The authors have not been able to account for the lack of agreement between tests and theory in this case. The study shows that the formulas apply equally well to a pipe bend having a large ratio of bend radius to pipe diameter, fabricated in the usual way, and to a pipe bend having a small ratio of bend radius to pipe diameter made up of a forged elbow with tangents welded to it.

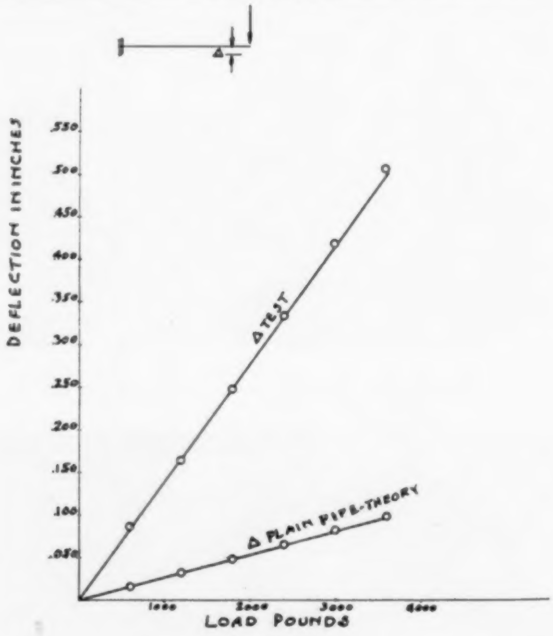

FIG. 77

This paper further shows the results of comparisons between corrugated and creased pipe bends and a corrugated tangent and plain pipe of the same major dimensions[8] as each corrugated and creased pipe. It was thought desirable to express in the form of a ratio the relation between flexibility obtained by test of each corrugated and creased pipe and that obtained by calculation of a plain pipe of the same major dimensions. The approximate average ratio for each kind of pipe is shown in the following table:

Kind of Pipe	Ratio
14-in., 90-deg. corrugated bend	2.2
14-in., 90-deg. corrugated bend	1.8
14-in., 90-deg. creased bend	1.3
14-in., 90-deg. creased bend, short radius	1.3
14-in. corrugated expansion U-bend	2.8
10-in. corrugated U-bend	4.5
14-in. corrugated tangent	5.1
14-in. corrugated tangent in torsion	0.9

As was to be expected, the corrugated tangent was less flexible in torsion than a plain pipe tangent of identical dimensions.

The authors would call attention to the fact that the tests were performed on a very small number of pipe bends of each kind. The results obtained and the conclusions drawn must be treated not as generalizations but rather as applying only to the particular pipe specimens tested. They fully realize that this work is fragmentary. It is believed, however, that it has been done in such a manner that others who may test pipe of the same general characteristics will be able to compare the results of their work with the results here reported.

ACKNOWLEDGMENT

The authors wish to acknowledge with thanks the assistance which certain of their associates in The Detroit Edison Company rendered in making the tests and computing the results. Without their assistance this work would not have been possible. Mr. J. H. Walker, engineer assistant to the general manager, Mr. Sabin Crocker, of the Engineering Division, and Mr. Frank Thorp, piping engineer, by their endorsement, made the investigation possible. Mr. W. F. Carter, plant engineer, and Mr. Frank Nadolni, assistant plant engineer, made available for use such equipment in Delray P. H. 1 as was necessary for carrying out the tests. The use of the partly dismantled equipment made unnecessary the construction of a bending table. This greatly reduced the cost of carrying out the tests. Mr. Samuel Smith, of the Drafting and Surveying Bureau, checked the computations and the sheets of curves. He also developed Appendix No. 2, which the authors believe is a unique solution for the determination of the sign of the rotation. Messrs. Harold Cartier, Fred Shapoe, Charles Moore, and Robert Gill, student apprentices

in the Research Department, carried most of the actual work of setting up the pipes for test and carrying out the loadings.

The authors further wish to thank the management of the Pittsburgh Piping and Equipment Company and that of Tube Turns, Incorporated, for the samples of their respective pipe bends made up especially for the tests.

Appendix No. 1

LIST OF SYMBOLS

The symbols used in this paper are defined below:

Δ = deflection in direction indicated, inches

Δ_X = deflection along the X-axis, inches

Δ_Y = deflection along the Y-axis, inches

Δ_Z = deflection along the Z-axis, inches

F = generalized force acting as shown, lb.

l = length of cantilever or section of pipe, inches

E = modulus of elasticity of pipe material at the working temperature of the piping, lb. per sq. in.

S = Section modulus

G = modulus of shearing elasticity = $\dfrac{E}{2(1 + \lambda)}$ lb. per sq. in.

λ = Poisson's ratio

I = moment of inertia of pipe cross-section, inches to the fourth power (in.^4)

J = polar moment of inertia = $2I$, inches to the fourth power (in.^4)

K = rigidity multiplication factor = $\dfrac{1 + 12h}{10 + 12h}$

h = $\dfrac{tR}{r^2}$ = pipe-bend ratio

t = thickness of pipe wall, inches

R = mean radius of bend, inches

r = mean radius of pipe cross-section, inches

ψ_M = rotation due to a moment at the end of a cantilever = area of rectangular bending-moment diagram, divided by EI

ψ_F = rotation due to a transverse force at the end of a cantilever = area of triangular bending-moment diagram, divided by EI

ψ_b, ψ_c, etc. = algebraic sum of the rotations of the elements between the point designated by the subscript and the fixed end of the section of piping = algebraic sum of the areas of the bending-moment diagrams to the left of the point designated by the subscript, divided by EI

Appendix No. 2

MATHEMATICAL DETERMINATION OF THE DIRECTIONS OF ROTATION IN PLANES AT RIGHT ANGLES TO THE PLANE OF THE QUARTER-BEND WHEN LOADED SIMILARLY TO CASES IX AND X[10]

It is seen from Cases IX and X that a couple acting at the free end of a quarter-bend and perpendicular to the plane of the bend produces rotations in both the planes at right angles to the plane of bend. In the derivation of formulas[11] for these rotations, there was not brought out the relationship between the direction (clockwise or counterclockwise) of these two rotations that exist for the different ways in which a quarter-bend can be anchored. Taking these formulas as a basis, the manner in which the relationship between the direction of the two rotations to account for the way in which the quarter-bend is anchored, is arrived at in the following manner. The different ways in which a quarter-bend can be anchored are shown in Fig. 80.

Consider the quarter-bends as shown in Fig. 81 with parts a, b, e, and f, having a couple at the free end in the plane perpendicular to the plane of the bend. Assume the couple acting on X-axis.

Let:

ψx_b = rotation along X-axis due to bending

ψx_t = rotation along X-axis due to twist

ψx = rotation along X-axis due to combined bending and twist

ψy_b = rotation along Y-axis due to bending

ψy_t = rotation along Y-axis due to twist

ψy = rotation along Y-axis due to combined bending and twist

$$GI_p = 2EI/2(1 + 0.3) = EI/1.3$$

$$\psi x_b =$$

$$\psi x_t = \frac{1.3MR}{EI}\int_0^{\pi/2}\sin^2\theta d\theta$$

$$= \frac{1.3MR}{EI}\left[\frac{\theta}{2}—\frac{1}{4}\sin 2\theta\right]_0^{\pi/2}$$

$$\therefore \psi x_t = \frac{1.3MR}{EI}\left(\frac{\pi}{4}—0\right) = \frac{1.3MR}{4\ EI}$$

$$\therefore \psi x = \psi x_b + \psi x_t = \text{positive value}$$

$$\psi y_b =$$

$$EId\psi y_b = EI_d\psi a_b \sin\theta$$

$$EId\psi a_b = —M\cos\theta Rd\theta$$

$$EId\psi y_b = —M\sin\theta\cos\theta Rd\theta$$

$$\psi y_b = —\frac{MR}{EI}\int_0^{\pi/2}\sin\theta\cos\theta d\theta$$

$$= \frac{MR}{EI}\left[\frac{\sin^2\theta}{2}\right]_0^{\pi/2}$$

$$= —\frac{MR}{2EI}\left(\frac{1}{2}—\frac{1}{2}\cos\theta\right)_0^{\pi/2}$$

$$= —\frac{MR}{2EI}\left(\frac{1}{2}+\frac{1}{2}—\frac{1}{2}+\frac{1}{2}\right)$$

$$\therefore \psi y_b = —\frac{MR}{2EI}$$

$$\psi y_t =$$

$$GJd\psi y_t = GJd\psi c_t \cos\theta$$

$$GJd\psi c_t = M\sin\theta Rd\theta$$

$$\frac{EI}{1.3}d\psi y_t = M\sin\theta\cos\theta Rd\theta$$

$$\psi y_t = \frac{1.3MR}{EI}\int_0^{\pi/2}\sin\theta\cos\theta d\theta$$

$$= \frac{1.3MR}{EI}\left(\frac{\sin^2\theta}{2}\right)_0^{\pi/2}$$

$$\therefore \psi y_t = \frac{1.3MR}{2EI} = \frac{0.65MR}{EI}$$

$$\therefore \psi_y = \psi y_b + \psi y_t = —\frac{MR}{2EI}+\frac{0.65MR}{EI} = \text{positive value.}$$

Thus when the quarter-bend is anchored as shown in Fig. 80, parts *a*, *b*, *e*, and *f*, the two rotations are both in the same direction.

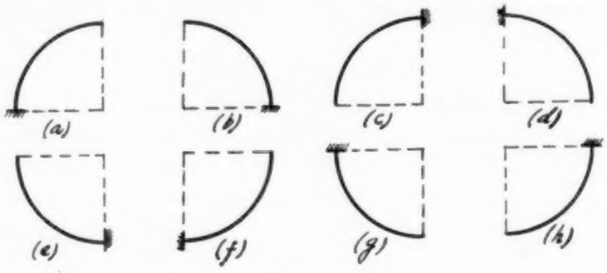

Fig. 80

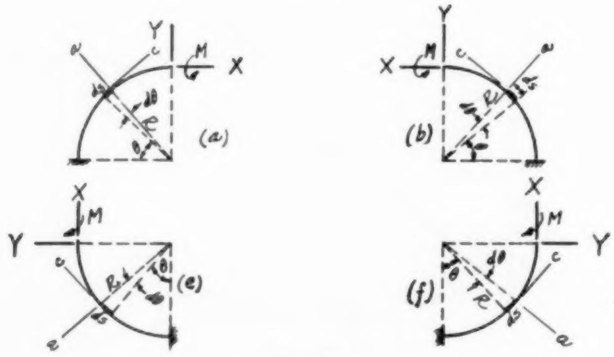

Fig. 81
(M_a = —$M \cos\theta$; M_c = $M\sin\theta$; d_s = $Rd\theta$.)

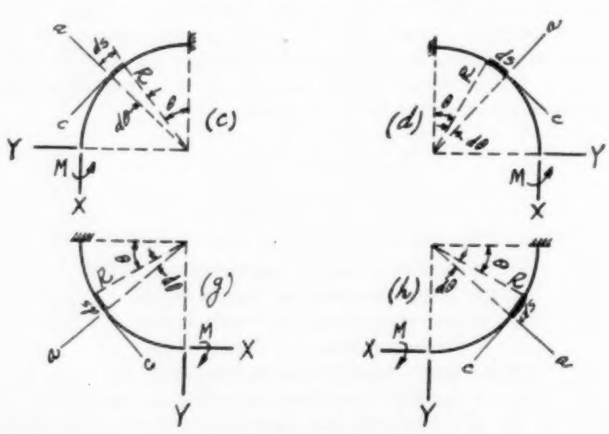

Fig. 82
(M_a = $M\cos\theta$; M_c = —$M\sin\theta$.)

Consider the quarter-bends as shown in Fig. 82, with parts *c*, *d*, *g*, and *h*, having a couple at the free end in the plane perpendicular to the plane of the bend. Assume the couple acting on the *X*-axis.

$$M_a = M\cos\theta$$

$$M_c = —M\sin\theta$$

$$\psi x_b =$$

$$EId\psi a_b = Mads = MaRd\theta = M\cos\theta Rd\theta$$

$$EId\psi x_b = EId\psi a_b \cos\theta$$

$$EId\psi x_b = M \cos^2 \theta R d\theta$$

$$\psi x_b = \frac{MR}{EI}\int_0^{\pi/2} \cos^2 \theta d\theta$$

$$\psi x_b = \frac{\pi MR}{4EI}$$

$$\psi x_t =$$

$$GJd\psi c_t = McRd\theta = -M \sin \theta R d\theta$$

$$GJd\psi x_t = -GJd\psi c_t \sin \theta$$

$$\frac{EI}{1.3} d\psi x_t = MR \sin^2 \theta d\theta$$

$$\psi x_t = \frac{1.3MR}{EI}\int_0^{\pi/2} \sin^2 \theta d\theta$$

$$\psi x_t = \frac{1.3\pi MR}{4EI}$$

$$\psi x = \psi x_b + \psi x_t = \text{positive value}$$

$$\psi y_b =$$

$$EId\psi y_b = EId\psi a_b \sin \theta$$

$$EId\psi a_b = M \cos \theta R d\theta$$

$$EId\psi y_b = M \sin \theta \cos \theta R d\theta$$

$$\psi y_b = \frac{MR}{EI}\int_0^{\pi/2} \sin \theta \cos \theta d\theta$$

$$\psi y_b = \frac{MR}{2EI}$$

$$\psi y_t =$$

$$GJd\psi y_t = GJd\psi c_t \cos \theta$$

$$GJd\psi c_t = -M \sin \theta R d\theta$$

$$\frac{EI}{1.3} d\psi y_t = -M \sin \theta \cos \theta R d\theta$$

$$\psi y_t = -\frac{1.3MR}{EI}\int_0^{\pi/2} \sin \theta \cos \theta d\theta$$

$$\psi y_t = -\frac{0.65MR}{EI}$$

$$\therefore \psi y = \psi y_b + \psi y_t = \frac{MR}{2EI} - \frac{0.65MR}{EI} = \text{negative value.}$$

Thus when the quarter-bend is anchored as shown in Fig. 80, parts *c*, *d*, *g*, and *h*, the two rotations are in opposite directions.

From the previous data the relationship between the direction of the rotations not in the plane of bend can readily be ascertained from the following diagram. Draw two lines at right angles to each other and let the intersection of these lines be considered as the anchored end of a quarter-bend. Each quadrant is given a number.

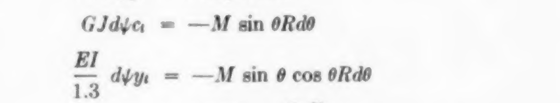

FIG. 83

From the previous data and Fig. 83 the following conclusions are noted: If the end of a quarter-bend is anchored so that the bend lies in quadrants I or II, the rotations in each plane at right angles to the plane of the bend are both in the same direction; but if the quarter-bend lies in quadrants III and IV, the rotations in each plane at right angles to the plane of the bend are in opposite directions.

Discussion

W. P. CURLEY.[12] This paper is of value, not only because it provides design data for corrugated and creased bends, but also because it adds another to the growing number of tests which are proving the present bending theory, as applied to plain pipe, to be substantially correct.

Tests made to check Case V in the "Piping Handbook" for the 10-in. plain bend and the 10-in. "tube-turn" with tangents prove the statement made in the paper "Frictional Resistance and Flexibility of Seamless-Tube Fittings Used in Pipe Welding," presented by Messrs. Crocker and McCutchan at the December, 1930, meeting of the A.S.M.E., that less reacting force is set up by a given deflection in the case of a short-radius fitting with tangents than in the case of a plain pipe bend.

No measurements are reported of the fiber stresses set up in the pipe walls due to bending. The use of strain gages in these tests would not have been practical. Perhaps there is a simpler method of estimating fiber stress, or of arriving at a safe working stress due to bending which may be used for design purposes.

It is evident, in most of the cases, that these stresses did not approach the elastic limit of the pipe material. In Fig. 63, however, the Δ_x and Δ_z test curves turn upward slightly when the applied force is between 8400 and 8800 lb. Since the relation, force to deflection, is a straight-line function, this indicates that the elastic limit of the material at some point in the pipe wall has been reached.

Current bending theory tells us that the maximum longitudinal bending stress S should occur at points e and g [Fig. 60(a)] and may be calculated from the formula

$$S = \frac{\beta Mr}{I} \text{ .... } [1]$$

where $\beta = \frac{2}{3K}\sqrt{\frac{6h^2 + 5}{18}}$ and M = bending moment. (Other symbols as given in Appendix No. 1, p. 27, of the paper.)

The moment arm at e or g is 121.69 in., so that $M = 121.69F$ in.-lb. β is found to be 1.39, r = 6.75 in., and I = 484 in. to the fourth power. Substituting these values in [1], $S = 2.36F$ lb. per sq. in.

For loads of 8400 and 8800 lb. the maximum longitudinal bending stresses are calculated to be approximately 19,800 and 20,800 lb. per sq. in., respectively.

If this one test were taken as representative for corrugated bends, it follows that such bends could be designed from [1] to operate at a stress slightly less than 19,800 lb. per sq. in. without exceeding the elastic limit of the material.

A procedure such as this should provide a simplified method for obtaining design data on any type of bend under any form of loading.

---

[12] Tube-Turns, Inc., Louisville, Ky.

The Δ_s test curve for the 10-in. plain bend (Fig. 17) also turns upward, at an applied force of 5000 lb. The maximum longitudinal fiber stress occurs at b [Fig. 16(a)] and is calculated from [1] to be 11,200 lb. per sq. in. for a load of 5000 lb. ($M = 73.81F$, $\beta = 0.94$, $r = 5.19$, $I = 160.7$.) Thus, at a calculated stress of only 11,200 lb. per sq. in. the elastic limit at some point in this bend has been exceeded. This is probably because nominal dimensions are used in making the calculations, no account being taken of the thinning of the outer wall or of the shearing which takes place during fabrication of the bend.

Although this one test cannot be taken as representative, it indicates that it is unwise to design a plain bend to operate at more than 11,200 lb. per sq. in. fiber stress if the elastic limit of the bend is not to be exceeded.

The other units were apparently not stressed beyond their elastic limits. The stress in the tube-turn unit at an applied force of 3000 lb. was only approximately 18,900 lb. per sq. in. from [1]. Professor Hovgaard, in experiments at the Massachusetts Institute of Technology,[13] found the elastic limit of this type of fitting to be 21,000 lb. per sq. in.

It does not seem accurate to assign a ratio of flexibility as high as 1.3 to the 90-deg. creased bends, since this value was reached or exceeded in only a few of the possible cases. If average values are considered, the ratio for both the plain bend and the tube-turn with tangents should also be approximately 1.3 because both of these units show excessive flexibility under certain loadings.

Apparently, for equal center-to-face dimensions and equal pipe size, the 90-deg. tube-turn with tangents and the 90-deg. creased bend are equally flexible. The advantage falls to one type under certain conditions of loading and to the other type under other conditions.

A. M. HOUSER[14] AND S. HIRSCHBERG.[15] The present trend of higher pressures and temperatures in the steam power plant emphasizes the importance of this paper as the problem of providing adequate flexibility becomes increasingly more intricate as the temperatures and pressures increase. The paper demonstrates the uniqueness of the theoretical application of the grapho-analytical method by the use of area-moment diagrams and the principles of superposition.

In their conclusions, the authors express in the form of a ratio of 1.3 the relation between flexibility obtained by tests of creased pipe bends and that obtained by calculation of plain pipe bends of the same major dimensions. Particular attention is called to the results obtained for Case VI (axial force acting at the free end in the plane of the bend) in comparing the test results of the creased bends and the theory of the plain bends of the same dimensions as illustrated in Figs. 48 and 54 of the paper. The writers conducted a series of tests on creased and plain pipe bends of the double-offset expansion U-bend type having the same major dimensions to compare their relative flexibility. The results of these tests did not indicate a flexibility relation of 1.3 of the creased bend over the plain bend, but indicated that the plain pipe bend is more flexible than the creased pipe bend.

Two sets of 3-in. and one set of 6-in. double-offset expansion U-bends were tested. The movement of the free end of the bend was measured in the direction of the axial force applied in the plane of the bend. The dimensions of the bends tested are shown by single line drawings in Figs. 87–89; the dimensions are to center lines. The test procedure applied is briefly described as follows:

The bends were mounted vertically with the run horizontal by bolting the fixed end to a cast-steel tee which in turn was securely bolted to an I-beam. A 3-ft. straight length of 3-in. extra strong steel pipe was bolted to the free end of the bend by means of a flange. The movement of the free end was restricted to the axial direction by guiding the straight length of pipe with two sets of guide rollers above and below the pipe. The test procedure for the 6-in. bends differed from that described above for the 3-in. bends, in that straight lengths of 6-in. extra strong steel pipe were bolted to both ends of the bend having guiding rollers located 10 pipe diameters (5 ft.) from the flanges on the bend.

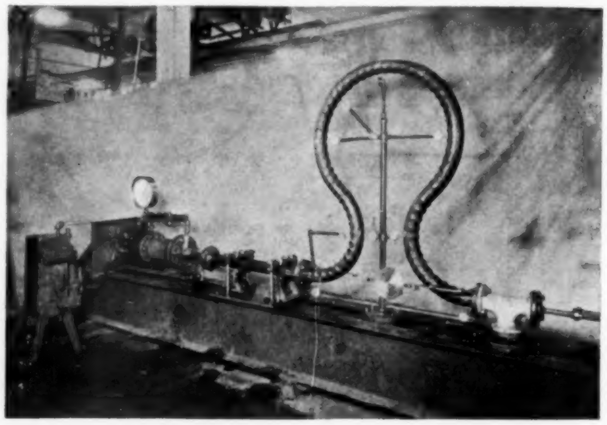

FIG. 84 TEST ARRANGEMENT FOR THE 3-IN. PIPE BENDS

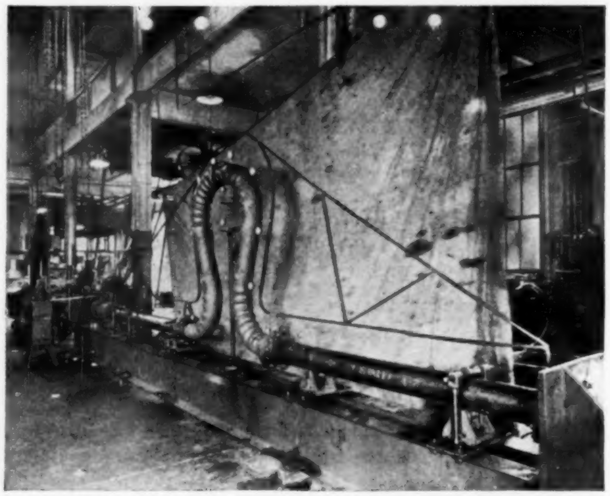

FIG. 85 TEST ARRANGEMENT FOR THE 6-IN. PIPE BENDS

The fixed end was anchored 2 ft. beyond the guiding roller; another roller was located 2 ft. from the first roller on the free end. The load or force was applied to the free end by a hydraulic pump and jack combination, having an area in compression of 25.2 sq. in. and in tension of 26.2 sq. in. The test assemblies of the various bends are shown in Figs. 84 and 85.

To duplicate as nearly as possible the action of pipe bends when installed in a steam line, 150 lb. steam pressure was permitted to flow through the bend during the tests. The steam was admitted at the tee connection near the fixed end, and exhausted on the free end at the extreme of the straight length of pipe. A dynamometer was attached across the flanged ends of the bends to note the amount of force exerted due to the temperature increase. All deflection readings were read on a fixed steel

scale at the free end of the bend. A needle-point indicator was attached on the free end of the bend, the movement of which could be easily read on the fixed scale. Ames indicating dials were placed at strategic points along the periphery of the bends to note the action of the bends under different conditions. Measurement of movement at the fixed end was also made, which revealed unexpected displacement of the fixed end during the progress of the test. This seems to be in accord with the authors' findings.

The values of loads and deflections obtained from actual tests are shown graphically in Fig. 86 for both the 3-in. creased and 3-in. plain pipe bends when in tension. Values for the same bends are shown graphically in Fig. 87 when the bends are subjected to compression.

Fig. 88 shows the deflections for different values of force, both graphically and tabulated for the 3-in. bends in compression. Fig. 88 illustrates the difference in design of this 3-in. bend as compared to the 3-in. bend shown in Fig. 87. Furthermore, it should be noted from Fig. 88 that the 3-in. bend with the long tangent is decidedly more flexible than the 3-in. bend shown in Fig. 87, although the overall dimensions are approximately equal. However, the proportional limit appears to be reached sooner with the long-tangent bend.

The tabulated results and curves of Fig. 89 show the deflections for different loads obtained from tests on the 6-in. creased bend and the 6-in. plain bend made to the same major dimensions.

The readings on the indicating dials proved that the bends move symmetrically with the vertical axis, although the vertical axis shifts as the deflection is changed, due to fixing of one end of the bend. When a bend is installed in a steam line, both ends are hypothetically "free" ends, the bend absorbing the expansion of pipe due to temperature between the anchors at both ends.

It may be interesting to know that the creased bends illustrated in Figs. 88 and 89 were fabricated in Crane Co.'s Corwith Works in Chicago, under the personal supervision of Mr. Alfred Schmidt, of Düsseldorf, Germany, the inventor of this type of bend.

Conclusions. The foregoing discussion shows the results of comparisons between creased pipe bends and plain pipe bends of the same major dimensions based on actual tests. Below is a table indicating in the form of average ratios the relation between flexibility of each creased pipe bend and plain pipe bend obtained from these tests:

Size	Kind of Bend	Ratio
3 in.	Double offset expansion U-bend, creased	0.83
3 in.	Double offset expansion U-bend, creased (long tangent)	0.77
6 in.	Double offset expansion U-bend, creased	0.92

The results obtained from actual tests conducted on creased and plain pipe bends made to the same major dimensions indicate a decided advantage of flexibility in favor of the plain pipe bend over the creased pipe bend. The results obtained by the authors when comparing actual test data of the creased bend with theoretical figures of the plain bend, indicate different characteristics. The writers believe, because of the importance of this subject, that more comparative test data on the various kinds of bends are necessary to establish a sufficient foundation for theoretical application.

B. R. Leapingwell.[16] As manufacturers of the corrugated pipes tested by the authors, we do not think that a corrugated bend should be compared with a plain bend of the same radius, because in the case of all the corrugated bends tested it would be manifestly impossible to manufacture plain bends to such small radii without thinning the tube excessively. It is of course recognized that uniform wall thickness can be obtained on plain bends of small radii by using tube turns, and welding tangents on. Such a method, however, would not be considered suitable in this country for the high pressures and temperatures which are now in use.

To keep the stress-multiplication factor down, the bends either have to be of a much larger radius or the tube has to be unnecessarily thick to allow for thinning during bending. An example of such thinning is shown in Fig. 90, which shows the reduction of wall thickness on the outside of the bend to be over 25 per cent.

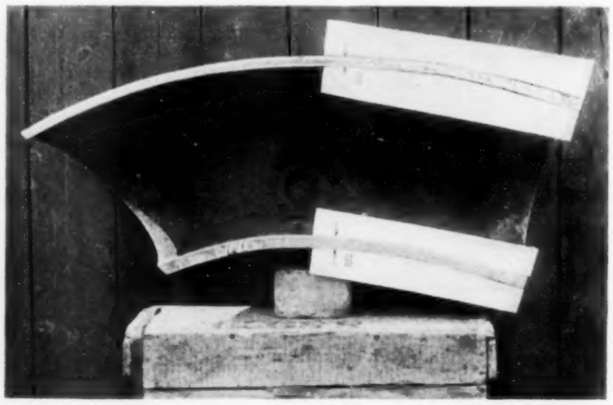

FIG. 90 SHOWING REDUCTION OF WALL THICKNESS ON OUTSIDE OF BEND

(Bore, 10 in.; thickness of straight tube, $^{23}/_{32}$ in.; mean radius of bend, 2 ft., 6 in.)

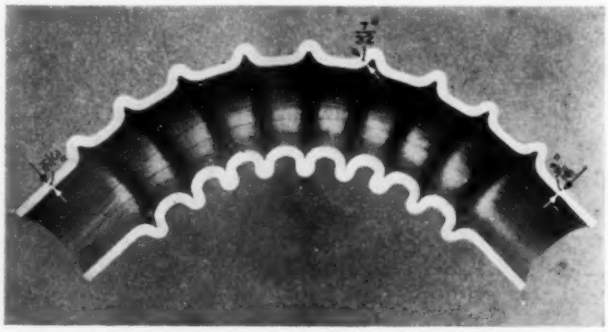

FIG. 91 SHOWING WALL THICKNESS OF CORRUGATIONS TO BE GREATER THAN THAT OF ORIGINAL TUBE

(Actual outside diameter of tube, $2^{3}/_{8}$ in.; mean radius of bend, $6^{3}/_{8}$ in.)

It is our practice to compare a corrugated bend or pipe to a pipe of similar dimensions but in which there is no flattening of the cross-section or thinning of the walls, thus leaving the effective moment of inertia the same as for the plain tube. We agree that for the reasons given by Professor Timoshenko no formula can be derived to obtain a factor of rigidity for corrugated pipes. We obtain this value for our pipes by actual test; however, the figures obtained are not very consistent, probably due to varying thickness of tube around the bore and consequent unevenness in height of corrugations; but generally speaking, the factor of rigidity rises as t/r increases in value. The results of the tests carried out by the authors are very interesting, particularly with regard to the flexibility under torsion for both corrugated tangents and bends; one would have expected the corrugated pipes to be less flexible under torsion. In a series of tests carried out on 2-in. nominal-bore corrugated pipes, owing to the large radius of the bend the rigidity factor for plain tube approached unity, and a less favorable flexibility ratio would be obtained for a corrugated pipe if compared to a plain pipe bend to a standard radius.

---

[16] Director, Aiton & Co., Ltd., Derby, England.

As The Detroit Edison was not able to obtain data as to the wall thickness of the corrugated pipes, owing to their being required for service at the Marysville Power Plant, the photograph, Fig. 91, may be of interest, as it shows that the wall thickness of the corrugations is appreciably more than that of the tube from which the corrugated pipe is made. There is a limiting height of corrugation at which the sides thereof touch; the correct height is from three to four times the thickness of the tube.

The results of the tests carried out by Detroit Edison show the great advantage that there is in corrugating a straight pipe, as the flexibility ratio is so much greater in the case of tangents than it is on bends. It is our practice to utilize corrugated tangents in piping layouts, as they both increase the flexibility and reduce the cost considerably.

Benjamin Mills, Jr.[17] The authors have made a very valuable contribution toward establishing a rational method of stress analysis for piping systems by the tests and calculations reported in their paper. As a number of their tests were made on creased bends it is felt that some further data relating to them will prove of interest.

Our company, The Pittsburgh Piping and Equipment Company, entered into the manufacture of this product at the instance of one of the large engineering organizations of this country and with the full knowledge that we were pioneering. Our investigations have convinced us that these bends have great merit when correctly made and properly used, that they are a decided advantage in close quarters, and that their continued manufacture is fully warranted.

Some of the difficulties encountered in the production of these bends have been enormous, as data for their proper manufacture and formulas governing their action in service when made of the thicknesses of pipe used in this country were sadly lacking in the information supplied us by the patentee. Bends as made in accordance with instructions received from that source did not prove to have the flexibility expected or desired. Extensive experiments were undertaken to determine the most suitable spacing and dimensions of creases in relation to the diameter and wall thickness of the pipe for various bending radii. We found it necessary to develop entirely different methods of manufacture from those used on the light-walled pipes in general use in Germany. Our tests have shown conclusively that in order to obtain the best results with creased bends, correct design and proper manufacture are of paramount importance.

One of our engineers during the past year visited the two plants in Germany where creased bends are manufactured and reports that one of these firms also makes corrugated pipe and bends. The corrugated type has been made for some years, but the creased bend is a recent development and is being used to a far greater extent than the corrugated. Two of the large builders of steam turbines, Siemens-Schuckert A. G. and the Brown Boveri A. G., are now using creased bends exclusively where they had previously used corrugated. Corrugated bends are now used only in cases where extreme flexibility is the determining factor and drop in pressure is of small consequence or at least of secondary importance. Comparative tests made in a state coal mine in Holland showed the pressure drop in corrugated bends to be $2^1/_2$ times greater than in creased bends of the same dimensions.

The latest power plants in Germany have made use of large numbers of creased bends not only to care for expansion but as a precautionary measure, as these bends are considered much safer than plain ones, due to the practically uniform wall thickness throughout.

The German works of a large American boiler manufacturer has made use of creased bends in its boiler construction in certain instances where it was found impossible to keep joints tight with plain bends.

These bends are not made only for the purpose of taking care of expansion but can be used to advantage in many cases. Large-diameter pipes of comparatively thin wall can be bent on short radii, which makes them particularly adaptable to exhaust and bleeder lines, reheat piping, and gas lines. A decided advantage is gained by their use on shipboard due to the cramped quarters, and it obviates the necessity of employing bends made up of welded sections, which latter gave serious trouble on one German ship and were replaced with creased bends.

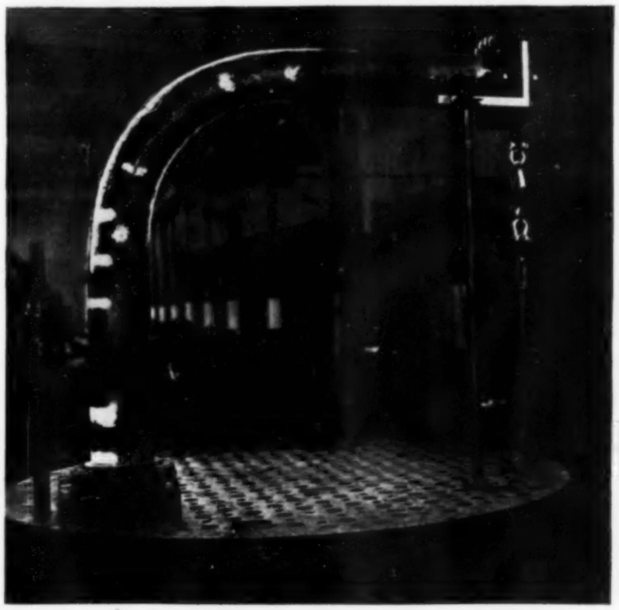

Fig. 92 Set-Up for Testing Plain Pipe Bend

In order to compare more directly the relative merits of creased and plain bends than has been done in the paper, we made up a plain square bend of 14-in. O.D. tubing $^1/_2$ in. thick on a 39-in. radius, duplicating the creased bend No. 1 (Fig. 5) used by the authors in their tests.

One of our bending tables was used in making the test set-up, a special steel plate $4^1/_2$ in. thick being used to make the connection between the end flange of the bend and the cast-iron plate of the table. A general view of the test set-up is shown in Fig. 92. A steel carpenter's square was used for making deflection measurements in both directions from a turned steel pin tapped into the pipe wall as shown in the figure, which shows also the traction dynamometer used to determine the loads imposed.

Gradually increasing loads were imposed on the bend until 9000 lb. was applied, and deflection measurements were taken at each 1000 lb. and at some 500 lb. intervals. No permanent set occurred, and the structure was loaded to 9000 lb. several times. The deflections have been plotted and are shown in Fig. 93 together with the deflections obtained by the authors in their test as shown in Fig. 47 and also the theoretical values. A very interesting feature is the close agreement of our test with the theory when the extreme shortness of this radius for plain bending of 14-in. pipe is considered. It gives us much pleasure to make this contribution toward substantiating the method of calculation used.

---

[17] Boston, Mass. Discussion prepared by Messrs. D. G. Jones, G. S. Larsen (Mem. A.S.M.E.), E. Vollmer (Jun. A.S.M.E.), and G. W. Petrie, Jr., members of the engineering staff of the Pittsburgh Piping and Equipment Company, Pittsburgh, Pa.

The plain-bend theory shows that the flexural rigidity of a bend decreases as the radius of the bend is shortened. The correctness of this theory has been substantiated by a great number of tests. The tests made by the authors and also by ourselves show that short-radius creased bends have even less flexural rigidity than would be indicated by the theory for a plain bend of the same radius. As the creased bends are made on much shorter radii than possible for plain bends, it is evident that considerable increase in flexibility may be obtained by substituting a short-radius creased bend for a standard-radius plain bend, all other conditions being equal. To illustrate, let us consider an expansion bend made of 10-in. 400-lb. pipe. If this bend is made up of four 90-deg. bends as shown on page 533 of the "Piping Handbook" with R = 60 in., the force required to deflect the bend 1 in. will be 3770 lb.; if the bend is made up of four 90-deg. bends of 30 in. radius with straight pipe between so that the total overall dimensions are the same as in the first case, the force required to deflect the bend 1 in. will be only 2100 lb.

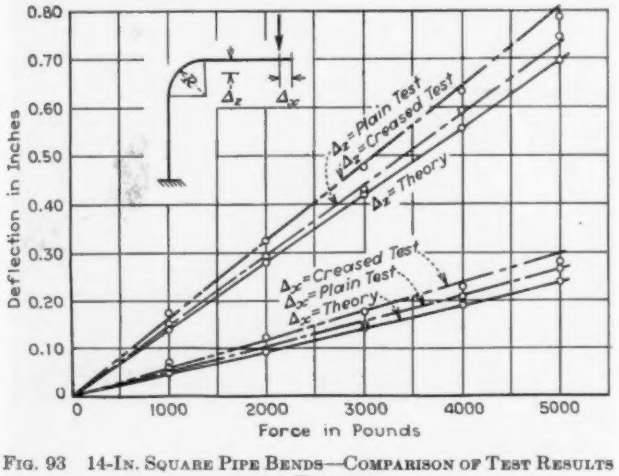

FIG. 93 14-IN. SQUARE PIPE BENDS—COMPARISON OF TEST RESULTS AND THEORY

Force, lb.	Deflections, in. Δ_x Theory	Δ_x Plain test	Δ_x Creased test	Δ_z Theory	Δ_z Plain test	Δ_z Creased test

2000	0.094	0.121	0.123	0.278	0.280	0.321
3000	0.141	0.145	0.173	0.417	0.430	0.477
4000	0.188	0.207	0.227	0.556	0.593	0.634
5000	0.235	0.262	0.279	0.695	0.745	0.789

Creased bends have been found to give much greater deflection under tension than plain bends. By referring to the paper, it will be seen that the authors' tests indicate this to be as much as 64.2 per cent in Fig. 48 and 63.6 per cent in Fig. 54. By combining the decidedly increased values under tension with the somewhat greater values under compression, it can be readily seen that creased bends will freely absorb much greater movement than plain bends even of the same radii. Our practice in designing these bends is to base our calculations on the rigidity factor of plain bends for the same radii, ignoring the additional flexibility imparted by creasing and thus obtaining a greatly increased margin of safety in the installation.

A point which would appear to be worthy of considerable investigation is the probably excessive creep in piping sections where corrugated piping is used. The greatly increased surface exposed to pressure at high temperatures will surely express itself, and we would like to ask how this has been taken care of in the installations made, and whether any measurements have been taken or are considered on this phase of the subject.

While making no extravagant claims for creased bends, we nevertheless desire to repeat that by their use the gain in flexibility of short-radius bends can be utilized to the full with safety, and that when installed to take full advantage of their peculiar characteristics, anchor forces and flange stresses can be reduced.

Harold E. Jenks.[18] The use of higher temperatures with consequent need for more flexible piping to care for added expansion has recently brought about the development of creased and corrugated pipe bends. In connection with the use of such bends, two main factors are to be considered:

1 Relative flexibility as compared with equivalent plain bends
2 Stresses obtained, as compared with those in equivalent plain bends carrying the same total expansion.

It is also possible that the resistance to flow or turbulence of flow inside the pipe caused by creases or corrugations may in some cases affect the design.

By "equivalent" plain bends is meant plain bends having the same center-line dimensions, effective diameter, and wall thickness as the creased or corrugated pipe.

The paper under discussion presents the results of experiments made to determine relative flexibility only. In the writer's opinion these results, although a step in the right direction, are somewhat faulty due to the attempt to keep one end of the pipe bends "fixed." An absolutely fixed end is difficult to obtain, and calculations indicate that it has not been obtained in these tests. A slight variation from the assumed fixed condition results in errors so large as to seriously impair the test data as an effective check on the theory.

Let us examine the first case (the 10-in. plain bend under vertical loading) presented on pages 7 and 8. Solution by the analytic method contributed by the writer to Mr. W. H. Shipman's paper in 1929 gives the following equations for Δ_z and Δ_x in terms of the flexibility constant K:

$$\Delta_z = P(10)^{-8}(1969 + 2829K)$$
$$\Delta_x = P(10)^{-8}(1845 + 5039K)$$

The constant K is here the reciprocal of the value used by the authors. Using the tabulated test values of Δ_z and Δ_x, we obtain K from the foregoing equations as follows:

P	1000	2000	3050	4000	5000
K(from Δ_z)	1.955	2.15	2.33	2.37	2.37
K(from Δ_x)	2.01	2.30	2.37	2.45	2.48

It would appear that the gradual increase in K with load is here caused by a movement (rotation or translation or both) of the "fixed" end, roughly proportional to the load.

Similar calculations for the second case presented on pages 8 and 9 (the same bend under horizontal loading) give the following values of K:

P	1000	2000	3000	4000
K(from Δ_z)	3.42	2.98	2.73	2.73
K(from Δ_x)	2.70	2.39	2.27	2.29

In this case the rapid decrease of K with load would indicate a rather abrupt change in end conditions. The values of K are in no case even close to the Karman theoretical value of 2.01.

It would certainly be impossible to make a close determination of K from either of the above sets of figures, and the lack of consistency and large variation from the theoretical value is undoubtedly due principally to change of fixity at the assumed fixed end.

---

[18] Atmospheric Nitrogen Corporation, Hopewell, Va.

It will be noted that the flexibility ratios given in the paper for the creased and corrugated bends are obtained by dividing the actual test results for the creased or corrugated bend by the theoretical results for an equivalent plain bend. Under the conditions of these experiments the theoretical results for plain bends are in all cases lower than actual results due to lack of perfect fixity as just explained, hence it is evident that the tabulated flexibility ratios are too high. For example, it is not at all impossible that the ratio for the creased bends is actually less than unity instead of 1.3 as tabulated, at least for loading in the plane of the bends. This possibility is strengthened by the fact that a ratio less than unity was actually found for one case and that this case represents the type of loading under which the 10-in. plain bend most nearly checked the theory. In connection with creased bends, the writer has before him data recently taken by a large pipe-manufacturing company. This company tested creased bends of a given size and shape against equivalent plain bends and found that the plain bends were in all cases more flexible than the creased bends. Loading was applied in the plane of the bend only. Unfortunately a good check on the theory was not obtainable for the reason that these experiments were attempted with both ends of the bends fixed, a condition that was not fully realized. However, it would seem that such a direct method of comparison would give more accurate flexibility ratios than would the indirect method of comparison with theoretical values for a hypothetical fixed-end bend, the method used in the present instance.

So far as actual flexibility results up to the present time are concerned, the writer must conclude that the creased bend is still a doubtful quantity, possibly slightly less flexible than an equivalent plain bend; and that the corrugated bend, while considerably more flexible than the plain bend, is probably somewhat less flexible than the tabulated ratios in this paper would indicate.

Experiments in which bends with hinged ends are used are believed to be the surest means toward obtaining reliable and consistent results. A few experiments made in this way under the simpler types of loading should give much valuable data. As pointed out in this paper, the flexibility ratios so obtained would not in general apply to a bend of any other size and shape than the one tested.

In many cases, notably those where high pressures as well as high temperatures are employed, the question of pipe stress becomes of importance. Professor Hovgaard has shown that in a plain pipe subject to expansion stresses only, the tangential, or flattening, stresses will at some points exceed the elastic limit long before the pipe as a whole shows a permanent set. That is, portions of the pipe may be in a plastic state and may fail when pressure stresses are added, or at least may corrode much more rapidly than they would otherwise do. Similar conditions may obtain in creased and corrugated bends. A corrugated bend of a given type under a given load may be found to deflect twice as much as an equivalent plain bend, but so far as we now know, it may at the same time be subject to three times the stress that the plain bend sustains.

It therefore seems desirable that strain measurements be made on creased and corrugated bends under load, in order that some idea of the stresses can be obtained. Stress and not flexibility is the basis of rational design and until we know something of stresses in these bends we shall be unable to properly design them or to determine their applicability to high-pressure, high-temperature service.

Alfred Schmidt.[19] With regard to the different types of bend considered, it would seem that bends made by welding pipe ends to a forged steel elbow will scarcely suffice for the highest-pressure work where large expansions have to be cared for, as the welds are subjected to bending stresses in taking up such expansions. It is the writer's belief that expansion bends as far as possible should be one-piece constructions.

According to the tests described in the paper, corrugated bends show a greater capacity for expansion as compared with creased bends, and at first sight would seem to be preferable to them. However, the tests on corrugated bends were not made on an equal basis as regards the creased bends, since in the former the corrugations extend into the tangent portions of the bends. To compare the two, it would be necessary to extend the creasing similarly in the tangent portions of the creased bends. However, the writer does not believe this to be desirable, since the idea involved in the creased-pipe patent is that of producing a flexible pipe with the lowest possible pressure drop. The creased pipe, at its outer wall where the steam impinges owing to its centrifugal force, is entirely smooth. The creases are so disposed that no more are used than are absolutely necessary. From tests made with corrugated and creased pipes having the same number of corrugations and creases, it has been found that the pressure drop in the former is about $2^1/_2$ times that in the latter. For the pipes tested by the authors it would be at least from 4 to 5 times. For this reason, the writer would advise taking up expansion only by creased pipes, and he believes that corrugated bends with corrugations in their straight parts should be used only in very difficult cases, where a very great expansion is to be cared for. Comparing now corrugated and creased bends having the same tangent lengths, the tests show only 10 per cent greater elasticity for the corrugated pipe, while, as already mentioned, the pressure drop is $2^1/_2$ times as much. Further, the method used in manufacturing corrugated bends is fundamentally different from that employed in making creased bends and results in much higher stresses in the material.

Of great interest are the tests comparing the flexibility of creased and plain bends in which a ratio of 1.3 has been determined. From numerous tests made in Düsseldorf a ratio of 1.5 has been obtained. It is possible that the difference may be due to the different materials used, and perhaps also to different methods of forming the creases.

It is very important to know that in the case of creased pipes the flexibility increases greatly with decreasing radius, without any thinning of the walls. It has also been observed during the tests that the flexibility of plain bends also increases with decreasing radius. These tests differ in this respect from those made by the authors, but the writer believes that further ones will help to clear up the discrepancy. Practically, however, it is impossible to use smaller radii for plain bends, because the thinning of the walls increases with decreasing radii. In practice plain bends should not be made with a smaller radius than 5 × pipe diameter D, or at the very lowest, $4D$. If we now compare a creased pipe bend with a radius of $2D$ and a plain pipe bend with a radius of $4D$ to $5D$, we get the following:

$$\frac{\text{Creased bend (radius } = 2D)}{\text{Plain bend (radius } = 4D)} = 4.17$$

$$\frac{\text{Creased bend (radius } = 2D)}{\text{Plain bend (radius } = 5D)} = 6.25$$

and for double-offset expansion U-bends,

$$\frac{\text{Creased double-offset expansion U-bend}}{\text{Plain double-offset expansion U-bend}} = 1.9 - 2.4.$$

These flexibility comparisons show clearly that the use of creased pipes offers many important advantages.

---

[19] Engineer, Düsseldorf, Germany.

A. E. R. de Jonge.[20] The writer thanks The Detroit Edison Company for allowing the publication of this information and the authors for having undertaken the arduous task of securing data on load-deflection relations in pipe bends.

Such experiments are always useful in two directions—first, because they give first-hand information about the actual behavior of the tested elements under loads approaching working conditions and, second, because they allow a check on the theories involved in the calculation of such members.

There are very few data on expansion by heat available for plain pipe bends and apparently none for corrugated and creased pipe bends, so that these tests fill a gap badly felt by designers of pipe lines. Thus a critical review of the tests and their results should benefit the profession as a whole.

Early during the year the writer's cooperation was asked in solving the mystery of the rather large discrepancies between theory and test results. But while he made at the time various suggestions, there still remain some points in connection with the test set-up and the execution of these tests about which he is not quite clear, and he would request the authors to kindly supply this information, as it is otherwise not possible to check the results.

1 How high above the ground, i.e., its foundations, does the turbine casing stand to which the pipe bends were fixed? It seems to the writer that with the bend standing above this casing the total height must have been some 15 ft. at least, and with the forces used there must have been some bending of the casing which may easily account for part of the deviations between the test results and those derived from theory. It is the more necessary to check the distortion of this casing very carefully, as the authors state that the fixed points were attached to the bending table or to the building. They have neglected, however, to state definitely in each instance where the fixed point was located. It would also be of interest to know the construction of the old turbine casing, its wall thickness, cross-sections, etc., so that a check regarding its deflection could be applied, if this has not already been allowed for.

2 Where exactly were the brass plug measuring points located on the pipes? To measure a deflection accurately so that it can be compared with that derived from theory it is necessary to either measure at the center line of the pipe or at two points at an equal distance from the center line on opposite sides of it. Was this done?

3 If points on the wall of the pipe were chosen, has due allowance been made for rotations of these points in Cases VIII, IX, and X?

4 The fixed end, according to (1), must have moved under the influence of the forces and moments applied. Apparently the motions of some pins near this end were observed, but relative to which fixed system—to the bending table or to the building? The writer had suggested that index arms be secured to the fixed end of a length of several feet so that any movement might easily be observed. It seems a pity that this was not done.

The writer regrets that on account of the lack of this information he has not been able to check the results obtained nor to account for the discrepancies found in the various cases. But there are other data lacking, which, if supplied, might have been helpful in tracing the source of the discrepancies.

The pipe bends are never exactly circular in cross-section, as the outer fibers have been stretched during the process of hot bending, while the inner ones have been compressed. Thus the outer wall of the bend is thinner and the inner wall thicker than the mean thickness of the bend. Besides, an unavoidable flattening takes place during this process. It seems regrettable that the actual dimensions of the cross-section have not been ascertained, and not only at one particular place but all along the center line in steps of, say, 12 in. Further, the deformation of the sections under load should have been obtained with reference to the dimensions of the sections at no load. A shift in the neutral axis influences in Cases IX and X the rotational component due to torsion and thus the deflection at the free end of the bend. It is true that Mr. Cope has given the writer, during the correspondence prior to the reading of this paper, in his letter two additional data with regard to the cross-section, but they are quite insufficient for a definite check.

The writer further regrets deeply that the test value of the plain tangent in Case II, as indicated in the table on the second page, has not been given in the paper. This might have given some valuable clue with regard to how far the test results differ from theory in this simplest case. It would have been still more valuable if this plain tangent had been tested under the influence of a torsion moment, as in Case IV, which was done for the corrugated tangent.

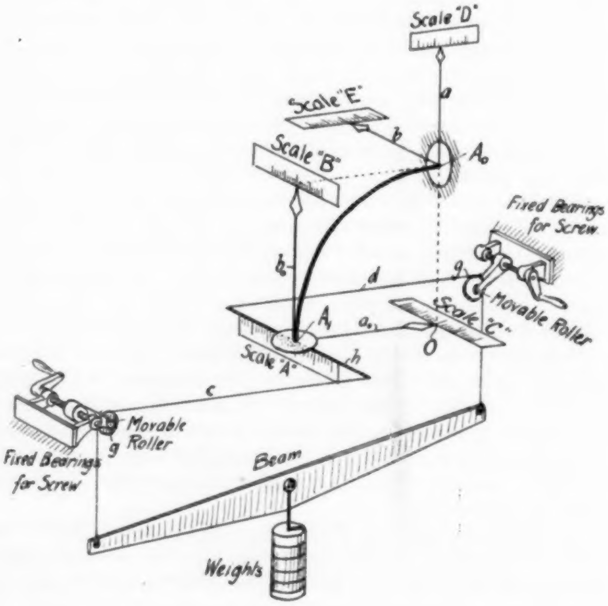

Fig. 94

It seems useless to endeavor to account for the cause of the discrepancy without having the means at hand to check the results, but it seems that the large discrepancies in Cases VIII, IX, and especially X, should have received the authors' most serious consideration with a view to finding their real cause.

With regard to the corrugated bend, there seems to have been some systematic error for the deflections under a load of 1000 lb., as practically all the test points fall widely off the curve. A careful investigation into the source of this error might have been indicated and might have revealed the source of the discrepancies.

About the test values obtained in the case of corrugated and creased bends there can be little said, as no direct comparison with theory can be effected at the present time. Attention may only be drawn to Fig. 79, in which the ordinates are given as "deflections." Should these not be given as "rotations," and if given in inches, should not the radius be stated on which these were measured?

Thus the experiments, as recorded, satisfy the first condition stated at the beginning, in that they give information about the behavior of large-size bends under working loads. They do not give information, however, with regard to the angular deviations or rotations in these cases, since the latter were apparently not determined, and thus have only a limited value with regard to satisfying the second condition, that of checking the theory.

---

[20] Dipl.-Ing., New York, N. Y. Mem. A.S.M.E.

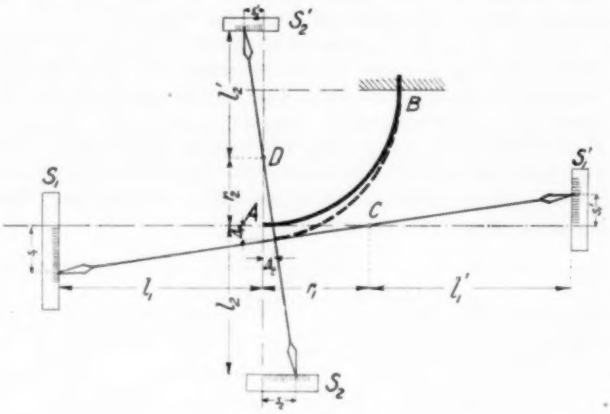

FIG. 95

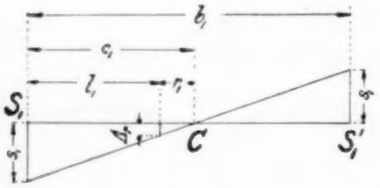

FIG. 96

It may be mentioned that the writer has made experiments with model pipes to test the theory. He has used a much more elaborate set-up than have the authors, which he was forced to adopt owing to certain errors occurring in his initial test results made with test set-ups similar to those of the authors. By gradually refining his methods he was able to get, even in the most sensitive Case X (see Fig. 94), fairly good agreement between test results and theory, the deviation in this case being less than 5 per cent, so that he may state that he feels that the formulas as given in the second edition of the "Piping Handbook" and in the writer's discussion to Messrs. Crocker and McCutchan's paper on "Frictional Resistance and Flexibility of Seamless-Tube Fittings Used in Pipe Welding," Trans. A.S.M.E., paper FSP-53-17, are fairly accurate in giving deflections and rotations, which latter the writer had included in his experiments, and may thus be used with confidence in the case of small pipes.

It is obviously impossible to give here all the results of these experiments. One example, however, may be given, as it will illustrate the way in which the difficulties of measuring exactly were overcome. This example refers to Case V, as listed in Walker and Crocker's "Piping Handbook."

All loads and measurements were taken in the metric system, and in the following description of the test and of the data regarding the pipe dimensions are thus given in kilograms and millimeters.

The pipe used was a copper tube of 6 mm. external and 5 mm. internal diameter. The pipe was annealed at a dull red heat for three hours. The modulus of elasticity was determined after the annealed tube had been allowed to rest at room temperature for one week and was found to be 11,050 kg. per sq. mm., or approximately 11,000 kg. per sq. mm., which figure was used in the calculations and is equivalent to about 15,645,000 lb. per sq. in.

The pipe was then lightly treated with acid and filled with tin solder, which was binding at the tube wall and thus formed, together with the tube, a solid rod, parts of which after cooling were bent to various diameters. The tube bend, the test results of which follow, had a radius of centerline of $R = 48$ mm. (radius at the inside of the bend 45 mm.) and consisted of a quarter bend. After the tube was bent cold to form, it was again heated in order to remove the solder, and was wiped clean of solder on the inside, so that a very fine coating only remained (which compensated for the oxide removed).

No noticeable flattening of the tube had occurred during these operations; at least no such flattening could be detected by means of a micrometer.

The tube was then provided with two steel index wires, as shown diagrammatically in Fig. 95, which extended along the tangent and the radius of the free end of the tube center line in both directions so as to allow the deviations to be read on four metric scales S_1, S_1', S_2, S_2'. The reason for this arrangement was that the deflections of the bend at the applied loads were so small that without magnification the readings would not have been accurate enough, as their order of magnitude was found to be in tenths of millimeters.

Besides, a very sharp and sensitive criterion for the accuracy of the measurements was thus obtained in the location of the points denoted by C and D and which according to the theory should have a location so that $AC = r_1 = \pi R/4$ and $AD = r_2 = \frac{1}{2} R$, where R is the radius of the tube-bend center line. Further, it was possible thereby to also determine the angular deviation of the tangent to the free end A of the bend as well as the deflections Δ_r in the direction of the radius and Δ_t in the direction of the tangent.

The set-up was as shown in Fig. 95, the pipe end B being fixed vertically downward, while the free end A of the bend was horizontal. The loads were applied by means of a knife edge at A at right-angles to the plane of the bend and by means of rings and thin but very strong silk cords in such a way that the indicator arm AS_2 was free to move between the cords, yet leaving the weights suspended always absolutely vertical below the end point A.

The length of the indicator arms was adjusted so that the distance of the scales from the points C or D was 10 times the respective distance AC or AD, or since $R = 48$ mm. and $AC = r_1 = \pi . 48/4 = 37.7$ mm., therefore $AS_1 = l_1 = 9r_1 = 339.3$ mm. and $CS_1' = l_1' = 10r_1 = 377$ mm., and likewise $AD = r_2 = \frac{1}{2} 48 = 24$ mm., thus $AS_2 = l_2 = 9r_2 = 216$ mm., and $DS_2' = l_2' = 10r_2 = 240$ mm.

If, therefore, the theory is correct, there must be $s_1' = s_1$, $s_2' = s_2$ and $\Delta_r = \dfrac{1}{10} s_1$, $\Delta_t = \dfrac{1}{10} s_2$.

If, however, it is found by observation that $s_1' \neq s_1$, $s_2' \neq s_2$, then there is, with reference to Figs. 95 and 96:

$$b_1 = l_1 + r_1 + l_1' = 754 \text{ mm.}$$

and likewise:

$$b_2 = l_2 + r_2 + l_2' = 480 \text{ mm.}$$

and if, as in Fig. 95, C' and D' are the respective points of intersection of the tangent and normal with the lines joining the ends of s_1 with s_1' and s_2 with s_2', respectively, then there is (see Fig. 96):

$$c_1 = \frac{s_1}{s_1 + s_1'} b_1$$

and

$$c_2 = \frac{s_2}{s_2 + s_2'} b_2$$

from which:

$$\Delta_r = s_1 - \frac{l_1}{b_1}(s_1 + s_1')$$

an

$$\Delta_t = s_2 - \frac{l_2}{b_2}(s_2 + s_2')$$

The values for Δ_s and Δ_t determined from these equations check well with those found from the theory, as shown from the following table:

Load	Observed						From theory	
F (kg.)	s_1 (mm.)	s_1 (mm.)	s_1' (mm.)	s_2' (mm.)	Δ_r (mm.)	Δ_t (mm.)	Δ_r (mm.)	Δ_t (mm.)
0.1.....	0.25	0.25	0.15	0.15	0.025	0.015	0.026	0.016
0.2.....	0.50	0.50	0.34	0.35	0.05	0.030	0.051	0.033
0.4.....	1.0	1.0	0.70	0.70	0.10	0.07	0.103	0.065
0.6.....	1.5	1.5	1.0	1.0	0.15	0.10	0.154	0.098
0.8.....	2.0	2.0	1.3	1.3	0.20	0.13	0.206	0.131
1.0.....	2.6	2.6	1.7	1.7	0.26	0.17	0.257	0.164
1.2.....	3.2	3.2	2.0	2.0	0.32	0.20	0.309	0.196
1.4.....	3.75	3.8	2.3	2.3	0.35	0.23	0.360	0.229
1.6.....	4.25	4.3	2.7	2.75	0.40	0.25	0.412	0.262
1.8.....	4.7	4.75	3.0	3.0	0.46	0.30	0.463	0.295

It may be seen from the table that the values agree fairly well, considering the very small quantities involved.

The bend was tested for all other Cases VI to X of the "Piping Handbook" with good agreement. Other bends were tested, too, having a different ratio of R/D, where D is the outside diameter of the pipe. Some tests were performed on solid rods, which also gave good agreement.

With regard to the larger sizes, the writer would reserve his decision until a more careful investigation has produced the cause of the deviations determined by the authors.

The writer may be allowed to mention that these experiments were carried out entirely on his own initiative and at his own expense in the interest of the profession.

There remains one point in the mathematical analysis of the so-called grapho-analytic method about which the writer would like to ask the authors. On the seventh page, in the tenth line from the bottom of the first column, the authors mention a "half-segment of a parabola." Should this not be a sinusoidal curve instead of a parabola?

Authors' Closure

Mr. Curley states that "a less reactive force is set up by a given deflection in the case of a short-radius fitting than in the case of one having a long radius." We are not able to find this conclusion stated in the Crocker-McCutchan paper (FSP-53-17). Attention is called to the results in a specific case of loading, and the reader is cautioned against sweeping conclusions. Mr. Curley's statement holds in Case V, also in Cases VIII and IX. In Case VI the reverse is true. Cases VII and X show mixed performance. Figs. 19 and 30 show the results of this kind of loading on two smooth pipe bends, one of normal radius of curvature and the other having a short radius. The dimensions of these bends are shown in Figs. 2 and 3, respectively. The values of I are as follows:

$$\text{Longer-radius bend:}\quad I = 160.7 \text{ in.}^4$$
$$\text{Short-radius bend:}\quad I = 159.9 \text{ in.}^4$$

In the tests the flange at the end of the longer tangent was bolted to the bending table. In neither case was there any allowance made for flattening of the tube during fabrication of the bend. The short-radius bend was stiffer, that is, showed less deflection for a given load than did the bend of longer radius. A further demonstration of the correctness of this conclusion is shown in Fig. 97, in which the values of the deflection in the direction of the force and perpendicular to it are shown in terms of the applied force. As the radius of the bend is decreased from seven pipe diameters the value of the deflections in both directions decreases. It is of interest to note that in the case in which the bend radius was eight pipe diameters, the bend was not as flexible as when the radius was seven pipe diameters.

In the case of the corrugated expansion U-bend, Fig. 6, to which attention is called by the discusser, the load-deflection relations of which are shown in Fig. 63, the pipe bend was intentionally loaded sufficiently to cause permanent set. This was done merely to find out at what load such set would begin. The pipe bend was actually 1 in. shorter after the loading than before it was applied. The portion of the wall in which plastic flow occurred was not determined.

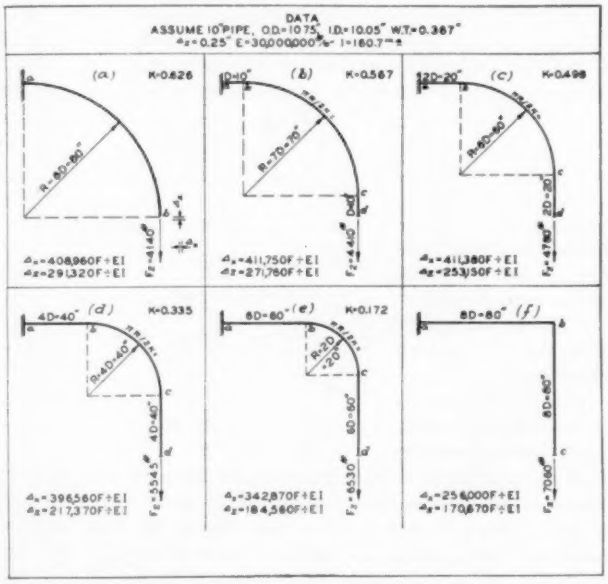

FIG. 97

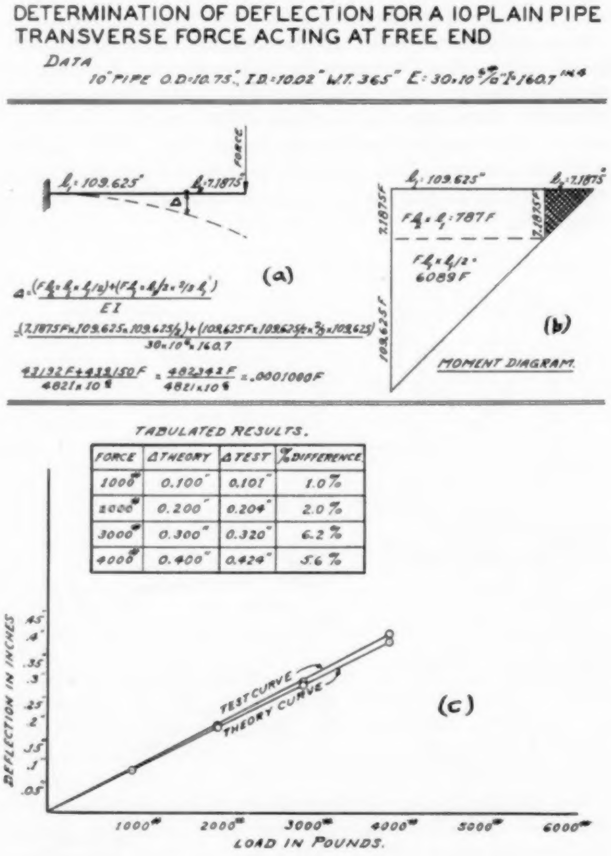
In setting down in the conclusions a table of ratios intended to show the approximate average values of the flexibility of creased and corrugated pipe bends in terms of the flexibility of smooth pipe bends of the same major dimensions, the authors intended only to show an approximate average value for each kind of pipe. The value of the ratio of flexibility in any case of loading should be taken from the load-deflection curve belonging to that case of loading. These values are obviously the results of dividing the deflections obtained by tests on creased or corrugated pipes by those obtained by calculation of an ideal smooth pipe bend of the same major dimensions.

The tests carried out by Messrs. Houser and Hirschberg are interesting, and the authors are indebted to them for contributing data obtained from tests on pipe of smaller size. The authors' experience has been confined to large sizes of pipe only. These tests represent loading in one plane and the combination of only two cases of loading.

The authors agree with Mr. Leapingwell that short-radius bends are not available generally; they are, however, procurable in the United States. There are at least two manufacturers who are prepared to furnish short-radius bends of acceptable uniformity of wall thickness. The question of the radius of smooth pipe bend to be used in the mathematical analysis for comparison of deflection of corrugated bends and smooth-pipe-bend equivalents was discussed by the authors, both between themselves and with other members of the engineering staff of their company. The opinion prevailed that for the purpose of comparison, the smooth pipe bend should be assumed to be of the same major dimensions as the corrugated bend under test. This opinion was supported by the fact (mentioned above) that short-radius bends are being made in America.

The following are values of measurements of wall thickness made on the quarter-bend portion of Fig. 3. These readings were made at intervals on the inside and the outside of the bend, and at the ends of diameters perpendicular to the plane of the bend. The values in inches of measurements made, with their position on the bend, are as follows:

In plane of bend Inside of bend		Outside of bend		Perpendicular to plane of bend			
a	0.355	*d*	0.350	*g*	0.350	*k*	0.358
b	0.350	*e*	0.361	*h*	0.353	*l*	0.342
c	0.365	*f*	0.362	*j*	0.355	*m*	0.348



FORCE	ΔTHEORY	ΔTEST	% DIFFERENCE
1000#	0.100"	0.101"	1.0%
2000#	0.200"	0.204"	2.0%
3000#	0.300"	0.320"	6.2%
4000#	0.400"	0.424"	5.6%

Fig. 98

These measurements were so made that *a*, *d*, *g*, and *k* were in the same plane perpendicular to the axis of the bend. This is also true of the readings *b*, *e*, *h*, and *l*, also *c*, *f*, *j*, and *m*. The average of these readings is 0.354 in. The maximum variation above and below the average are: above 3.1 per cent; below, 3.4 per cent.

The authors are indebted to Mr. Mills for publication of the results of tests carried out on a smooth pipe bend of the same major dimensions as creased bend No. 1, Fig. 5. The results of this one test are a confirmation of the test methods used by the authors, which were essentially the same as those used by Mr. Mills, and of the mathematical solution as applied to smooth pipe bends in this method of loading.

Up to the present time, no measurements have been made to determine whether or not permanent deformation has occurred in the walls of any of the corrugated bends. As soon as opportunity to measure one or more of these corrugated bends arrives, measurements to determine permanent deformation will be made. The rigid fastening of the fixed end of each pipe tested was a matter of as much concern to the authors during the setting up of the pipes for test as it was to Mr. Jenks in attempting to explain the divergence between the results of tests and of calculations. Each pipe tested was fitted with A.S.A. standard flanges. The nuts on the bolts which held the fixed end to the bending table were drawn up using a standard-length wrench and a sledge hammer, as is the usual practice in making up high-pressure steam-pipe joints. Fig. 98 shows the results of a previously unpublished test carried out by the authors before the pipe bends were tested. The method of loading is shown at (*a*); (*c*) shows a comparison between the results of the test and the results of calculations of load-deflection values for an ideal pipe of the same major dimensions. It is to be noted that the test results are within about 5 per cent of the calculated ones. There could scarcely have been a serious deviation from "fixed-end" conditions during this test. In all of the tests in which "fixed ends" were established the procedure was identical with that described.

The authors regret that it was not possible to obtain strain measurements on the corrugated and creased pipe bends during the tests.

Mr. de Jonge has called attention to certain features of the tests which he feels make difficult, if not impossible, a definite comparison of the deflections obtained by test with those obtained by calculation. The authors wish first to restate the fundamental purpose of the tests. This has been done in the second paragraph of the paper. They were particularly interested in comparing the behavior of pipe bends bought for use in a definite steam line and even now performing their intended function in that steam line, with the calculated performance of ideal pipe bends of the same major dimensions.

The height, diameter, etc., of the old turbine, the top of which was used as a bending table, were not measured. The turbine top was a single casting approximately 12 ft. in diameter and 4 in. thick. It was fastened to the turbine casing or shell by ninety-six $1^1/_4$-in. bolts. The whole structure was very rigid. In most cases the measurements were made between a station on the pipe and one attached to the turbine top. In such cases a possible deflection of the turbine casing could have no effect on the value of the measurement. The actual deflection of the turbine and base is impossible of exact solution because of the construction of the base. If one takes such dimensions as are available and makes a rough calculation of the probable deflection, the value obtained is so small that it could have only a negligible effect on the measurements made. The following calculation based on approximate dimensions shows the correctness of this conclusion:

Outside diameter of turbine casing....................	11 ft.
Inside diameter of turbine casing.....................	10 ft. 7 in.
Height of turbine casing above foundation............	14 ft.
Height of point of application of load above foundation of casing..	20 ft.
Value of *E* for material of turbine casing..............	15×10^6
Load applied to free end of pipe as shown in Fig. 10 was..	5000 lb.

The deflection at the top of the turbine casing may then be calculated by substituting in the usual formula for the deflection of a cantilever beam.

Substituting the values in the equation for deflection, Δ = 0.0004 in. The lower section of the turbine base was not circular, but consisted of a heavy rectangular box which constituted the shell of the condenser. The walls were approximately 2 in. thick and were tied together by cross-braces, making a complex structure of great rigidity.

Measurement at the center line of the pipe could have been carried out, but would have entailed a greater expenditure of time than the authors were able to give. The load was applied to the blind flange, which was tightly bolted to the flange on the pipe, except in the case of the pipe shown in Fig. 3, which had flanges welded to the tangents. In no case was the load applied to the pipe section. All flanges were of standard size. There were found, after a diligent search, no mathematical formulas which could be applied to this form of loading, by which deformation or flattening of the pipe could be obtained. The authors would be grateful to Mr. de Jonge if he could suggest a means of determining the amount of this deformation. If the flanges were not tightly bolted together, the load would have been carried on the top of the pipe in Case V loading. Any deformation of the pipe would have decreased the vertical diameter, thus showing less deflection than would have been shown if the pipe section were not deformed. In the various test set-ups the bolts holding the flanges together were drawn up tightly so that the Van Stone end of the pipe was tightly clamped between the flanges. The test shown in Fig. 98 shows no serious effect of flattening of the pipe.

Rotation of the reference points on the pipe in cases 8, 9, and 10 was not measured because the measuring tool, as described in the second paragraph, page 2, was in most instances as long as 5 ft. The error introduced was negligible, since the displacement of the point at which readings were made in Case IX (shown in Fig. 25) was 0.020 in. along the X-axis and 0.003 in. along the Z-axis at 5000 lb. load. The departure of the value of the reading made from the movement parallel to the Y-axis was in this case the difference between 1.000, the cosine of the angle of 0 deg., and the cosine of the angle the sine of which is 0.0202 (the combined movement along the X- and Z-axes) divided by 60. The angle whose natural sine or tangent is 0.0202 divided by 60 is 0 deg., 1 min. The natural cosine of this angle is given as 1.0000.

In Case X loading, under a torque moment of 360,000 in-lb., the displacement of the point at which readings were made was 0.014 in. along the X-axis and 0.048 in. along the Z-axis. The combined displacement was 0.050 in. The angle, the sine or tangent of which is 0.50 divided by 60, is 0 deg., 2 min., 44 sec. The natural cosine of this angle is given as 1.0000.

The effect of deflection of the turbine top on the apparent deflection of the bend is small. Calculations have been made using the equation published on page 208, Vol. 1, of the 1920 edition of "Drang and Zwang," by A. and L. Föppl. The assumptions made were:

Diameter of top	12 ft.
Thickness of top	4 in.
Load of 5000 lb. applied as in Fig. 16 on the 10-in. bend shown in Fig. 12:	
E for cast iron	10 × 10^6 lb. per sq. in.

For the sake of simplifying the problem, the turbine top was assumed to be a flat plate of uniform thickness held rigidly at the circumference. By the solution of the equation noted above the deflection of the plate at the outside circumference of the Van Stone flange was obtained. This deflection produced a rotation of the pipe bend as a whole. Transferred to the point d, Fig. 16, the downward deflection due to this rotation was equal to 0.015 in. The deflection of the pipe at d recorded as shown in Fig. 17 was 0.717 in. The error chargeable to this source would be of the order of 2 per cent.

Measurements were also made as indicated in the fourth paragraph under "Test Procedure Applied to 90-Deg. Pipe Bends," found on page 2. The arm used in making these measurements is clearly shown near the fixed end of the bends in Figs. 9, 12, and 14. The arm used was clamped to the pipe. This arm was 4 ft. $10^1/_4$ in. long from center of pipe to the reference point. The following data are taken from the original report of these tests:

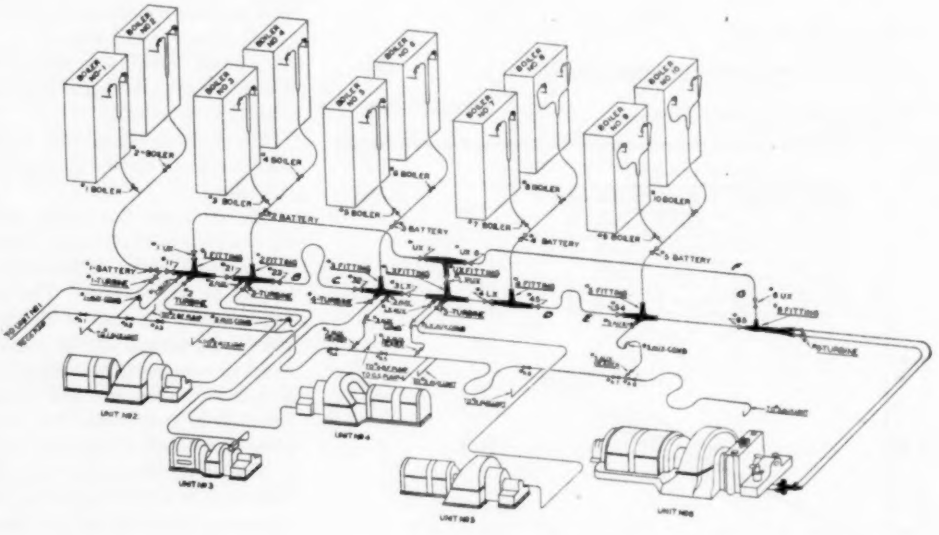


FIG. 99

Loading 10-in. pipe, Fig. 2	Load in-lb.	Deflection at 4 ft. $10^1/_4$ in. from center of pipe, in.
Case V	1000	0.003
	2000	0.010
	3000	0.017
	4000	0.023
	4975	0.030
Case VI	1000	0.012
	2000	0.021
	3000	0.031
	4000	0.043

The arm was located $6^3/_8$ in. above the surface of the bending table.

The results of the test on a smooth pipe tangent are shown in Fig. 98. This has been introduced in the answer to Mr. Jenks's discussion. The results of this test have direct bearing on the answer to Mr. de Jonge's fear that the deflection of the turbine top would vitiate the accuracy of the tests.

Torsional deformation of the pipe may be expressed either as angular displacement or as the tangential displacement of an arm of fixed and known length, when the deformation is small. In the comparison of actual and ideal pipes the length of the arm was taken the same. Perhaps it would have been better in this paper to have used angular rather than tangential displacement in plotting the load-deflection curves.

Mr. de Jonge is correct in stating that the curved boundaries of the bending moment diagrams are sinusoidal rather than parabolic curves. Since the plotted shapes of the boundaries were not used in determining the moments of areas, this error had no effect on the calculations of deflections.

The authors congratulate Mr. de Jonge on being able to produce a quarter-bend which reacted so splendidly under the various cases of loading. They are at somewhat of a loss to see just how to make application of torque loading, as shown in Fig. 94 where the torsional moment is 400,000 in-lb. or even more.

A satisfactory explanation of the apparent departure of the test results from those calculated, in Case X, has not been secured. The authors are still attempting to answer this question. Below are tabulated ratios obtained by dividing the deflection obtained by test by those obtained by calculation for seven pipe bends. Attention is particularly called to the fact that the ratio for Case X loading is uniformly approximately twice that for the cases in which the load is applied in the plane of the bend.

	Approximate ratio of test deflection to calculated deflection			
Pipe specimen	Case V	Case VI	Case VII	Case X
10-in. smooth bend, Fig. 2	1.15	1.19	1.14	2.21
10-in. tube turn with tangents, Fig. 3	1.08	1.15	1.23	2.12
14-in. corrugated bend, Fig. 14, right	2.30	2.07	2.30	4.60
14-in. corrugated bend, Fig. 14, left	2.00	1.80	1.60	3.40
14-in. creased bend, Fig. 15, No. 1	1.15	1.40	1.15	2.45
14-in. creased bend, Fig. 15, No. 2	1.18	1.35	0.82	2.60
12-in. creased bend O. D. 12.695, I. D. 11.850, Ctr. to face 7 ft., 0 min. and 5 ft., 0 min	1.36	1.91	1.46	2.70

The authors agree with Mr. Schmidt that at present the welded-pipe-bend member is not an accepted substitute for the one-piece bend in high-pressure piping. Mr. Schmidt's objection to a direct comparison of the particular creased and corrugated bends tested is a valid one. The authors recognize that the corrugations on the tangents of the corrugated bends introduce a source of extra flexibility. However, they reported the bends as they were tested. It should be again noted that no generalized conclusions were drawn. The fact that so few of each kind of bend were tested made any generalized statement unwise.

The pressure drop through the corrugated pipe bend has been the subject of considerable speculation. At the Marysville Plant, tests were conducted to measure the pressure drop between points *B* and *C*, points *D* and *E*, and points *F* and *G*, Fig. 99. The section of pipe between *B* and *C* is an expansion U-bend made of smooth pipe, 14 in. outside diameter. The section between points *D* and *E* is the corrugated expansion U-bend shown in Fig. 6. That between *F* and *G* is a corrugated 90-deg. bend similar to the bends shown in Fig. 4 except that the radius of the bend was 3 ft. 0 in. The tests were made at night when the load on the plant was small enough so that Unit No. 6 could carry it alone. The pressure drops between points *B* and *C* and between points *D* and *E* were first measured. Steam was taken from boilers No. 1 and No. 2 only, and delivered to Unit No. 6 through the steam header. The east crossover between valve No. 1UX and valve No. UX1 was cut off by closing valve No. UX1. The west crossover between valve No. UX6 and valve No. 6UX was cut off by closing valve No. 6UX. In consequence, all of the steam taken by Unit No. 6 passed through both of the expansion U-bends. Pressure drop was measured by a differential mercury manometer built for use on high-pressure work. The results of these tests are tabulated as follows:

Steam flow, 1000 lb. per hour	Steam pressure, lb. per sq. in. gage	Steam temp., deg. fahr.	Pressure drop, lb. per sq. in., Bend *B-C*, smooth pipe	Bend *D-E*, corrugated pipe
177	278	625	0.92	1.71
231	274	624	1.45	2.62
280	274	660	2.27	4.55
315	272	650	2.87	5.50
378	264	655	3.84	7.68

At the maximum steam flow the velocity of the steam was of the order of 13,700 ft. per min.

Fixed anchors are located at No. 1 fitting, No. LX fitting, and No. 6 fitting. The length of pipe between No. 1 and No. LX fittings is 85 ft. 9 in. Between No. LX fitting and No. 6 fitting there are 115 ft. 6 in. of pipe. There is, therefore, 34 per cent greater expansion to provide for at bend *D-E* than at bend *B-C*. Bend *B-C* is 45 ft. high and 25 ft. 4 in. between flanges. Bend *D-E* is 10 ft. high and 20 ft. between flanges.

The test of pressure drop through the corrugated bend between points *F* and *G* was carried out by bypassing the steam from the main header to the west crossover between No. LX fitting and No. 6 fitting. This was accomplished by opening valve No. 6UX (closed during the previous test) and closing valve No. 65 (open during the previous test). Pressure drop between points *F* and *G* was measured in the same manner as described above. The values obtained from this test are as follows:

Steam flow, 1000 lb. per hr.	Steam pressure lb. per sq. in. gage	Steam temp., deg. fahr.	Pressure drop, lb. per sq. in.
176	279	640	0.58
219	276	648	0.94
266	273	655	1.38
292	272	670	1.92
348	266	666	2.54

The velocity at maximum steam flow was approximately 12,600 ft. per min. through the corrugated bend.

In order to show the effect of the bending moment and stress in the pipe, as calculated for three combinations of bends and tangents in the simple case shown in Fig. 100, the necessary calculations were carried out. The two ends of the pipe were considered as rigidly fixed. This is the condition assumed in the analysis of any pipe line subject to thrusts and moments due to thermal expansion. The corrugated tangent was assumed to be five times as flexible as a smooth tangent of the same material and the same major dimensions. This relationship was taken from Figs. 77 and 78. The creased bends employed were assumed to be equal in flexibility to smooth bends of the same material and dimensions. If corrugated bends had been employed, they would have shown greater flexibility than the creased bends used. For a description of the method of analysis used in analyzing the moments and stresses in these three cases, the reader is referred to Chapter VII of the second edition of "Piping Handbook," by J. H. Walker and Sabin Crocker.

The pipe was assumed to have been installed when its temperature was 60 deg. fahr., and to be operated at 700 deg. fahr. The other data, pipe diameter, wall thickness, etc., are shown on Fig. 100. It is to be noted that the forces and moments acting at the right-hand end of the pipe are much reduced when a corrugated tangent is substituted for a smooth pipe. The force perpendicular to the axis is reduced most in the (*c*) combination, Fig. 100. It is, however, to be noted that the moment decreases in that section of the pipe in which the corrugated tangent has been substituted for a plain tangent. This is best illustrated by

FIG. 100

comparing the moment at point *a* Fig. 100 (*a*) and (*b*), and point *d*, Fig. 100 (*a*) and (*c*).

At point *a*, Fig. 100 (*a*), moment = 464,400 in-lb.
At point *a*, Fig. 100 (*b*), moment = 165,900 in-lb.
At point *d*, Fig. 100 (*a*), moment = 766,500 in-lb.
At point *d*, Fig. 100 (*c*), moment = 234,100 in-lb.

There are at present no published data by which the stresses in a creased or corrugated pipe may be calculated. The authors are undertaking to analyze additional data which they have collected in the tests of other creased pipe bends and hope to be able to separate out the flexibility of the creased quarter-bend from that of a creased quarter-bend and its tangents. Considerable progress has been made to date. If the material shows promise of sufficiently consistent results on the six creased bends tested, they hope to publish the results in the near future

In Appendix No. 3 of this closure are shown the values of rotation and deflection for smooth pipe bends of 22¹/₂ deg., 30 deg., 45 deg., and 60 deg. These coefficients are based on work submitted by Mr. A. E. R. de Jonge and published in the closure of the paper on "Frictional Resistance and Flexibility of Seamless Tube Fittings Used in Pipe Welding," by Sabin Crocker and Arthur McCutchan, presented at the December, 1930, meeting of the A.S.M.E.

There is also included Appendix No. 4. This presents the analysis of loadings, both forces and moments applied to a smooth-pipe cantilever when the pipe is in an inclined position. This work was carried out by Mr. Samuel Smith of the Drafting and Surveying Bureau, The Detroit Edison Company.

The inclusion of the last appendix furnishes the piping designer with the remaining, at present unpublished, data for analyzing piping design under all ordinary conditions of direction, curvature, loading, etc.

Appendix No. 3

ARRANGEMENT IN TABULATED FORM OF THE MOMENT, ROTATION AND DEFLECTION OF 60-, 45-, 30-, AND 22¹/₂-DEG. ARCS OF BENDS[21]

In a piping layout it is at times convenient to use arcs of bends other than 90 deg. The 60-, 45-, 30-, and 22¹/₂-deg. arcs of bends are more commonly used, and it is therefore thought advisable, so as to simplify their application in problems dealing with the flexibility of pipe, to arrange in tabulated form the moment, rotation, and deflection of these bends for the more usual cases necessary to use in determining the flexibility of a pipe line by the grapho-analytic method. The results shown in these tables are derived from the general formulas[22] for the arcs of bends acted upon in various ways.

Appendix No. 4

MATHEMATICAL FORMULAS FOR THE ROTATION AND DEFLECTION OF STRAIGHT CANTILEVER PIPES INCLINED AT AN ANGLE TO THE HORIZONTAL PLANE[23]

Straight cantilever pipes inclined at an angle to the horizontal plane are very often inserted in pipe lines, and it therefore is advisable to be able to determine their effect on the flexibility of these lines. In order to apply these diagonals in problems

dealing with the flexibility of pipe it is necessary to know the rotation and deflection of these diagonals when acted upon at the free end either by a force or moment. Formulas for these are available if the force or moment acting at the free end is in the plane of the diagonal, but the authors are unaware of any if the force or moment is not in the plane of the diagonal. Therefore this appendix is confined only to developing formulas for the rotation and deflection of straight cantilever diagonals when acted upon at the free end either by a force or moment not in the plane of the diagonal. These formulas can readily be applied to the grapho-analytic method for determining the flexibility of a pipe layout.

High-Pressure Boiler and Turbine Operation at Northeast Station

By J. A. Keeth,[1] Kansas City, Mo.

This paper describes the installation and major problems that came up during $2^1/_2$ years' operation of the high-pressure equipment at the Northeast Station of the Kansas City Power & Light Company. Reheater equipment is discussed, together with the experimental work involved in raising the steam temperature to the desired point, and incidentally obtaining a type of construction that would withstand the high furnace temperatures and give reasonable life. The effect of the reheater troubles on the use obtained from the equipment is also covered.

A general operating history of the turbine is given, dealing in considerable detail with the turbine-blade deposits. Discussion of this phase of the troubles brings out the various changes that have been made in boiler feedwater in an effort to find a relationship between boiler-water concentration and turbine-scale formation. The method used for turbine-scale removal is given.

Only minor troubles were experienced with boilers, high-pressure superheater, and auxiliaries. The effect of continued operation on boiler efficiency has been covered graphically, and the operating performance of the high-pressure equipment as well as the whole station for a typical month has been given showing the heat consumption of the two pressure turbines, the load distribution, and the net result for the station. Considerable detail is given concerning the utility factor of the entire installation and the effect the various individual parts have had on this factor.

In a paper of this nature, it is necessary to discuss the faults more in detail than those parts which have functioned perfectly from the start. It is safe to assume that the Northeast high-pressure installation has been no different from others in that some one part or parts have given more or less trouble. It must be remembered that, when this installation was made, equipment of the nature needed was not entirely past the experimental stage. The manufacturers offered equipment the fundamental design of which was based on experience obtained on other installations of lower pressure where they believed operating conditions were similar. In the installation described, present experience has shown that, due to one cause or another, conditions obtained on this job were not entirely what was expected by the manufacturer, and some of the troubles covered in this paper have been the result. Where troubles of this nature occur in what might be considered pioneering installations, criticisms of manufacturers or designing engineers should not be of a destructive nature.

While this paper must of necessity stress certain parts of the equipment more than others, it is not the intent or desire of the author to cast reflections on any manufacturer or his product.

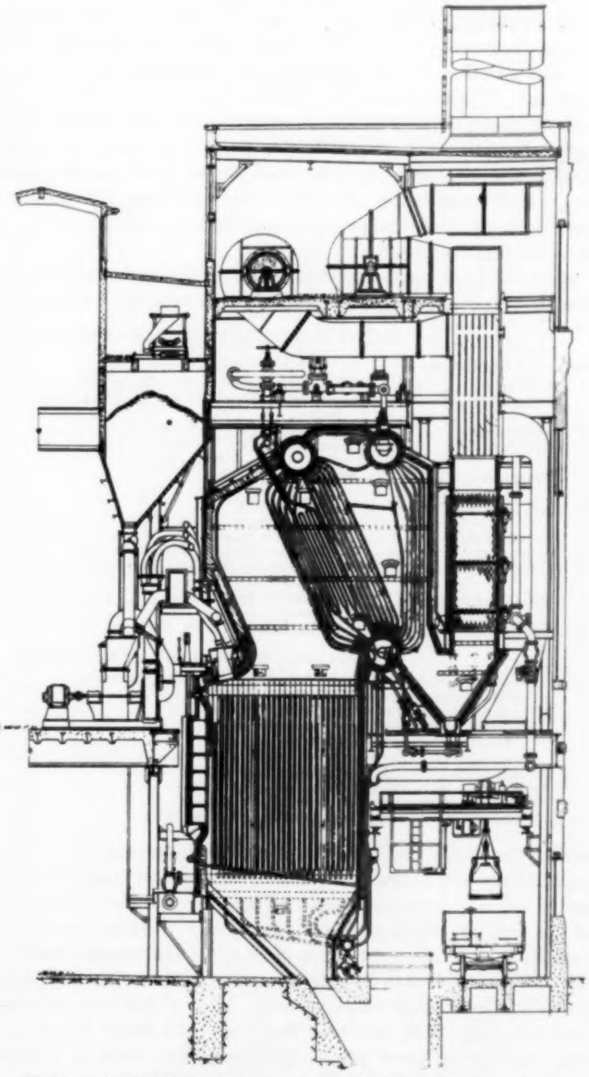

Fig. 1 Cross-Section Through 1400-Lb. Boiler Unit

While errors have occurred, they were in most instances from causes which were beyond both the manufacturers' and the engineers' scope of knowledge or control at the time the design was made. The most whole-hearted cooperation has been experienced in every case between the manufacturers and the purchaser's engineers. The solving of the problems has undoubtedly broadened the industry knowledge, and it is through the working

---

[1] Assistant to Vice-President in charge of production, Kansas City Power & Light Company. Assoc-Mem. A.S.M.E. Mr. Keeth attended Carnegie Institute of Technology and Armour Institute of Technology and received the degree of B.S. from the latter school. He has been continuously in the employ of the above company since leaving school with duties involving power-plant design, construction, and operation.

Presented at the Kansas City Meeting, Kansas City, Mo., Sept. 7 to 9, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

out of difficulties of this nature that the art of engineering advances.

Many descriptions have appeared in various engineering publications of high-pressure boiler and turbine installations made in this country. Among these have been some brief comments on the high-pressure equipment at the Northeast Station of the Kansas City Power & Light Company. Most of these articles have been written from the design and construction point of view and have touched on the predicted performance only as it was necessary to justify the investment. While many of the high-pressure units have been in operation for several years, few figures covering the actual performance of the equipment have appeared. It can be safely assumed that the installations have been successful, otherwise the use of the higher pressures would not have come into such wide use.

In February, 1929, a paper was presented at the Midwest Power Conference in Chicago which showed the economic basis for the selection of the high-pressure equipment at Northeast Station.[1] The boilers and turbine had been put in service only a short time previous to the presentation of that paper, hence any comments made therein had to be in the nature of predictions. More than two years have now elapsed and it should, therefore, be of considerable interest to see how near the estimates have been met in actual practice, and also to know something of the operating experiences.

Since the equipment was first put in service in January, 1929, a considerable amount of experimental work with many changes resulting therefrom, had to be done on the radiant reheaters. These experiments and changes extended over a period of nearly a year and a half and were the primary cause for the low utility factor of the equipment as a whole. It usually required one to two months to determine the effect of many of the changes made, as they frequently had to do with the ability of materials to stand up under continued high temperatures. Most of this work was completed in July, 1930, and from that time until about February of this year, operation of the equipment settled down to a regular routine which, it was believed, would be indicative of operation during the normal life of the equipment. However, in February some trouble began to develop which showed that certain parts of the reheaters would not stand up against the temperatures obtaining and give a reasonable life. Further changes were decided upon, the materials for which could not be obtained until June, thus leaving the answer for its entire success to some date in the future.

MAJOR EQUIPMENT OF NORTHEAST STATION

No.	Equipment	Manufacturer and Type	Size
2	Boilers	Combustion Engr. Corp., Type VX	16,950 sq. ft.
	Water walls	Combustion Engr. Corp., Bare and finned tube	3,050 sq. ft. per boiler
2	Superheaters	Superheater Co., Convection	2,650 sq. ft. per boiler
2	Reheaters	Superheater Co., Shielded Radiant	
6	Pulverizers	Raymond Imp. No. 90	15,000 lb. per hr. each, 3 to each boiler
36	Coal burners	Lopulco	9—8 in. to each boiler 9—4 in. to each boiler
2	Economizers	Combustion Engr. Corp., Finned tube	10,891 sq. ft. each
2	Air heaters	Combustion Engr. Corp., Plate type	39,270 sq. ft. each
2	Boiler-feed pumps	A. S. Cameron, 6-stage centrifugal, motor driven	900 g.p.m.
1	Boiler-feed pump	DeLaval Steam Turbine Co., motor driven	900 g.p.m.
1	Turbo-generator	Westinghouse E. & M. Co.	12,500 kva.

GENERAL OPERATING CONDITIONS

Maximum pressure for which boiler is designed, lb. gage	1,400
Normal operating drum pressure, lb. gage	1,350
Maximum evaporation per boiler, lb. per hr	225,000
Normal evaporation per boiler, lb. per hr	185,000
Pressure at turbine throttle, lb. gage	1,250
Temperature at turbine throttle, deg. fahr	725
Back pressure at turbine exhaust, lb. gage	315
Superheat in exhaust at full load, deg. fahr	22
Pressure of steam out of reheater, lb. gage	290
Temperature of steam out of reheater, deg. fahr	700

Equipment and Operating Conditions

The equipment consists of two 1700-hp., 1400-lb. boilers and one 10,000-kw., 1200-lb. turbine. The boilers are arranged for pulverized-coal firing, using the unit system. Furnaces are completely water walled, with radiant reheaters, originally shielded by water-wall tubes, located in the side walls. The superheater is of the convection type, located in the first pass of the boiler. Fig. 1 shows a cross-section of the boiler unit.

Reheaters

The early months of the operation of this installation involved frequent interruptions. However, after the first few weeks practically all of the outages were due to reheaters. It was apparent from the start that the reheaters had insufficient surface, under the furnace conditions that prevailed, to raise the temperature of the exhaust steam to a point even approximating that desired. The many changes made in the reheaters and burners, and also air adjust-

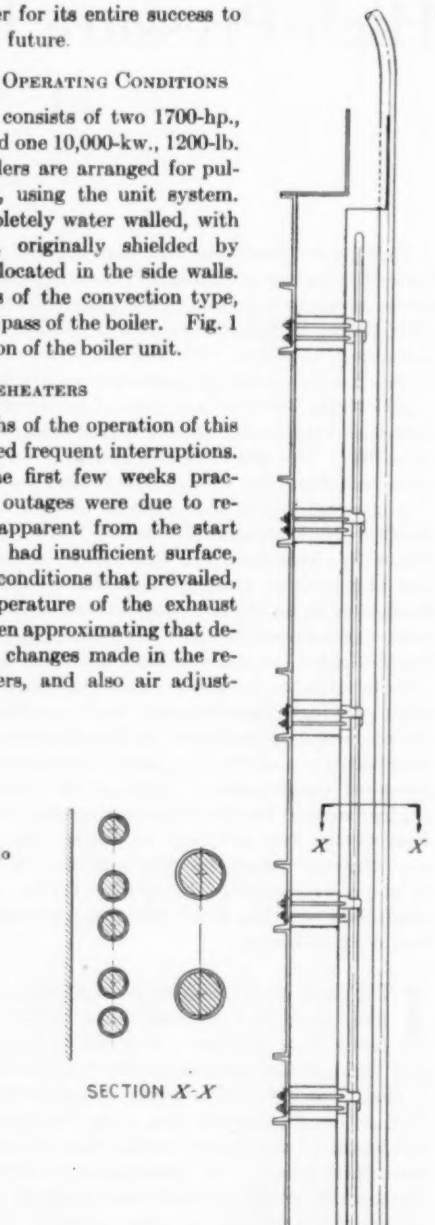

Fig. 2 Original Reheater Arrangement

---

[1] "High-Pressure Turbine Installation of Kansas City Power & Light Company," by Edwin Jowett, Trans. A.S.M.E., vol. 51, no. 1.

ments, involved much "cutting and trying." This resulted in one or the other of the boilers being out of service almost continually until the changes completed in July, 1930, had been made. Many of the changes made on these reheaters required anywhere from a week to six weeks to complete and required also the manufacture and shipment of new tubes and other miscellaneous parts, all of which involved the customary delays in obtaining material from the mill and in shipment. After the July change was made, very reliable service was obtained from the equipment until February, 1931. At that time, leaks began to develop in the reheater tubes which, examination showed, were due to overheating of the tube walls. It was possible, however, to continue operation with occasional shutdowns until June, 1931, after which a further change was made in tube materials with the view of obtaining better life from the reheaters.

While the problem of increasing the reheat temperature would appear to involve nothing more than an increase in surface, this very solution became particularly difficult to accomplish due to lack of space and excessive temperature resulting from the scrubbing action of the flame where space could be found available. Fig. 2 shows the original reheater arrangement in each side wall of each boiler. The reheater was designed for a rise of 250 deg., whereas only 125 deg. was obtained. The lack of temperature rise was due, at least in part, to the fact that the path of flame travel in the furnace exposed only a portion of the reheater surface to radiant heat. When changes were made in the firing conditions to eliminate this trouble, large quantities of slag accumulated on the reheater and water-wall tubes which offset any gain made. Various arrangements of slag blowers were tried without effective results.

The next effort to increase reheat temperature was made by removing every other water-wall tube, thus reducing the shielding effect on the reheater tubes. While this change had some effect, it was far from adequate to meet the needs. Additional reheater elements were next attached to the furnace side of the water-wall tubes as shown in Fig. 3. These gave practically the desired temperature, but the life

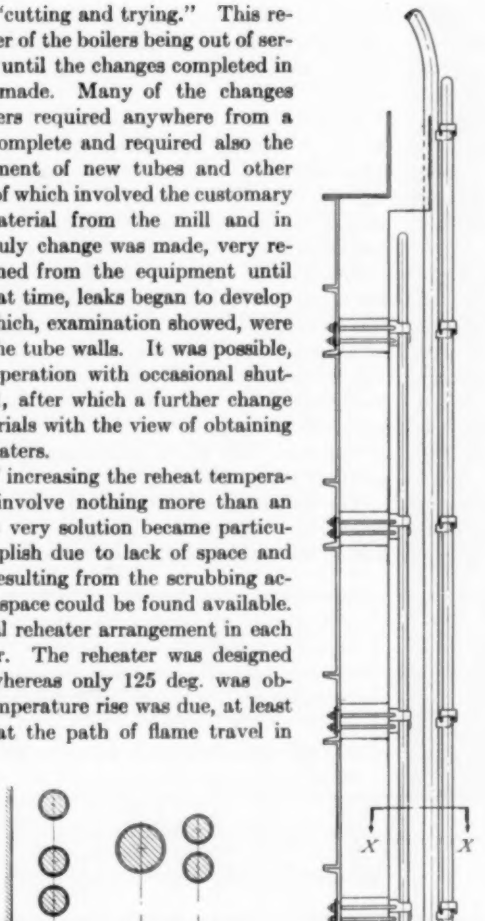

Fig. 3 First Major Change in Reheater

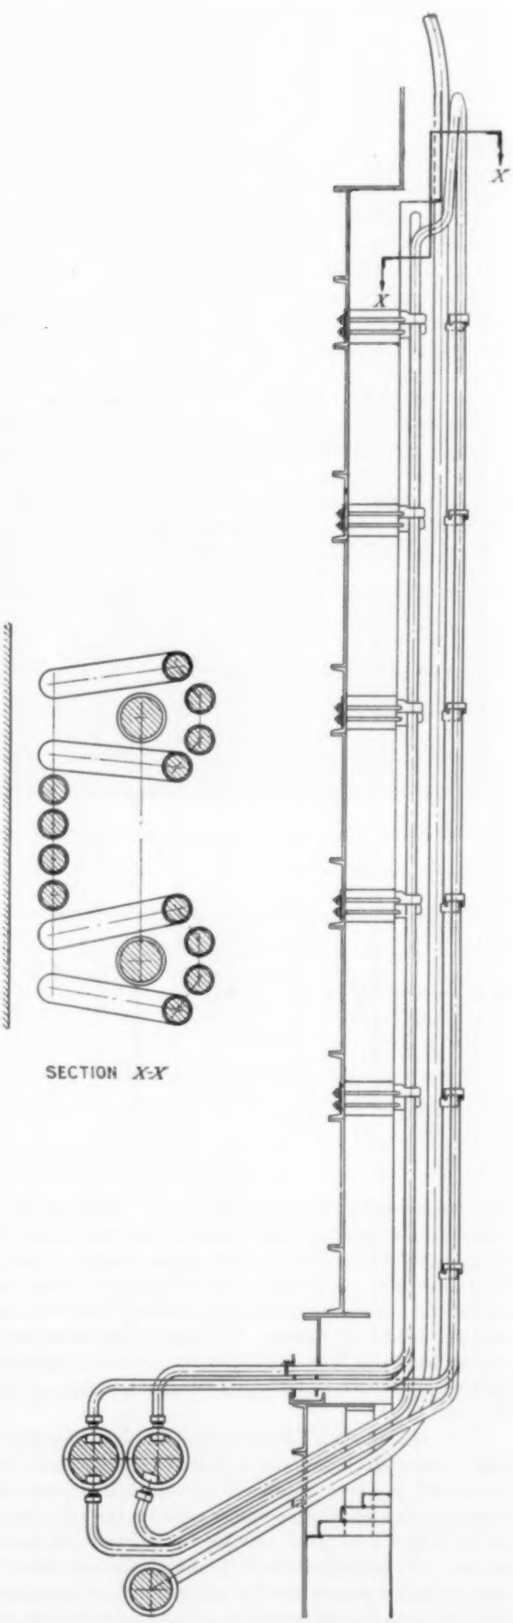

Fig. 4 Second Major Change in Reheater

of the tubes in certain locations of the side walls proved to be only a few days. Thermal couples embedded in the tube walls showed temperatures on the hot or outlet leg as high as 1200 deg. These temperatures were taken at point *A*, Fig. 3, so that tube-metal temperatures considerably in excess of this existed within the furnace. The additional elements were, therefore, removed from these hotter parts of the walls, and only those were left in where subjected to less severe conditions. The final result was a temperature rise but little better than that originally obtained.

It was noted, however, when the change shown in Fig. 3 was made that only the outlet tube or hot leg of the element attached to the furnace side of the water-wall tube failed or showed any distress due to excessive heat. It was, therefore, believed that elements could be made with inlet legs on the outside or furnace side of the water-wall tubes and outlet legs behind and shielded by the water-wall tubes. Accordingly, this arrangement was made up and installed as shown in Fig. 4. All of the old elements behind the water-wall tubes were left in place except those that had to be removed to make room for the hot leg of the new elements. This change was completed in July, 1930, and appeared to be the permanent solution to the problem.

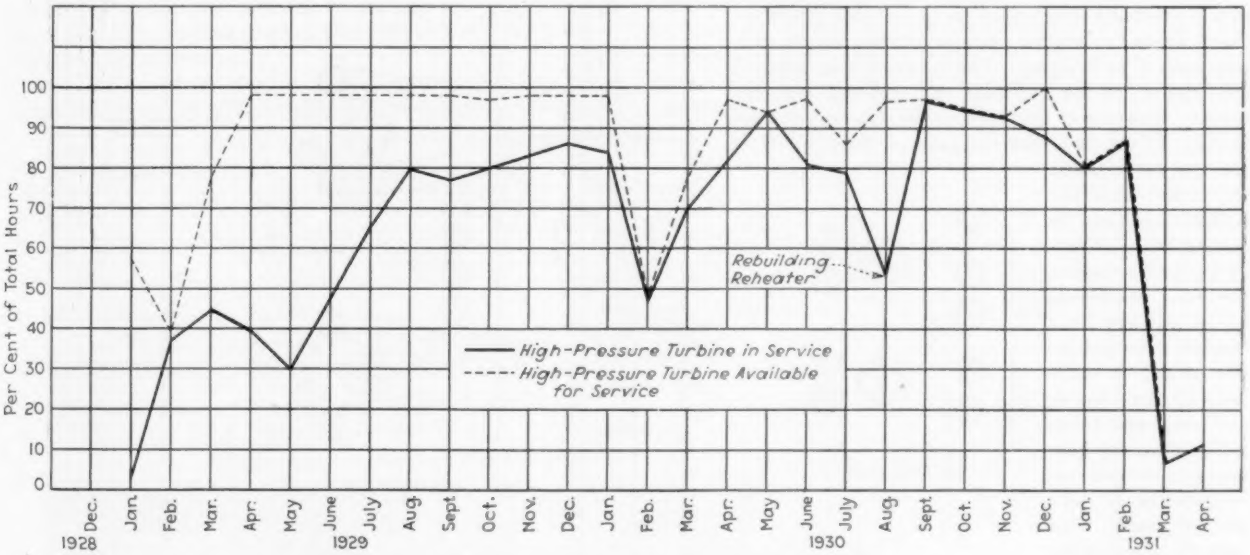

Fig. 5 Turbine Service and Availability Record

The proper reheat was being obtained. However, as previously mentioned, occasional leaks began to develop in the furnace side reheater tube near the top after seven months of practically continuous service. Laboratory examinations of these tube failures showed that metal temperatures of around 1100 deg. had obtained near the points of failure. Sections of the tubes removed from points near the failure showed no alarming signs of overheat externally, but showed a heavy internal coating of magnetic oxide of iron.

Up to this time all reheater tubes had been manufactured from low carbon steel meeting A.S.T.M. specification No. A83-27. Inasmuch as there appeared to be, on this particular job, no other location for reheaters more suitable, the only solution seemed to be to find a material suitable for the tubes in the existing location. An investigation of Enduro or KA-2 showed it unsuitable at high temperature for use where fuels contained sulphur, and also that KA-2S would be unsuitable where the sulphur content of the fuel exceeded 2.5 per cent. Inasmuch as most of the fuel used at the station contains at least 3 per cent sulphur, these two alloys, representing the best of their class, were ruled out. Experience at the plant on booster superheaters shows the chrome-vanadium alloys to be little or no better than low-carbon steel.

A year's use of the experimental high-temperature superheater at Detroit had shown calorized low-carbon-steel tubes quite effective in resisting high temperatures both outside and inside the tube. While the year's use seemed to show some thinning of the outer calorized coating, it was believed to be in such condition that a very reasonable life could be expected from the calorized units. As these metals just mentioned seemed to cover the better known high-temperature resisting metals for tubes, it was decided to try the calorizing. Accordingly, two complete sets of elements were made up to the same form as those shown in Fig. 4, except that the leg attached on the furnace side of the water-wall tube was calorized both inside and out. The two reheaters so equipped were put in service the early part of August of this year, and will, it is confidently believed, prove the final solution to the reheater trouble.

The preceding outlines only the major changes made to the reheaters. Many minor changes were made on the first and second installations such as the use of orifices for changing steam distribution, alteration of burners, and finally the addition of auxiliary burners near the bottom of the side walls. All of these changes, particularly the latter, have contributed their share in the solution of the problem. The last-mentioned item, namely, the auxiliary burners, has been particularly effective in improving furnace conditions and reducing slag. While all of the changes were more or less of a "cut-and try" nature, they were all based on careful experiment and observation which took much time to accomplish.

Particular reference has been made to this reheater trouble because of its bearing on the utility factor of the equipment. During the first six weeks' operation, there were, of course, many other difficulties which caused some outages. These were, however, of a nature more or less expected with the starting of new equipment and were soon overcome.

High-Pressure Turbine

The dependability or service availability of the turbine has been high. Some trouble was experienced during the first three months with balance of the generator rotor and turbine alignment. However, after correcting these troubles, its service availability was nearly 100 per cent until its first inspection after 13 months' use. With the exception of a few minor items, the turbine was found to be in perfect condition. During the second year the turbine continued to give almost equally good service from the mechanical standpoint. However, trouble experienced during the first year from scale deposit on the blades continued throughout this second year, necessitating frequent washing. This trouble evidenced itself by loss of load and a gradual building up of the pressure on the reaction blading. More detailed comment is made later concerning turbine-scale troubles.

About the first of March of this year, the high-pressure turbine was taken out of service for its second annual inspection. The unit had apparently been operating well up to this time, but it had been noted that the last two washings had not had the usual effect in increasing its load-carrying capacity or reducing the pressure on the reaction blading. It was presumed that the blades were badly scaled up and would require scraping. On opening the turbine, it was found that many of the wedges holding the revolving impulse blading had come out, and some had passed through the reaction blading, bending it so badly that the area through the blading was greatly reduced. It was this condition, and not the scale formation, which had caused the last load reduction. The manufacturer felt that the wedges had been loosened by the sudden temperature changes while washing the turbine and recommended returning the spindle to the factory to have a different type of wedge installed which would be less subject to this objection.

This was accordingly done, and in addition some field changes were made to the wedges for the nozzle and impulse blades. Some defective material used in the high-pressure and dummy packing had also failed, causing considerable damage to the remainder of the packing. New packing was installed on the high-pressure end of the unit. There seems to be little doubt

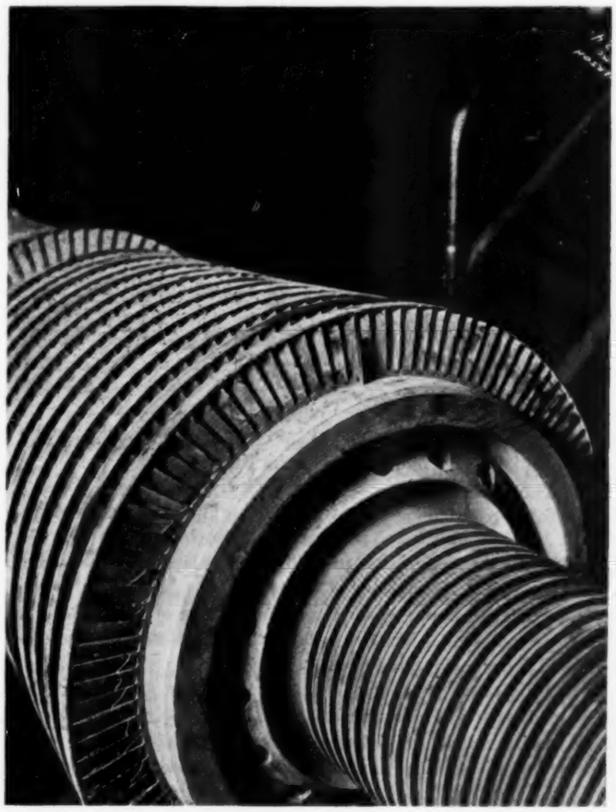

FIG. 6 TURBINE SCALE DEPOSIT

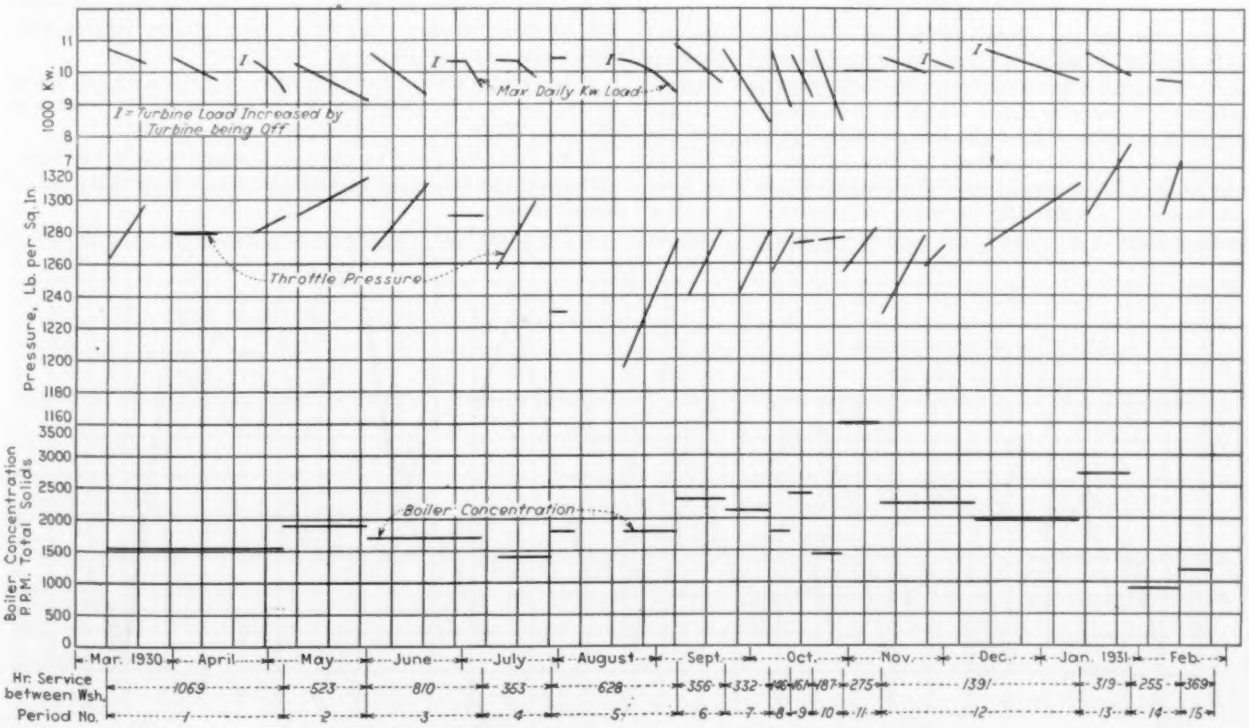

FIG. 7 CURVES SHOWING EFFECT OF SCALE ON TURBINE BLADES

that the troubles which appeared at this inspection have been permanently corrected. There was at no point in the unit any evidence whatever of water cutting or erosion, both the stainless-steel impulse and nickel-reaction blading being in perfect condition. There had been no leakage in the casing joint. The trouble with the wedges was probably due to lack of knowledge on the part of the manufacturer of the conditions that the unit would have to meet in being washed, and in the case of the packing, to defective material. Neither case of trouble could be attributed to the high operating pressure.

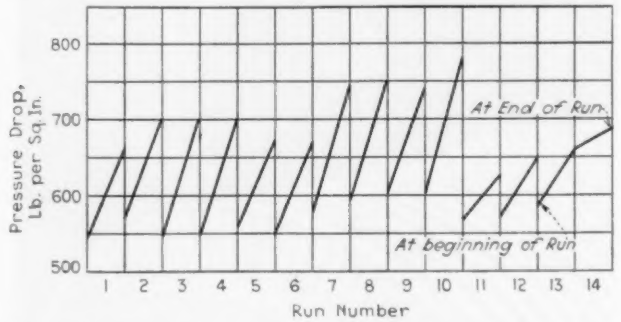

FIG. 8 CURVES SHOWING EFFECT OF WASHING ON PRESSURE DROP THROUGH REACTION BLADING

During the early months of this year some trouble was experienced with the oil-balanced throttle valve. Several changes were made which have apparently corrected the troubles. These troubles with the throttle valve accounted for the decrease in the availability of the turbine just prior to the March overhaul.

Curves, Fig. 5, show the amount of time the turbine has actually been in service and also the amount of time the turbine has been available for service.

TURBINE-BLADE SCALE

The trouble with scale deposit on the turbine blades has been, and still is, sufficiently serious to warrant somewhat detailed comment.

No scale deposit has ever been formed in either the primary superheater or reheater tubes. It seems to form only on the last three rows of blades of the high-pressure turbine and again in the lower stages of the low-pressure turbines operating off the exhaust of the high-pressure unit. The analysis of the scale from both locations is essentially the same and shows it to consist largely of silicates of iron and aluminum which are quite insoluble in water. Fig. 6 shows the scale deposit found on the last row of high-pressure turbine blades at the time of the first annual inspection of the turbine.

In general, the scale has been quite effectively removed by washing the unit with saturated steam when operating at less than 1000 r.p.m., and exhausting to atmosphere. Due to the insoluble character of the scale, it is believed that the washing effects a cracking of the scale due to temperature change, and also an actual scrubbing action due to the entrained water. In some cases, allowing the unit to stand idle for sufficient time to become cold has proved quite effective in scale removal. Here the action must be purely a weathering or cracking.

Curves, Fig. 7, show the operation of the turbine from March, 1930, to March, 1931, divided into periods between washings. On these curves are plotted the maximum possible daily kilowatt load, throttle pressure, and boiler-water concentration. The letter *I* opposite the maximum daily loads indicates the increase in load due to the unit having been out of service at least long enough to cool off. The failure to increase the load by washing as shown the latter part of January and middle of February was explained by the bent condition of the turbine blades as found on inspection and as previously described. Fig. 8 shows the effect on the pressure drop through the reaction blading by each washing.

An enormous amount of experimental work has been done in an effort to eliminate the scale formation on the turbine blades. While it may seem that a solution should have been reached by this time, it must be remembered that the collecting of data for a study of this kind requires much time. This same problem of turbine scale is confronting some of the largest plants in the country and is commanding the study of many research engineers, including Dr. Straub of the University of Illinois. He estimates that his investigation program will take nearly two years to complete. In general, the experimental work done here and the conclusions drawn therefrom are enumerated below:

1 Numerous tests were made to determine the carry-over with various boiler-water concentrations. Results showed no apparent difference in carry-over with concentrations varying from 3600 p.p.m. down to 100 p.p.m.

2 Tests were made to note the effect of water level and rating on carry-over. No difference was observed within reasonable operating limits.

3 All make-up going to the high-pressure boilers was eliminated to reduce concentration and impurities. Results showed no improvement.

4 The phosphate feed was reduced and the PO_4 in the boiler

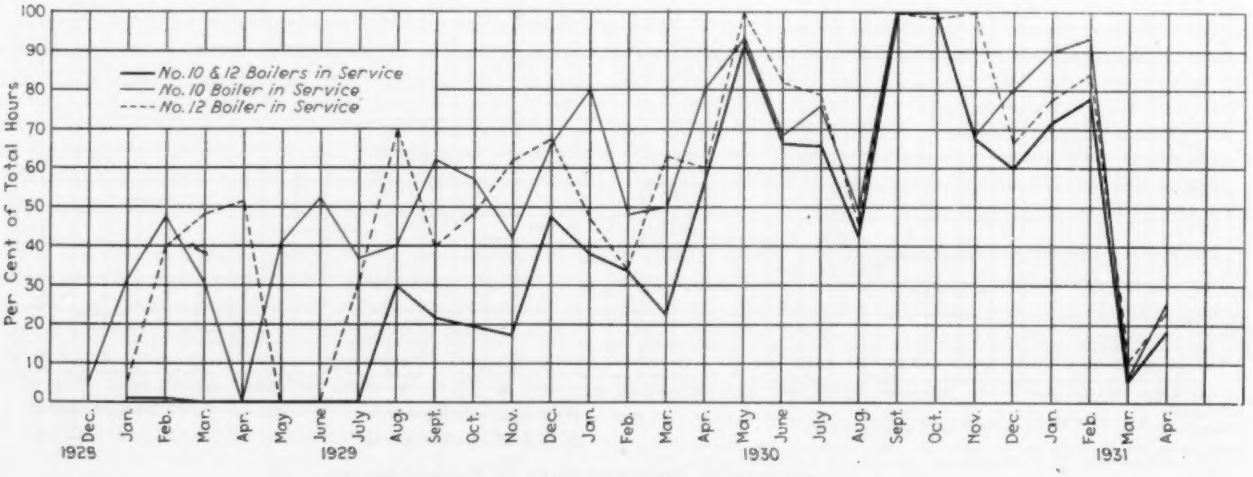

FIG. 9 BOILER SERVICE AND AVAILABILITY RECORD

water was cut from 60 p.p.m. to 3 p.p.m. This reduction has showed no benefits.

5 The concentration was reduced again to about 200 p.p.m. to see if the carry-over tests in item 1 were correct. Scale formation was apparently just as rapid.

A definite plan for further investigation of the turbine-scale trouble along other lines has been laid out and is in progress, and it is hoped that a solution will soon be found.

Boilers and Auxiliaries

The boilers, water walls, superheater, and economizer have developed no defects and give no indications that maintenance will be any higher than on the 300-lb. pressure boiler units in the plant. There have been three boiler-tube failures—the first due to a defective tube, the second damaged due to the first failure, and the third due to almost complete stoppage of circulation in the tube by mud resulting from a serious condenser leak. The tubes are absolutely free of scale and have never been turbined. Careful and correct control of the oxygen content of the feedwater has successfully prevented any pitting or corrosion either in the boiler, water walls, or economizer.

Boiler auxiliaries which include pulverizers, forced- and induced-draft fans, and boiler-feed pumps have proved quite as dependable as the low-pressure service and, therefore, require no particular comment. The same can be said of feedwater regulators, valves, pipe joints, and piping.

NORTHEAST STATION PERFORMANCE, SEPTEMBER, 1930

Total power generated, kw-hr.	39,407,000
Net output, kw-hr.	36,705,700
Generated on high-pressure turbine, kw-hr.	6,561,000
Generated on 300-lb. turbines on exhaust from high-pressure unit, kw-hr.	22,150,000
Generated on 1200-lb.–300-lb. combination, kw-hr.	28,711,000
Generated on 300-lb. units with steam from 300-lb. boilers, kw-hr.	10,696,000
Auxiliary power used by high-pressure boilers, kw-hr.	1,334,600
Auxiliary power used by 300-lb. units operating on exhaust from high-pressure unit, kw-hr.	735,000
Total auxiliary power used by 1200-lb.–300-lb. combination, kw-hr.	2,069,600
Auxiliary power used by 300-lb. units with 300-lb. boilers, kw-hr.	632,400
Heat rate of high-pressure unit based on 82.5 per cent boiler efficiency, B.t.u. per kw-hr.	4,400
Heat rate of 300-lb. units operating on exhaust from high-pressure unit, B.t.u. per kw-hr.	15,955
Heat rate of 300-lb. units operating with 300-lb. boilers,[a] B.t.u. per kw-hr.	17,206
Heat consumption high-pressure unit (6,561,000 × 4400), million B.t.u.	28,869
Heat consumption 300-lb. units on exhaust of high-pressure unit (22,150,000 × 15,955), million B.t.u.	353,390
Heat consumption of 300-lb. units on steam from 300-lb. boilers (10,696,000 × 17,206) million B.t.u.	184,030
Total consumption, million B.t.u.	566, 289

[a] Actual 300-lb. boiler efficiency 76.5 per cent due to large amount of banking.

$$\text{B.t.u. per kw-hr. generated} = \frac{566{,}289{,}000{,}000}{39{,}407{,}000} = 14{,}370$$

$$\text{B.t.u. per kw-hr. output} = \frac{566{,}289{,}000{,}000}{36{,}705{,}700} = 15{,}414$$

Reference has been made in several places to the service factor of the equipment and a curve is given to show the service and availability of the turbine. Curves, Fig. 9, show the service obtained from each of the high-pressure boilers. As graphic proof of the statement made regarding reheaters, a curve, Fig. 10, is shown to indicate the percentage of outage due to reheaters. A gradual increase in the service will be noted up to the time of the completion of the reheater rebuilding in June, 1930, after which time, and up to the turbine overhaul in March, 1931, a condition obtained which marked a very good service record. The period of outage during March and April was due to turbine repairs as previously described. After the reheater troubles are permanently repaired, continuous runs for the boilers of from 100 to 125 days will probably mark the practical limit. After such intervals, some repair work or replacements are required on the induced-draft fans. A general cleaning of the boiler and air heater has proved advisable and usually some minor refractory repairs must be made after such a period.

There is very little change in the operating efficiency of the boiler units over continuous runs of 100 days or more. This is very clearly indicated by Fig. 11, which shows all essential operating pressures and temperatures for each day throughout a 106-day operating period. A study of this curve sheet indicates that considerable credit should be given to the methods which have been devised and utilized for removing slag while in service, particularly when the type of coal used is considered. The coals contain more than 15 per cent low-fusing ash and have a high sulphur content. Space limitations restricted the furnace size such that a normal combustion rate of nearly 20,000 B.t.u. per cu. ft. is maintained without the use of turbulent burners. The slag problem at first appeared the most serious factor against even reasonably long operating periods and its solution has been the result of untiring effort toward better combustion and improved slag-removal facilities. The nine 4-in. auxiliary burners near the bottom of the furnace have done much toward obtaining more complete combustion within the furnace proper, and have thus greatly reduced the slag deposit within the boiler itself.

From the time the two high-pressure boilers first came into service up to May, 1931, a period of 28 months, they were out of service 42.6 per cent of the time. The reheaters caused 40 per cent of this outage. If the reheaters had given no trouble, the boilers could have been in service 74.4 per cent of the total time, even including the earliest operating period. The boilers were out of service during March and April, 1931, for overhauling of the turbine, or 6.5 per cent of the 28-month period. If this outage along with the reheater trouble were not charged against the boilers, they would have been available 80.9 per cent of the time. For the year 1930 alone, the boiler availability was approximately 85 per cent.

Operating Economies

Now that it has been fairly well established that the equipment is dependable and that the original estimate that the equipment could be operated at an annual load factor of about 80 per cent is reasonable, it should be of interest to note what the actual economy of the installation has been. Accordingly the following data taken from the monthly operating report of Northeast Station for September, 1930, shows what is being accomplished by the operation of this unit. It should be borne in mind that the efficiency of this cycle was somewhat impaired during this month and also during several previous months by the reduction in output of the high-pressure unit by the scale deposit on the blades. When this trouble is corrected, results should be somewhat better.

Had there been no high-pressure equipment operated at the plant during this month, the 300-lb. pressure boilers would have operated at an overall efficiency including banking of about 79 per cent instead of 76.5 per cent as shown, lower banking losses and better boiler load factor accounting for the difference. This difference in boiler efficiency along with the normal auxiliary power consumption would have resulted in a plant heat rate of 17,600 B.t.u. per kw-hr. net output. This is a reduction for the plant heat rate of 2186 B.t.u. per net kw-hr. due to the use of the high-pressure equipment during this particular month. This is a reduction somewhat in excess of that originally calculated. It was, however, obtained under more favorable conditions; namely, the proportion of total load carried on the 1200-lb.–300-lb. combination was higher than that originally anticipated. Failure of the system load to increase, due primarily to the business depression, has brought about this condition.

The results obtained from the high-pressure equipment has been such, however, that there is no question regarding its justification. The cost of the installation was about $1,650,000, and based on the actual operating economy of the equipment a load factor of 36.5 per cent would result in a saving which would justify the increase in investment over 300-lb. equipment using coal at the original calculated cost of 67,000 B.t.u. for 1 cent.

The situation can be summarized by saying that, all things considered, this company is satisfied the investment was justified and that operation at this pressure is entirely practical. Unless newer and unforeseen developments prove better, or unless the cost of fuel has become too low to justify the investment, when the time comes for further expansion of this station, the use of additional 1200-lb. equipment will be made.

Discussion

M. K. Drewry.[3] The author does well to call special attention to the turbine clogging problem. It is felt that most stations are possibly losing a per cent or two in station economy due to undetected turbine clogging. Continuous operation of high-pressure turbines has served to point out the existence of these losses that escape detection in usual operation of condensing machines. The percentage capacity loss in the former case is greatly more, and is readily detected therefore.

---

[3] Assistant Chief Engineer, Power Plants, Milwaukee Elec. Ry. & Light Co., Milwaukee, Wis. Jun. A.S.M.E.

Low boiler-water concentration is the only known positive corrective of turbine clogging at the Lakeside Station. Long-time experience with four high-pressure turbines proves the method thoroughly efficient, but learning the technique of correct boiler-water treatment with high make-up or the elements of proper boiler design for negligible entrainment is certainly desirable for less favorable conditions.

Reliable means of measuring boiler-water carry-over are needed to intelligently study this subject of turbine clogging. When dealing with boiler-water concentrations of 100 p.p.m. and carry-over of 0.1 per cent, only $^1/_{10}$ of 1 p.p.m. of boiler water appears in the condensed steam. Obviously, extremely sensitive measurements are necessary. Electrical conductivity measurements are affected by dissolved gases to the extent that several hundred per cent error may occur under some conditions. Sensitive phosphate tests after concentration by evaporation appear to offer practical help. Priming to the extent of 3 per cent moisture carry-over has been noticed twice after adding 100 p.p.m. of sodium phosphate to high-pressure boilers. Chemistry of the boiler water is of major importance in this problem.

The freedom from corrosion mentioned by the author shows commendable operation. Absence of feed-pump troubles is also of special interest. Outlet flue-gas temperature is well maintained at about 320 deg. fahr. for 100-day periods. A 73 per cent station generation by 1200-lb. equipment reduced the low-pressure station heat consumption by $12^1/_2$ per cent, indicating that the higher pressure is 17 per cent more efficient.

Bert Houghton.[4] It has been a pleasure to read the frank discussion of the difficulties in developing the Northeast Station's high-pressure installation. Definite progress can be made when basic facts are clearly disclosed, and the Kansas City Power and Light Company is to be congratulated on its initiative in putting in one of the first high-pressure installations and then in coming forward with detailed experiences.

Now that this boiler, reheater, and turbine have apparently been brought to a point where any major change in design is not to be expected, it would be interesting to have the benefit of a careful and detailed test on the operating characteristics of each element. The operating performance integrated over a period of time, as given in the paper, is of course valuable information and useful in justifying high-pressure installations; but it is also most interesting and necessary to have the efficiency characteristics over the range of loading, and for this installation it would complete the story which already has been so freely given. It would be also of interest to have the design heat rates included so that the three items could be compared—i.e., design heat rate, test heat rate, and operating heat rate.

John Hunter.[5] The paper has much of interest, particularly the last paragraph in which it is stated that the investment was justified and that the operation of 1200-lb. steam pressure is entirely satisfactory, and for further expansion of the station 1200-lb. will be used.

In the development of this high-pressure equipment, it has taken a great amount of courage, as well as engineering study and skill, and the men who have put forth this effort are to be congratulated for obtaining the results as shown by this paper on the Northeast installation.

The author lays stress on the trouble encountered with the reheater which no doubt was very aggravating, but engineers have found when placing tubes in the furnace exposed to radiant heat, carrying a gas only, that they have a serious condition with which to contend. This was demonstrated when the first superheater tubes were placed in a furnace exposed to the radiant heat. Many different designs and metals were used, causing interruptions in serviceability of the boiler units. However, the final difficulties were overcome by the manufacturers and operating engineers. It is gratifying to note by the paper that the troubles with the reheaters, like the superheaters, have been overcome.

John J. Grebe.[6] In view of the difficulties encountered by scale deposits in the turbines at the low-temperature end, it might be asked if any experimental work has been done to determine whether such scaling can be reduced by carrying out the first part of the superheating of the steam in tubes which have a carefully limited metal temperature. With a low steam velocity and low metal temperature, the solids may have a chance to precipitate in this section of the superheater, from which they might be removed with less trouble. The reason for this remark is that we expect in our design of a combination steam and diphenyloxide boiler to reduce the carry-over of the solids to a minimum by drying and preheating the steam with diphenyloxide-heated surfaces at approximately 700 deg. fahr.

John Van Brunt.[7] Referring to the auxiliary burners installed along the bottom of the side wall, the writer would confirm the statement by the author that the installation of these burners resulted in the shifting of the hot-flame area further forward in the furnace, giving a more even distribution of heat to the side-wall reheaters. The writer would commend to the attention of operators in general the very excellent results over a period of 106 days as indicated in Fig. 11. This chart evidences the fact that efficiency was well sustained for the entire period, that slag accumulation in the furnace or boiler was well under control, and that the operation in general reflects great credit upon the operating force.

Author's Closure

As to the effect of concentration on turbine-blade deposit, as brought forth in the paper, the amount of deposit on turbine blades did not appear to be any less when operating boilers with low concentration than with high concentration. Both tests operating at low concentration were unfortunately of rather short duration due to other causes necessitating removal of the turbine from service. The fact that the rate of decrease in load during these two short periods of low-concentration operation was practically as rapid as with high-concentration prompted the statement that in this case concentration did not appear to be the determining factor. Certain tests conducted by C. W. Foulk[8] seem to substantiate the author's belief that it is possible to have greater carry-over with low concentration.

Since presentation of the paper, operation of the boilers has been continued for about 90 days with a total concentration of about 100 p.p.m., with practically no improvement in the turbine-blade-scale trouble.

The author does not believe that turbine-blade-scale trouble can be remedied by the use of a low-steam-velocity superheater, as suggested by Mr. Grebe. The velocity of the steam does not seem to have any direct bearing on the dropping out of solids. The velocity of the steam through the lower stages of the turbine is many times that in the superheater, yet the deposit occurs in the turbine and not in the superheater.

[8] Paper on "Foaming and Priming of Boiler Water," presented at A.S.M.E. Annual Meeting, 1931.

Concerning the operating efficiency over the entire range of load, the installation described by the author was designed for base-load operation at its most economical capacity, namely, full load, and has been operated most of the time at as near that point as the condition of equipment would permit. The turbine operates either at 2500-kw. load or approximately 10,000-kw. load, depending upon whether one or two boilers are in service. The gain in economy with only one boiler in service, or when operating at 2500 kw., is low due to the high water rate of the single-valve turbine at light load. In this particular case, it is felt that the two boilers can be kept in service a sufficient amount of time to justify the full-load design.

Decomposition of Sodium Carbonate in Steam Boilers[1]

By REINHOLD F. LARSON,[2] URBANA, ILL.

This paper deals quantitatively with the extent of decomposition of sodium carbonate, which is present in many boiler waters and has an important bearing on the inhibition of caustic embrittlement and corrosion. Data are presented in the form of curves obtained from tests on a steaming laboratory boiler at various high pressures and with various feedwaters. The extent of decomposition occurring is found to be dependent upon several factors, the principal one being the amount of sodium carbonate in the feedwater. An attempt is made to correlate laboratory data with those obtained from operating plant boilers.

SODIUM CARBONATE as a dissolved salt in the water of a steaming boiler is not stable. The carbonic acid formed by hydrolysis cannot exist at the higher temperatures, but loses its carbon dioxide to the vapor phase. The continuous evolution of steam carries with it the carbon dioxide liberated.

As early as 1891, Paul[3] noticed the increase in causticity in boilers in which carbonate of soda was present in the feedwater, but apparently did not detect the carbon dioxide in the evolved steam. He described the reaction as follows:

$$Na_2CO_3 + H_2O \longrightarrow HCO_2Na + NaOH + {}^1/_2O_2 \ldots [1]$$

Hall, Kartch, and Robb,[4] who made an extended study of this decomposition reaction, paying particular attention to the noncondensible gases in the steam evolved from a small laboratory boiler at various low pressures, pointed out that the reaction is best expressed by:

$$Na_2CO_3 + 2H_2O \longrightarrow 2NaOH + H_2O + CO_2 \ldots\ldots [2]$$

They detected an enormous increase in the carbon-dioxide contents of the steam taken off when sodium carbonate was present in the boiler water. The oxygen content remained about the same as before introducing carbonate. The boiler water increased steadily in hydroxyl alkalinity. They found no evidence for believing that reaction [1] took place. Various other investigators have shown that reaction [2] occurs, but at temperatures below 50 deg. cent. is too slow to be measured.

The reaction is simply one in which one of the products is continuously carried away, the other remaining to increase the concentration of soluble salts in the boiler water. In an operating commercial boiler a continuous supply of reacting carbonate is brought into the boiler with the feedwater. Undoubtedly the amount decomposed is influenced by the partial pressure of the carbon dioxide in the vapor phase that is maintained. Temperature is known to accelerate the reaction. It has therefore been stated that the rate of decomposition of sodium carbonate is a function of the operating pressure and the percentage rating of the boiler.

Investigations concerning the quantitative determination of this decomposition reaction have been confined principally to laboratory apparatus that did not duplicate boiler-plant operation. Pressures and rates of boiling have been considerably lower than those used in modern boiler plants. Conditions of continuous feed and constant water level have in general not been maintained; consequently, the information obtained has had little application in a practical way.

An attempt to obtain information from an operating boiler was reported by C. E. Joos.[5] Some interesting information was obtained. He also reported a survey made of a large number of power boilers operated at various pressures and ratings and gave complete boiler-water data. The amounts of sodium hydroxide and sodium carbonate in a boiler water, if expressed as sodium carbonate and arranged in the ratio

$$\frac{NaOH \text{ as } Na_2CO_3}{(NaOH \text{ plus } Na_2CO_3) \text{ as } Na_2CO_3}$$

express the degree to which decomposition has proceeded, if all of the sodium hydroxide may be assumed to have originated from the carbonate. This ratio may be expressed as per cent decomposition. In these data it varies from 18.8 per cent to 88.9 per cent. There appears to be little correlation between per cent decomposition and either pressure or rating. No conclusions can be drawn, therefore, from these data other than that much of the sodium carbonate in a boiler is converted to sodium hydroxide, and the proportions of these that may exist in an operating boiler cover a wide range.

IMPORTANCE OF THE REACTION

It is desirable to know more about this decomposition and the extent to which it may occur in any particular boiler and in boilers in general. Many natural waters used as boiler feed contain sodium carbonate in large quantities. The pretreatment of feedwater to remove scale-forming calcium and magnesium com-

pounds often leaves considerable sodium carbonate in the treated water. Soda ash is a chief constituent of many boiler compounds.

It may be well to observe at this time that this decomposition phenomenon is common to all carbonates found in boiler feedwaters. However, many of these are only slightly soluble, and their contribution to the carbon-dioxide content of the steam and the increasing causticity of the boiler water is so slight in comparison to that contributed by sodium carbonate alone that for most purposes they can be neglected. The presence of magnesium chloride is known to accelerate the decomposition of calcium carbonate somewhat by precipitating out the highly insoluble magnesium hydroxide, thus preventing the accumulation of the hydroxyl ion. The use of sodium phosphate as a secondary treatment in the boiler drum effects a base exchange reaction precipitating out the insoluble calcium phosphate, thus building up the sodium-carbonate content, which in turn decomposes with a resultant increase in causticity. Where soluble phosphate is maintained in the boiler water, calcium carbonate may be considered potential sodium carbonate.

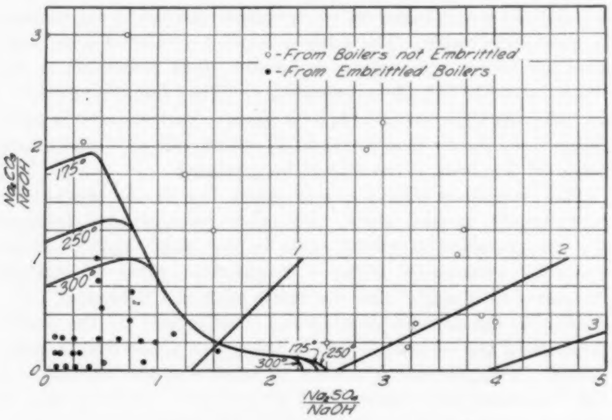

FIG. 1 RATIOS OF $\frac{Na_2CO_3}{NaOH}$ AND $\frac{Na_2SO_4}{NaOH}$ NECESSARY TO PREVENT EMBRITTLEMENT

The presence of hydroxyl alkalinity to a limited extent has been shown to inhibit corrosion. The maintenance of a hydroxyl-ion concentration of about 100 parts per million and a pH value of from 9 to 10.5 have been recommended. Soda ash is often used in small quantities to build up hydroxyl alkalinity and at the same time increase the pH value.

The presence of sodium hydroxide and the absence of sufficient quantities of certain inhibitors has been established as the chief contributing cause of caustic embrittlement, an intercrystalline cracking of the boiler plate which occurs in the seams and highly stressed areas of the boiler. Parr and Straub have definitely shown that the concentration of this caustic is possible in the seams and capillary spaces of the boiler, and to an extent sufficient to attack the grain boundaries of the adjacent highly stressed metal. Among the inhibitors are sodium carbonate and sodium sulphate. The presence of the latter in sufficient quantities is known to effectively prevent this type of cracking, and is recommended in the A.S.M.E. Code. In calculating the quantity of sodium sulphate necessary, the carbonate has been assumed as potential hydroxide, and the ratios for various pressures based on total alkalinity. The maintenance of these ratios has put a heavy burden on the boiler-plant operator who is also striving to keep concentration down by means of blowdown. It naturally results in excessive blowdown.

Later developments in the study of embrittlement have shown that the 1 to 1 ratio may be a trifle low, the other ratios amply safe, and that the sodium carbonate present may also act as an inhibitor. Fig. 1 is a chart taken from Bulletin No. 216 of the University of Illinois Engineering Experiment Station, "Embrittlement in Boilers," by Professor F. G. Straub. It is drawn from data on the solubility relations of sodium carbonate and sodium sulphate in a solution of 100 grams per liter of sodium hydroxide, a concentration of caustic found necessary to embrittle specimens in the laboratory. Wherever this concentration could be reached with sodium carbonate and sodium sulphate still in solution, embrittlement has occurred; wherever the ratios were such that these salts would precipitate out before this dangerous concentration was reached in the boiler seams, boilers were not embrittled. This chart shows clearly the extent to which carbonate is an inhibitor, and explains why certain boilers have operated for years with a high carbonate content in the boiler and with little sulphate, and have experienced no embrittlement. It offers the plant operator a chance to use the inhibiting power of carbonate in calculating the amount of sulphate necessary to insure safety from this type of cracking.

LABORATORY TEST WORK

Object. This series of tests is an attempt to study the decomposition reaction in various synthetic carbonate waters at various operating pressures and boiler ratings, and to seek an explanation for cases of extremely high and extremely low decomposition found in some operating boilers.

Test Apparatus. The apparatus used is pictured in Figs. 2 and 3. It consisted of a 10-in. extra-heavy seamless tube 30 in. long and heavily flanged at the ends so as to make up a cylindrical boiler suitable for high pressures. All connections to the boiler were made through the flanges, as shown in Fig. 3. The boiler was then suspended from a steel frame, and the furnace chamber was bricked in as shown. At a later date Transite baffles were added to protect the studs from the action of excessive heat.

The feedwater inlet was at the left or front end. A special high-pressure gage glass was procured and installed as shown. A blowdown line with valve was installed, as was also a blowdown condenser permitting volumetric measurement of blowdown at room temperature. A steel thermocouple well was installed as shown and bent so as to be completely immersed. An iron-constantan couple was made and inserted, with leads properly insulated with asbestos. A Leeds & Northrup recording potentiometer was used to obtain a temperature check on the reading of a pressure gage installed on the opposite end of the boiler.

In the rear flange was fitted a steam outlet with a needle-valve control. This led to a steam condenser from which condensate could be drawn into 5-gal. bottles and analyzed for alkalinity and carbon dioxide. Samples of boiler water were drawn off through a carbon filter and capillary tube into a steel bomb of about 300 cc. capacity. This bomb could then be disconnected and cooled before releasing the pressure.

Gas was used as a fuel, air being supplied by a fan. Separate valves for gas and air enabled considerable adjustment of gas-air ratios. The furnace was baffled so as to obtain a fairly long gas travel, the boiler being heated on all sides.

Feedwater was supplied by means of a displacement pump having an adjustable stroke, and driven by means of an induction motor through belt and speed-reducing gears. The source of water for building up the synthetic feeds used was condensed steam collected from radiators used to heat the building, and was stored in a steel barrel. This condensed steam averaged about 170 deg. fahr. and was practically free from dissolved carbon dioxide. The feed line was projected to the bottom of the barrel and kept the barrel full and at a maximum temperature at all times.

Synthetic feedwater was made up by weight in 100-lb. and

40-lb. lots, the required salts being weighed accurately in the anhydrous state on an analytical balance.

Operation. In most tests the boiler was filled about half full of the solution to be used as feed, and the boiler was fired. When the pressure had risen to the correct value, the steam take-off was begun and a sample of boiler water was drawn. The time taken to build up pressure varied for the various tests from $^1/_2$ hour to $1^1/_2$ hours, the latter for the higher pressures. The feed pump was then started and the steam valve manipulated so as to maintain a constant predetermined water level. It generally required an hour to secure the intended steaming rate. The pump was then allowed to run continuously, and being induction-motor driven, ran at approximately constant speed. Steam pressure was maintained by gas-burner adjustment. In general, the water level did not vary more than $^1/_4$ in. from normal when samples were drawn and pressure not more than 5 per cent. This condition was attained through constant attention of the operator in the early stages of a test.

A careful check was made on the total water fed to the boiler. All tests, unless specified, were run at the same setting of the pump stroke, but due to the variation in the volumetric efficiency of the pump and the regulation of the motor, the actual rates varied from about 95 lb. per hour at 150 lb. gage pressure to about 82 lb. per hour at a steam pressure of 1500 lb.

Water Analysis. The amount of boiler water drawn off for each sample varied from 0.4 to 0.6 lb., depending on how well the boiler pressure would fill the bomb. No difference in results was obtained by evacuating the bomb other than obtaining a full bomb each time, so that this procedure was given up. The sampling operation generally took several minutes, and no noticeable disturbance took place in the boiler. It is felt that a representative sample was obtained, as blowdown samples were identical with those taken from the bomb at the same time. The samples obtained were generally quite clear, although at times an iron-oxide suspension was noticeable. This settled within several hours and did not interfere with analysis. Samples were kept stoppered in flasks awaiting analysis.

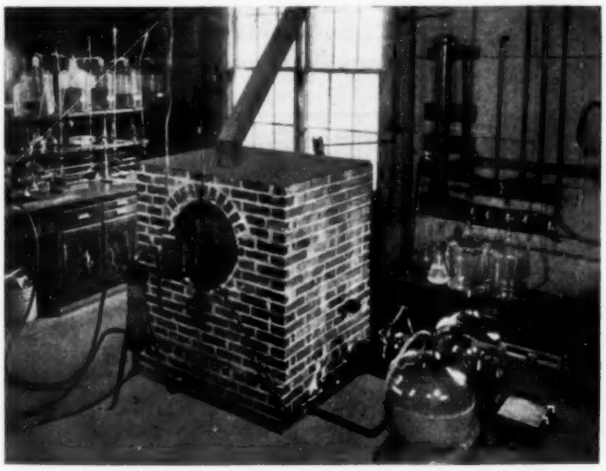

FIG. 2 APPARATUS USED IN TESTS OF DECOMPOSITION REACTION IN VARIOUS SYNTHETIC CARBONATE WATERS

Approximately $^1/_{10}$ normal hydrochloric acid was used in the ordinary double titration with phenolphthalein and methyl orange as indicators. The modified Winkler barium-chloride method was used as a check. Equal amounts were measured out in a pipette and transferred to separate flasks. The amounts used were such that at least 20 cc. of acid was used to obtain an end-point. For strongly concentrated waters a stronger standardized acid was used, as extreme dilution by the acid makes the methyl-orange end-point difficult to check. To the second sample was added 5 to 10 cc. of very slightly alkaline barium chloride. A 10 per cent solution was used, made alkaline with sodium hydroxide to set any dissolved carbon dioxide, and then neutralized to the end-point of phenolphthalein. The sample was then well shaken and allowed to stand about 5 minutes. It was then titrated with acid, being continuously agitated to avoid acid concentration, to the phenolphthalein end-point. The cubic centimeters used were recorded as hydroxide. The checks obtained by the two methods were very good when only carbonate and hydroxide were present in the boiler water.

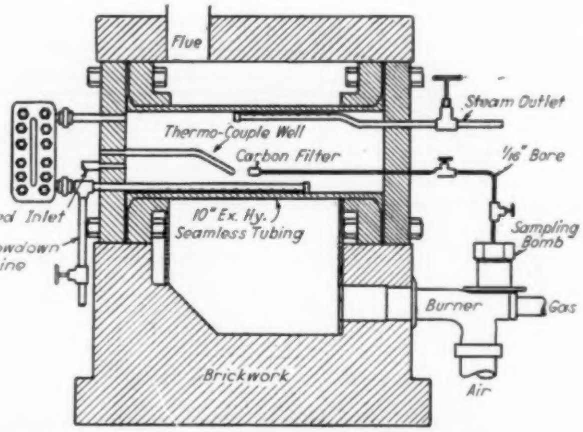

FIG. 3 SECTION THROUGH BOILER OF TEST APPARATUS

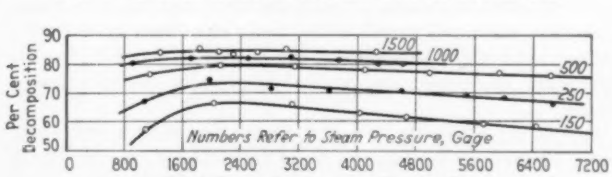

FIG. 4 400 P.P.M. NA_2CO_3 FEED

With the double-titration method there is a slight tendency to stop short of the true phenolphthalein end-point, giving a slightly higher carbonate content. Where only hydroxide is present, as in the case of the second titration, the end-point is sharply defined. In all of the foregoing titrations care was taken to keep all flasks stoppered and titrations were made as rapidly as possible in order to avoid contamination with carbon dioxide from air and breath. Such contamination increases the carbonate and decreases the hydroxide.

DISCUSSION OF RESULTS

Expressing the ratio:

$$\frac{\text{sodium hydroxide expressed as sodium carbonate}}{\text{total alkalinity expressed as sodium carbonate}}$$

in terms of per cent decomposition, and plotting these values against time and against total alkalinity, well-defined smooth curves are obtained. Fig. 4 is the series obtained from the tests using 400 parts per million sodium carbonate in the feedwater. It is apparent that a balance or equilibrium is soon established between the decomposition rate and the incoming sodium carbonate. The maximum per cent decomposition was obtained about two hours after steaming was started, thereafter decreasing steadily with increase in boiler-water concentration. It is noticeable that the higher pressures have proportionately less effect than the lower pressures. In all of these tests slightly over two concentrations occurred per hour.

Fig. 5 was obtained from tests using 150 parts per million sodium carbonate, and shows a similar balance after a somewhat longer time. Fig. 6 was obtained from a 50 parts per million feed. The extremely slow approach to equilibrium is noticeable especially so at the higher pressures. The irregular building up is probably due to failure to exactly duplicate the steaming rates during the first hour or so. Had these tests been run for a longer time, the maximums would undoubtedly have been more clearly defined. As might be expected, the decomposition is higher for this purer feedwater, and operating pressure becomes less a factor.

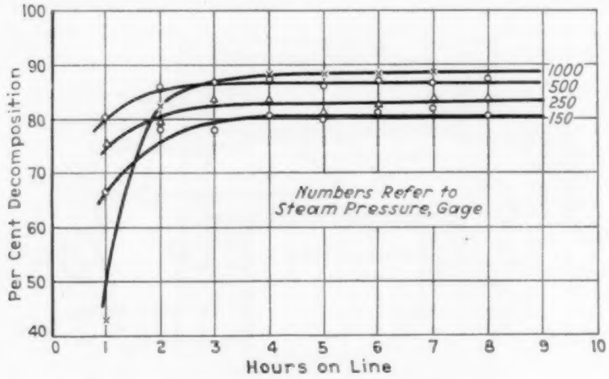

FIG. 5 150 P.P.M. Na_2CO_3 FEED

It was not advisable to run a similar test with a still purer water because of the time required to build up an appreciable concentration. Therefore the boiler was charged with a more concentrated solution at the start, and a 10 parts per million feed of sodium carbonate begun. Two such tests were run, the initial charges being 500 parts per million and 4000 parts per million sodium carbonate. The maximum per cents obtained were 91.5 and 90.4, respectively, with an operating pressure of 250 lb. A change in pressure to 500 lb. caused an increase of 1.2 per cent in the first test. Untreated water was then fed for five hours in the latter test, the decomposition rising to 94.2 per cent as an average for the last three hours.

In most tests a slight loss in boiler-water alkalinity was noticeable. Condensed steam from the boiler showed from 10 to 20 parts per million methyl-orange alkalinity expressed as sodium bicarbonate, indicating some carry-over. This did not change appreciably with boiler-water concentration. The presence of a few small leaks in connections below the water level at high pressures, and the possibility of baking of the salt on the surface above the water level, may account for the fact that total alkalinity actually decreased when 10 parts per million sodium carbonate was fed.

It was noticed in several tests that a sample drawn while the water level was falling would show a higher decomposition, and the opposite for a rising water level, coming back to normal when the water level was kept constant. This would indicate an equilibrium controlled by the partial pressure of the carbon dioxide in the steam space. A test was therefore run with sodium bicarbonate only in the feed, and in quantity sufficient to give the same sodium concentration, but twice the amount of available carbon dioxide. Fig. 7 gives the results obtained and indicates that the amount of available carbon dioxide in the feedwater and consequently the partial pressure of carbon dioxide in the steam space is a controlling factor.

A steady decrease in decomposition with increase in total alkalinity of the boiler water is especially noticeable in the case of 400 parts per million feedwater. Later tests revealed the same dropping-off tendency in the case of 150 parts per million sodium carbonate in the feedwater, but to lesser extent. This would indicate that total alkalinity or possibly sodium-hydroxide alkalinity alone was a factor. Several tests were run at various concentrations, keeping the total alkalinity constant with various amounts of blowdown ranging from 4 to 30 per cent. The fact was noticed that while the total alkalinity was kept constant, the decomposition also became constant, and consequently the sodium-hydroxide concentration was kept constant. A heavy blowdown as was necessary at a low boiler-water concentration was accompanied by a decrease in decomposition. This was to be expected, as the blowdown also carries out carbonate undecomposed, and if increased to the limiting case, or 100 per cent, would result in a decomposition approaching zero. A 30 per cent blowdown with a 150 part per million feed dropped the decomposition about 6 per cent, and a $7^1/_2$ per cent blowdown dropped the decomposition about 1.2 per cent, both at 250 lb. operating pressure.

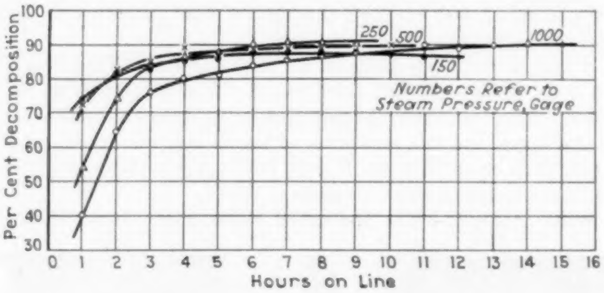

FIG. 6 50 P.P.M. Na_2CO_3 FEED

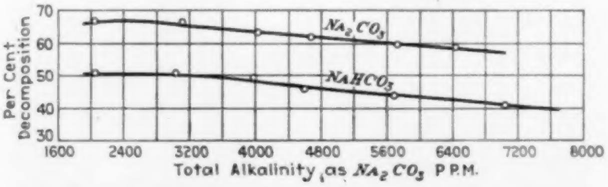

FIG. 7 EFFECT OF PARTIAL PRESSURE OF CO_2 ON DECOMPOSITION OF Na_2CO_3 AT 150 LB. STEAM PRESSURE, 400 P.P.M. FEED

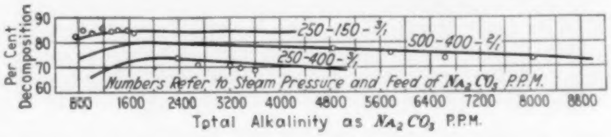

FIG. 8 DECOMPOSITION OF Na_2CO_3 IN THE PRESENCE OF LARGE AMOUNTS OF Na_2SO_4

(Curves represent decomposition obtained with Na_2SO_4 absent. Approximate ratios Na_2SO_4 to alkalinity as Na_2CO_3 are indicated.)

To check whether total ionic strength, through its effect on activity coefficients, might be a factor, several tests were run with large quantities of sodium sulphate added to the feedwater. Fig. 8 shows the plotted results of such tests. The curves were drawn from previous data obtained using sodium carbonate alone. The fair agreement indicates that total ionic strength has but slight effect over the ranges run in these tests. The maintenance of the A.S.M.E. ratios of sulphate to alkalinity should not appreciably affect the decomposition that can be expected.

It was discovered that with sodium sulphate present in the boiler water the Winkler barium-chloride method of hydroxide determination is unreliable. The phenolphthalein end-point comes too soon, indicating too little hydroxide. It was thought that the large quantity of barium sulphate brought down was masking the true end-point. Excessive dilution of the sample and subsequent titration gave the same result. The loss in hydroxide seems to increase with the amount of barium chloride used. Solubility data on barium hydroxide do not explain this loss of hydroxyl ion from the solution. Even small quantities of sulphate radical in the boiler water cause a similar loss in hydroxide when this method is used.

The calculation of decomposition in these later tests with sulphate present was based entirely on double titration, using phenolphthalein and methyl-orange indicators. This method of determination gave consistent results, however; the color change of methyl orange is less marked in the presence of sodium sulphate, and quite broad in dilute solutions. It is better to use a stronger acid and a larger sample in titrating highly concentrated boiler waters.

Early in the schedule of testing several runs were made with different rates of steaming. Fig. 9 gives the results obtained and indicates that boiler rating alone has little effect on decomposition and is not a factor in these accelerated tests. An additional high-steaming-rate test was run with 400 parts per million feed, and showed fair agreement with a previous low-rate test.

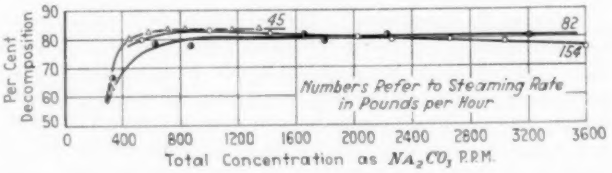

FIG. 9 VARIABLE STEAMING RATE 150 LB. PER SQ. IN., 150 P.P.M. Na_2CO_3

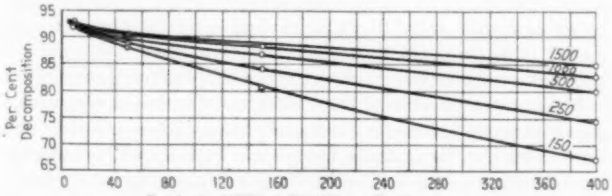

FIG. 10 MAXIMUM DECOMPOSITION OF Na_2CO_3 FOR VARIOUS PRESSURES AND COMPOSITION OF FEEDWATER
(Total boiler-water alkalinity 2400 p.p.m. as Na_2CO_3.)

An attempt was made to correlate decomposition data for various pressures and composition of feedwater, for some particular boiler-water concentration that might be maintained by means of blowdown. The curves in Fig. 10 were drawn from selected data on decomposition at about 2400 parts per million total boiler-water alkalinity expressed as sodium carbonate. The curves are extrapolated somewhat on the assumption that decomposition would approach 100 per cent for a very pure feedwater. A similar family of curves might be drawn for a higher boiler-water concentration or alkalinity, and also for a lower total alkalinity, differing somewhat at higher feedwater concentrations of carbonate, but very little for feedwaters containing very little sodium carbonate.

Such a chart as Fig. 10 might be useful in estimating decomposition and checking boiler-water analyses, unless there exist other factors of equal importance that have not been investigated. The curves are based on attaining the equilibrium previously referred to, a condition which may not always occur in the operating boiler at all times. Quick or sudden changes in steaming rate of great magnitude and intermittent blowdown are probably factors.

Fig. 11 was obtained from a calculation of partial pressure of carbon dioxide in the steam based on decomposition data at a total alkalinity of 2400 parts per million. The curves are drawn as straight lines that converge at a point, indicating about 92 per cent decomposition at zero partial pressure. Theoretically, the decomposition should proceed to 100 per cent completion on reducing the partial pressure of the carbon dioxide to zero and allowing sufficient time. However, removing the carbon dioxide is a dilution process and very slow in the last stages. It appears that a small amount of carbon dioxide has at this point tremendous effect on the completion of this reaction, and practically the limit of decomposition from a feedwater containing but very little potential carbon dioxide seems to be from 92 to 94 per cent.

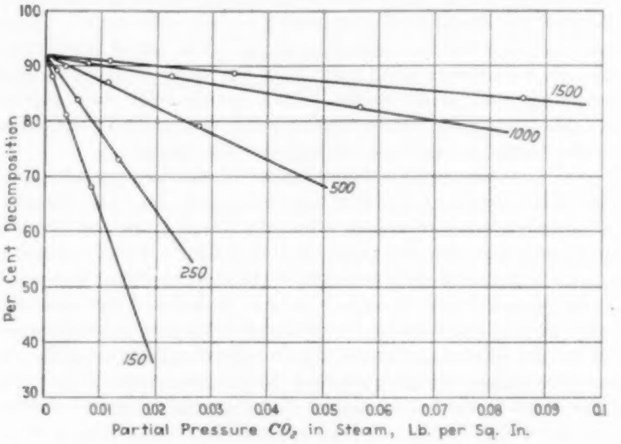

FIG. 11 EFFECT OF CO_2 PARTIAL PRESSURE ON DECOMPOSITION OF Na_2CO_3
(Total boiler-water alkalinity 2400 p.p.m. as Na_2CO_3.)

To check this, two tests were run, using for a feedwater the purest water available—namely, that used in making up these various synthetic solutions. This water showed a methyl-orange alkalinity equivalent to 10 parts per million sodium carbonate, but an accurate carbon-dioxide evolution test accounted for only 5 parts per million expressed as sodium carbonate. Starting with a maximum decomposition of 91.5 per cent obtained with a 10 part per million feed at 250 lb. pressure, the purer water was fed to the boiler for two hours. The final sample drawn showed a decomposition of 93.7 per cent at a total boiler-water alkalinity of 321 parts per million. A second similar test was started with a decomposition of 90.4 per cent similarly obtained, and regular steaming was continued for five hours. The last three samples were almost the same and averaged 94.2 per cent at a boiler-water alkalinity of 3500 parts per million.

No chemical reaction is absolutely instantaneous, but requires some time. Under some conditions the time required may approach zero. Usually in the early stages the speed is very rapid, but as completion is approached and the amount of reacting substance becomes small, the speed decreases considerably. Even under favorable conditions it may require considerable time for completion. Judging from this line of reasoning, it may be possible in the rapidly steaming modern high-pressure boiler, where as many as 15 concentrations may occur in an hour, that the decomposition rate for a very pure water may be exceeded and sodium carbonate accumulate in the boiler faster than it can decompose to maintain an equilibrium dependent upon partial pressure of the carbon dioxide. Such a boiler would show a lower decomposition, and this may be the reason for the low decomposition occurring in some boilers. In the test boiler a change of from one concentration per hour to almost four per hour did not produce any appreciable drop in decomposition.

Most of the boiler-water data that the author has examined show per cents of decomposition lower than that predicted by the curves on Fig. 10, or what might be predicted at some other boiler-water alkalinity corresponding to the case at hand. There are various ways that this may occur. The use of insufficient lime in a lime-soda plant may leave the water bicarbonate and be interpreted as carbonate. Some plants treat with carbon dioxide after passing the softening plant to prevent precipitation of the normal carbonate in the feed lines and heater.

The methods used for determination of carbonate and hydroxide in the average boiler plant are open to error. The presence of certain organic matter in a boiler water is known to displace the methyl-orange end-point and to indicate high carbonate. In the presence of sodium sulphate the methyl-orange end-point is not so easily defined, is likely to be exceeded, and indicates high carbonate. The Winkler barium-chloride method in the presence of sodium sulphate gives too low an indication of hydroxide. In all, the ordinary methods are likely to indicate low decomposition. The direct method of breaking down the carbonates and absorbing the carbon dioxide evolved is tedious and hardly adapted to boiler-plant routine.

Some plants have reported decomposition higher than 95 per cent. Such might occur in a central station using a small evaporated make-up. However, overtreatment with lime in a lime-soda softening plant would result in such a boiler water, high in hydroxyl ion and indicating a higher decomposition than actually exists. A recent test with sodium hydroxide also in the water gave a decomposition several per cent higher than what could be predicted from the sodium carbonate alone.

Summary and Conclusions

The principal controlling factor in establishment of the extent of decomposition of sodium carbonate in a boiler water is the partial pressure of the carbon dioxide in the vapor phase. This in turn depends on the amount and availability of the potential carbon dioxide contained in the feedwater.

The effect of boiler operating pressure decreases with a decrease in carbonate content of the feedwater.

For the range of steaming rates covered in these tests, boiler rating does not appear to be a factor governing the extent of decomposition.

The total alkalinity existing in a boiler water is a factor, the extent of decomposition decreasing with increase in boiler-water alkalinity.

Discussion

W. L. Abbott.[6] For several years past the Engineering Experiment Station of the University of Illinois has been investigating the phenomenon of caustic embrittlement of boilers due to the decomposition of sodium carbonate contained in the boiler water. This study, which has been carried on by the author of the paper and Professor Straub, at first under the direction of Dr. Parr and later under Dr. Keyes, is tardily being recognized as a great achievement in increasing the safety of steam boilers.

In the light of these discoveries the cause of many mysterious boiler explosions is made plain and the means for foreseeing and preventing such disasters are recognized and understood by such authorities as boiler manufacturers, boiler insurance companies, and the Boiler Code Committee of the A.S.M.E.

Naturally such a radical doctrine as the theory of caustic embrittlement, which ran counter to time-honored theories, which appeared to be at variance with experience in numerous instances, and which jostled business interests, had to prove its merit before being generally accepted; however, few there are now who deny the reality and the danger of the phenomenon of caustic embrittlement, although some would call it by some other name.

Fortunate, indeed, are boiler makers and boiler users that this discovery of the nature and cause of caustic embrittlement came as early as it did and preceded the higher boiler pressures and the higher boiler ratings now in general use, as it is in high temperatures and in high concentrations of solubles in the boiler water that the embrittling action is most pronounced.

Dr. Samuel W. Parr will long be remembered for his many and valuable contributions to science and industry in the field of applied chemistry, but none of those discoveries better illustrate his keen and practical research instinct than is shown in his discovery, isolation, and treatment of the bacillus of embrittlement and none of them are of a greater and more practical value to industry.

Everett P. Partridge.[7] The subject of carbonate decomposition in steam boilers has always been obscured by inadequate data. The extensive investigation by Mr. Larson is the first important contribution in this field, but it also suffers from this same defect, since carbonate concentrations were determined by standard methods which give high values, and the figures for decomposition are therefore somewhat lower than the true values. This is the case particularly in the more dilute solutions. Thus when an apparent decomposition of 90.4 per cent was obtained with a feed containing 10 p.p.m. sodium carbonate, and this increased to an apparent value of 94.2 per cent after feeding untreated water, it is probable that practically complete decomposition had really been obtained before the last three samples were taken.

In laboratory studies of the hydrolysis of carbonates at atmospheric pressure the writer has found that a dilute carbonate solution which had been almost completely hydrolyzed, as indicated by determination of its carbon dioxide content by an evolution process, showed an apparent residual carbonate of as high as 20 per cent of the total alkalinity when titrated with phenolphthalein and methyl orange.

In a paper soon to be published by Schroeder and Partridge it is shown that both the standard phenolphthalein-methyl orange and the Winkler barium chloride titrations give inaccurate high values for carbonate in solutions containing small concentrations of carbonate and relatively high concentrations of hydroxide. Among other things this work checks the observations of Mr. Larson on the unreliability of the Winkler method in solutions containing sulphates. It should be noted that checks between the phenolphthalein-methyl orange and barium chloride methods do not necessarily indicate accuracy in the determination of carbonate.

The fact that the analytical methods employed by the author tend to give high values for carbonate means that the lines in all of his figures showing per cent decomposition should actually lie somewhat higher than they do. In Figs. 10 and 11 the lines should actually reach 100 when the abscissas are zero.

The author has referred at several points to a condition of "equilibrium" in his experimental boiler. It would seem highly desirable in this work of a chemical nature to refer to this condition as a "steady state" and to reserve the term "equilibrium" for use in its precise sense. Thus, if the author had used a closed system in which the steam produced was condensed and returned to the boiler with its content of carbon dioxide, the eventual balance between hydroxide and carbonate in solution and carbon dioxide in the steam might have approached true equilibrium at low ratings. If the author had closed his boiler tightly and held it at constant temperature for a sufficient period of time, true equilibrium would probably have been attained. Incidentally, it is to be regretted that this was not done, since a determination of the actual equilibrium at each boiler pressure would have made it possible to measure the deviation from equilibrium of any steady state during operation, and would have made it possible to verify experimentally the statement that the partial pressure of carbon dioxide in the steam is the factor which principally controls the decomposition reaction. It is also unfortunate that carry-over of boiler water prevented accurate determination of the carbon dioxide in the steam.

---

[6] Chief Operating Engineer, Commonwealth Edison Company, Chicago, Ill. Mem. A.S.M.E.

[7] Supervising Engineer, Non-Metallic Minerals Experiment Station, U. S. Bureau of Mines, New Brunswick, N. J.

As the author has recognized, the process of converting carbonate into hydroxide with the evolution of carbon dioxide in the steam may be regarded as occurring in two steps, the first step being the hydrolysis of carbonate to hydroxide with the production of dissolved carbon dioxide, and the second being the transfer of this carbon dioxide from the solution to the vapor phase. The ionic reactions of the first step probably proceed more rapidly than the essentially physical process of the second step. The partial pressure of carbon dioxide in the steam will then control the rate of decomposition only in so far as equilibrium exists between it and the dissolved carbon dioxide in the solution.

It is the belief of the writer that the partial pressure of carbon dioxide in the steam should be regarded more as a result of conditions in the boiler water than as a principal factor in controlling these conditions. The greater degree of decomposition obtained with falling water level and the smaller degree of decomposition with rising water level do not necessarily indicate an equilibrium controlled by the partial pressure of carbon dioxide in the steam space. These effects may rather be interpreted as due to change in the rate of introduction of carbonate relative to the more or less constant rate of removal of carbon dioxide in the steam. The results from the use of $NaHCO_3$ in place of Na_2CO_3 likewise do not demonstrate that the partial pressure of carbon dioxide in the steam controls the decomposition, although the amount of carbon dioxide which must be transferred from the water to the steam does undoubtedly determine the degree of decomposition.

Bearing in mind the fact that the author's figures for carbonate decomposition are probably consistently low, it is apparent from his results that the actual amount of carbonate present in any boiler operating under ordinary conditions is so low as to be almost negligible from the standpoint of regarding sodium carbonate as an inhibitor of caustic embrittlement.

Leo F. Collins.[8] During 1929 a set of experiments, similar to those conducted by the author, were run at the Congress Street Heating Plant of The Detroit Edison Company. These experiments were instigated because of the fact that when using sodium carbonate as a boiler-water conditioner it was difficult to maintain the proper ratios of sulphate to carbonate to prevent scale and also to meet the A.S.M.E. recommendations to thwart intercrystalline cracking of the boiler metal. The rapid decomposition of sodium carbonate was the controlling factor. Accordingly it was decided to determine, if possible, what those factors are which govern the decomposition of sodium carbonate as criteria for improving the method of treatment. Since the conclusions drawn were substantially the same as those drawn by the author, it is hoped that the presentation of some of the data will be appropriate.

The first attempt made was to determine the rate of decomposition in an operating boiler. The boiler, a W-type Stirling (operating at 125 lb. gage and having a rated capacity of 36,600 lb. of steam per hour), was filled with fresh water containing no sodium alkalinity and was put into operation at its rated capacity.

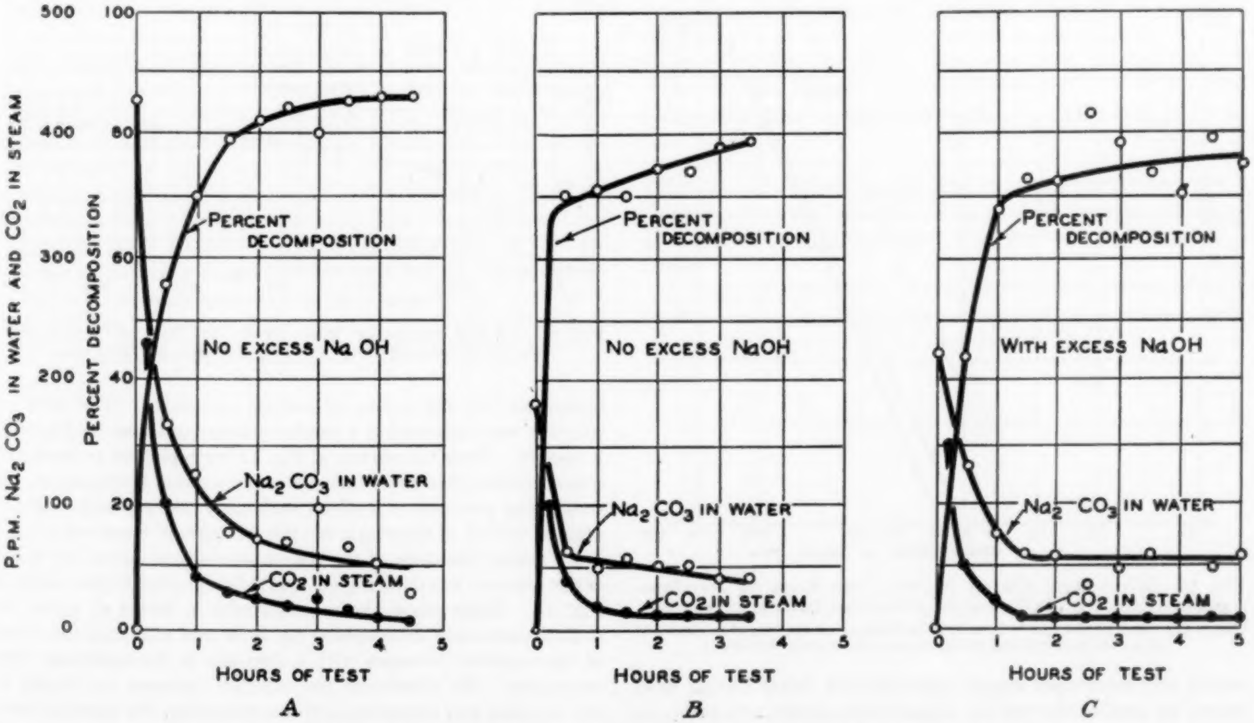

Fig. 12 Curves Showing the Progress of Decomposition of Sodium Carbonate in a Boiler

(With and without an excess of sodium hydroxide present. Boiler operating at 125 lb. pressure and at 100 per cent of rating.)

---

[8] Chemist, The Detroit Edison Company, Detroit, Mich.

A weighed amount of sodium carbonate, 430 p.p.m., was then introduced directly into the boiler through the auxiliary feed line. At half-hour intervals samples of feedwater, blowoff water, and condensed steam were collected (after having been cooled by passing through the copper cooling coils) and analyzed. In this manner the data for test *A*, Fig. 12, were collected. In a similar manner the data for test *B* were collected, but the initial dosage was only 188 p.p.m. of sodium carbonate. It will be noted that in these tests complete decomposition was not attained. This, it is believed, was caused by the presence of approximately 10 p.p.m. of CO_2 in the feedwater, which retarded the decomposition.

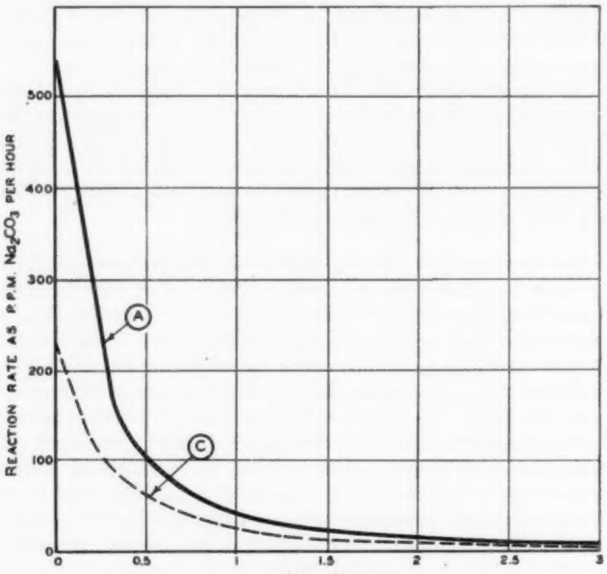

FIG. 13 CURVES SHOWING REACTION RATE $\Delta C/\Delta T$ DURING DECOMPOSITION OF Na_2CO_3

(As shown by tests *A* and *C* of Fig. 12. ΔC = rate of decomposition, p.p.m. Na_2CO_3 per hour. ΔT = time in hours. Curve *A* = without excess NaOH and with high concentration Na_2CO_3. Curve *C* = with excess NaOH and with small concentration Na_2CO_3.)

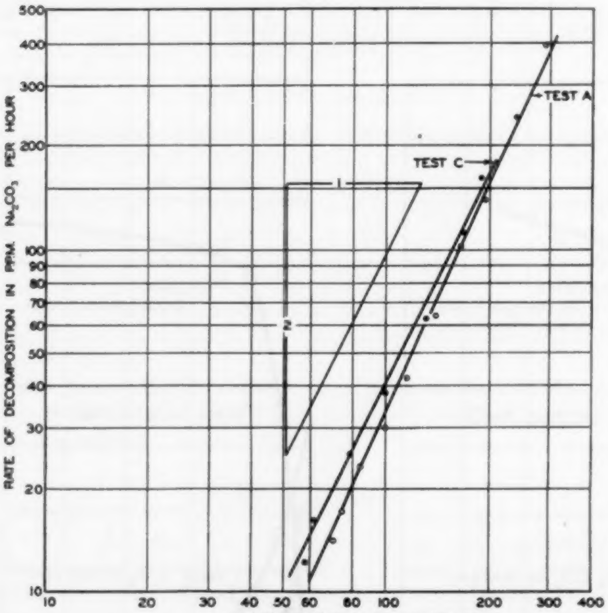

FIG. 14 LOGARITHMIC GRAPH SHOWING THE RATE OF DECOMPOSITION OF Na_2CO_3 AS A FUNCTION OF THE Na_2CO_3 CONCENTRATION

(Since the slope of the line is 2 to 1, it indicates that the reaction proceeds at a rate proportional to the square of the concentration.)

In both of these tests it will be noted that there was initially present no sodium hydroxide. It was desired to know what the effect of this alkali was on the rate of decomposition of sodium carbonate. Accordingly when it was found, in test *B*, that the reaction had practically ceased, although there was still present about 40 p.p.m. of sodium carbonate, the boiler was given another dosage of 188 p.p.m. of the salt. Hence at the beginning of test *C*, the boiler water contained about 111 p.p.m. of sodium hydroxide and 228 p.p.m. of sodium carbonate. The data for this test were collected in a similar manner to those used in tests *A* and *B*. Thus the curves of Fig. 12 were plotted to show the concentration of sodium carbonate and sodium hydroxide in the water, the per cent of sodium carbonate decomposed, and the amount of CO_2 in the steam for the duration of these tests.

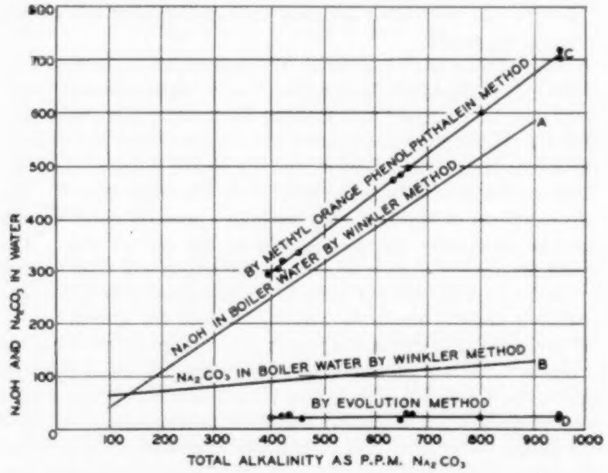

FIG. 15 CURVES SHOWING INCREASE IN Na_2CO_3 CAUSED BY INCREASING NaOH CONCENTRATION IN BOILER WATER

(The CO_2 in steam remained practically constant at about 15 p.p.m.)

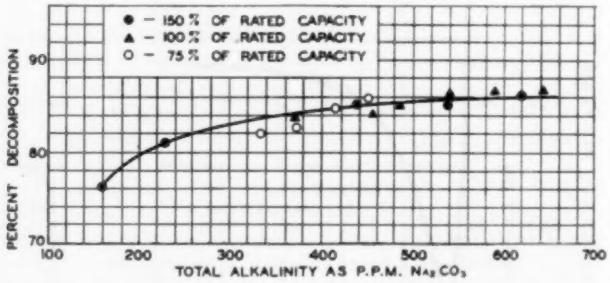

FIG. 16 CURVE SHOWING PER CENT OF BOILER ALKALINITY THAT IS NaOH FOR DIFFERENT BOILER RATINGS

By taking the slope of the sodium-carbonate curve, the speed of the reaction was determined, and this is plotted in the curves of Fig. 13. These show the reaction rate in terms of p.p.m. of sodium carbonate decomposed per hour and also that the speed of the reaction decreases with a decrease in the carbonate concentration. To determine the relation between the speed of the reaction and the carbonate concentration, the reaction rates from the curves of Fig. 13 and the concentration of sodium carbonate present in the water, from the appropriate curves of Fig.

12 (tests *A* and *B*) for the same time interval, were plotted on a log scale.

These curves, Fig. 14, have a slope of approximately 2 to 1. The slope of the curve for test *C* is less than for test *A*, which indicates that the presence of sodium hydroxide decreased the rate of the reaction. Both of the curves, however, indicate that for the conditions encountered the rate of decomposition is approximately proportional to the square of the concentration of sodium carbonate present.

With these data as criteria it was decided to determine just how high the concentration of sodium carbonate could be raised in this boiler by increasing the sodium-hydroxide concentration. The concentration of sodium hydroxide was increased as shown by curve *A*, Fig. 15, and it was found that the sodium-carbonate concentration increased as shown by curve *B*. The data for these curves were collected with the boiler operating at 75, 100, and 150 per cent of rated capacity. The effect of differences in steaming rates could not be noted. The curve of Fig. 16 demonstrates this fact. The points as plotted in Fig. 16 are average values for many analyses and were obtained when a constant amount of sodium carbonate was being added to the feedwater.

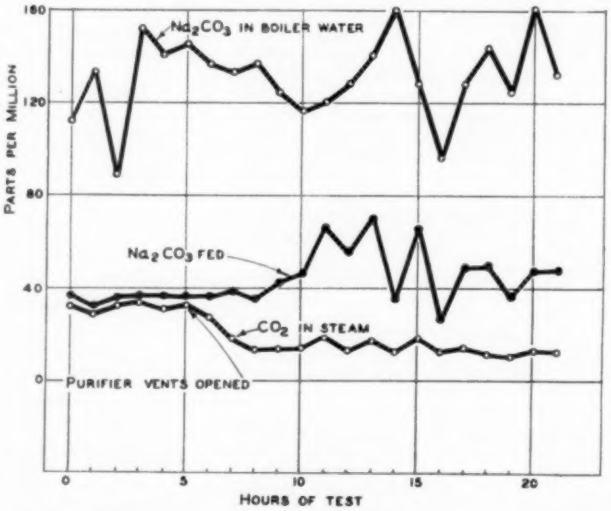

Fig. 17 Curves Showing Interrelation of Sodium Carbonate in Boiler Water, Sodium Carbonate Fed, and CO_2 in Steam Leaving Boiler

(The purifier vents were closed for the first five hours of the test, and then were opened.)

In the foregoing tests the hydroxide and carbonate were determined by the Winkler method. In collecting the data for Fig. 12 there was present no appreciable quantity of sodium sulphate, and hence it is believed that the data are quantitative. However, the data for curves *A* and *B* of Fig. 15 are not believed to be quantitative because of the inaccuracy of the Winkler method when sodium sulphate is present. On the same plot are shown the hydroxide and carbonate concentrations determined by the more accurate methods, and these figures are believed quantitative.

The agreement between the two methods is poor, but each indicates that the sodium carbonate increases with increase in the hydroxide concentration of the water, and this was the object of the test. The relation holds true, however, when the CO_2 and sodium carbonate entering the boiler are constant quantities. Fluctuations in the concentration of either will noticeably affect the carbonate concentration in the boiler water, as is shown in Fig. 17. Blowing down a boiler has the same effect.

In conclusion it appears that for the conditions encountered in these tests the decomposition of sodium carbonate is governed by the following:

(*a*) The partial pressure of CO_2 in the vapor phase

(*b*) The concentration of sodium carbonate present in the boiler water

(*c*) The concentration of sodium hydroxide in the boiler water.

These conclusions, drawn from an operating boiler, are substantially the same as those drawn by Mr. Larson in the laboratory.

Author's Closure

The author has on hand data that will substantiate the accuracy of the methods of analysis used in these series of experiments. No blanks were deducted from the titration values, but inasmuch as the amounts of acid used were for the most part 20 cc. or more, the error introduced should not exceed a few per cent. Particular care was taken to keep this source of error small. If the amount of sample and the concentration are such that only a few cubic centimeters of acid are used, this error is proportionately large and may account for the apparent high carbonate observed by Mr. Partridge. The author has checked the A.P.-H.A. and the Winkler barium-chloride methods with a carefully conducted CO_2 evolution on the same sample of pure solution where the per cent decomposition was approximately 90 per cent and the total carbonate content about 200 p.p.m. The determination of carbonate content for 100 p.p.m. or less by CO_2 evolution calls for excessively large samples in order that errors in the analytical balance and those due to contamination be small.

A series of experiments with the true chemical equilibrium of this reaction at high pressures is under way, the data from which are to be published at an early date.

Radiant-Superheater Developments

By M. K. DREWRY,[1] MILWAUKEE, WIS.

Sustained high steam temperatures at all operating ratings, not peak readings at one narrow load range, are being sought in the industry's quest for higher operating efficiencies. Uniform average temperatures, not maximum values, determine commercial economy and even safety of higher steam temperatures. Since premiums are paid for high-temperature equipment on the basis of maximum temperatures, it is important that operating temperatures be uniformly high. Decreasing trends of boiler duty and increasing tendencies of superheater and reheater duty, plus multi-valving of turbines, emphasize the inadequacy of purely convection surfaces for maintaining uniform temperatures. A 200-deg. fahr. drop in reheated-steam temperature from full load to quarter load when using only convection surfaces was diminished to 20-deg. fahr. decrease in the planning of a recent large 1200-lb., 850-deg. fahr., single-turbine, single-boiler installation, simply by prescribing two-thirds radiant-superheating equipment. Objectives of this paper are:

1 To tell of considerable experiences with radiant superheaters in a station operating many since 1923, showing that their design and operation are based upon sound fundamental principles that have been proved by successful service.

2 To give operating data evaluating the desirable "rising" radiant characteristic at lower loads and to state basic differences of radiant and convection superheaters.

3 To treat the proper applications and to list the incidental merits of radiant superheaters.

4 To treat desirable application of radiant superheaters and reheaters in future large high-temperature, high-pressure, single-boiler, single-turbine installations, illustrating with calculated data based upon experience that essentially constant temperature can be obtained at all ratings.

Experiences in only one station are cited, yet developments of the industry prompting use of all designs of radiant superheaters are treated.

PART I

Operating Experiences

TWENTY boiler-units at the Lakeside Station have been equipped since 1923 with various types of radiant superheaters as the art advanced, and thoroughly satisfactory installations (shown in Figs. 4, 5, and 6) were developed. Original installations employing the special heavy forged-steel elements proved that massiveness of element structure was unnecessary, and in fact undesirable, for 300-lb. steam-pressure service.

Figs. 1 to 3 show these early superheaters. Fig. 7 contrasts their heavy cross-section with the simple light-weight elements later found so desirable. Table 1 gives major information and data of all installations, treating them chronologically.

Since the simple, light-weight round-tube design first used in 1927 is the basis of present designs, and since information gathered during its development is still of constructive value, this paper will deal with it almost wholly. Fig. 4 pictures the first installation, and data are given in the "Installation F" column of Table 1.

The Starting Problem

How to get the light 2-in. tubes past the starting period, when no steam was available to cool them, without overheating, was a problem difficult of practical solution. Unlike the case of their predecessors, scarcely no storage of heat in the metal of the elements could be depended upon to prevent overheating, for the new elements weighed only one-tenth as much per equivalent heat-absorption area. Calculations showed exceedingly rapid heating, and served to warn of the starting dangers.

Cooling with steam from other boilers, or with its own after exceeding atmospheric pressure, was found not only inadequate, but impractical. Calculations showed that opening reasonable-sized bleeders would give only a false sense of security. Since the radiant elements were in series with convection ones, high excess-air variations would be of no value in reducing steam temperatures because of the opposing temperature characteristics of the two sections.

Furnace temperature taken previously in a similar furnace suggested that if the coal-feed rate was set at a certain particular value immediately upon lighting the burners, and maintained positively uniform until header pressure was reached and steam flow created, then starting would be reasonably rapid, and maximum flame temperature at the superheaters would not exceed 1000 deg. fahr. Obviously, the tubes could not exceed the flame temperature however long they were exposed. If the installation could be brought into service within a reasonable length of time, and if the operating personnel could be acquainted with the new method and would use it consistently, then the first step toward success of the new elements was assured.

Previous starting practice consisted of gradually increasing coal feed until it became quite high upon opening of the non-return valves, and consumed three hours when starting with cold boiler water. The special steady-coal-feed method of starting required four hours, but was considered practical in view of benefits likewise derived by other portions of the boiler unit.

Element-metal temperatures, furnace temperatures, radiant-

---

[1] Assistant Chief Engineer, Power Plants, Milwaukee Elec. Ry. & Light Co. Jun. A.S.M.E. Mr. Drewry was graduated from the mechanical-engineering course of the University of Wisconsin in 1922, and was subsequently employed by the Allis-Chalmers Manufacturing Company for two years and the Milwaukee Electric Railway and Light Company for the past seven years. Most of his work with the latter has been concentrated in the Lakeside Power Station.

Contributed by the Power Division and presented at the Hartford, Conn., Meeting, June 1–3, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

16 Normal transfer rate, B.t.u. per sq. ft. per hr.	35,000	53,000	44,000	45,000	53,500	57,000	37,500	37,500	44,000	45,000	45,000
17 Estimated maximum metal temp., deg. fahr.	.....	1,050	1,050	950	1,050	950	950	950	950	900	900

(Elements changed from special rectangular cross-section to simple round tubes. Weights per square foot of exposed area decreased from 80 lb. to 8 lb. Steam velocities increased from 90 ft. per sec. to 160 ft. per sec. for better metal cooling. The 1300-lb. pressure superheaters are the most recent, and though their steam is 40 deg. fahr. higher and its velocity is lower, their metal temperature is 50 deg. fahr. lower than that of the 300-lb. elements. Experience with 37 radiant-superheater installations is summarized.)

NOTE: "Rect." signifies rectangular shape shown in cross-section, Fig. 7. Installation A superheated half of boiler output. Areas of installations J and K are based upon projected tube area, as are transfer rates.

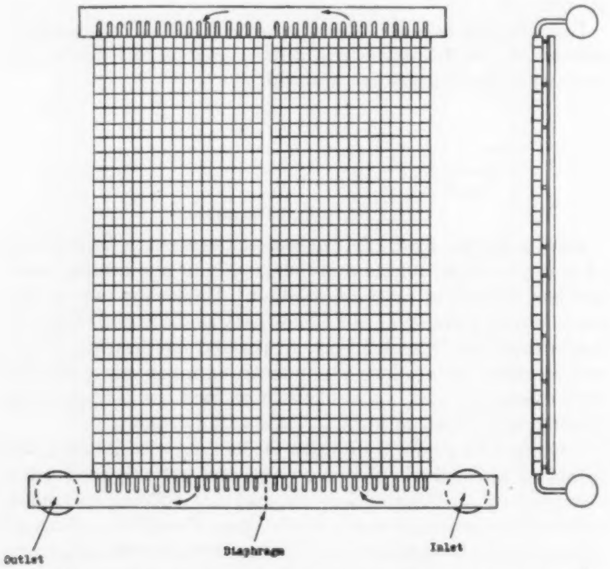

FIG. 1 INSTALLATION A; TRIAL RADIANT SUPERHEATER, NO. 7 BOILER

(Half of a convection superheater was removed to try this installation composed of cast-iron blocks shrunk on to 2-in. steel tubes. Heat-transfer rates and other characteristics were obtained, but the cast-iron element construction was proved impractical, and steel elements were later substituted. This installation was made in 1923, and upon it was based the design of completely radiant superheaters for eight 150,000-lb.-per-hr. boiler units, installation B.)

heat transfer rates, and all significant information were taken continuously during the starting and first days of operation. Conscientious, practical opinion had conceded only a few hours' life of the new elements, and reliance upon theory, only, was not reassuring enough to eliminate doubts of their safety after passing the starting period. One had only to look at the small tubes projecting into the almost white-hot flames to doubt all theory and suspect rapid failure.

Contrary to almost general expectations, the simple carbon-steel tubes lasted the day, the week, the month, and finally the year, without a single failure. Half of them are still in service after three and one-half years' operation. There are 800 other similar elements of a slightly better metal that have been in service three years with only two failures.

TABLE 2 METAL ANALYSES AND CONDUCTIVITIES

Metal	Carbon steel	Chrome-vanadium	Enduro A
Used in boilers	No. 5	All except No. 5 and No. 3	No. 3
Analysis:			
Carbon	0.10	0.20	0.10
Chromium	.....	1.0	17.0
Silicon	0.05	0.15	1.0
Manganese	0.41	0.75	0.40
Phosphorus	0.012	0.01	0.02
Sulphur	0.49	0.04	0.15
Nickel	.....	..	0.20
Vanadium	.....	0.20	.....
Thermal conductivity at 600 deg. fahr., B.t.u. per sq. ft., per inch thick, per deg. fahr., per hr	310	..	170
Relative values, per cent	100	..	55

(The chrome-vanadium steel is essentially only a refined carbon steel and is used extensively in the automobile industry—S.A.E. No. 6120. Its cost in tube form is about 15 cents per pound, and that of Enduro A is in excess of 50 cents per pound. Tensile-test properties are given in Fig. 14, and creep characteristics in Fig. 15.)

Application of exact physical laws, not approximate judgment, had suggested the way to an important development. Further replacements of the special heavy rectangular elements were made with tubes of a slightly better steel (see Table 2), and shortly 16 boilers were so equipped.

RADIANT-HEAT TRANSFER

That the new elements effectively absorbed heat throughout their periphery was proved immediately by the fact that only 60 per cent as many as of the heavy elements were required initially to get full steam temperature. Reflection from the brickwork backing wall not only helped maintenance of the elements by maintaining uniform metal temperatures front and rear, but increased heat-absorption efficiency. In radiant-superheater design it is desirable whenever steam scrubs a surface, and thus causes pressure drop, that useful-heat absorption occurs at that point. The superseded elements were not efficient from this standpoint, for only one face was heated, and connecting nipples caused much of the pressure loss. Study of the cross-sections in Fig. 7 will convey a comparison of the old and new elements.

METAL TEMPERATURES 950 DEG. FAHR.

Obviously, metal temperature, not steam temperature, is the vital determinant of radiant-superheater maintenance. Consideration of the reliability of high steam temperatures too often omits study of the temperature difference between heated steam and heating metal.

At the time when the first round-tube elements were installed, little information on the heat-transfer rate from metal tubes to

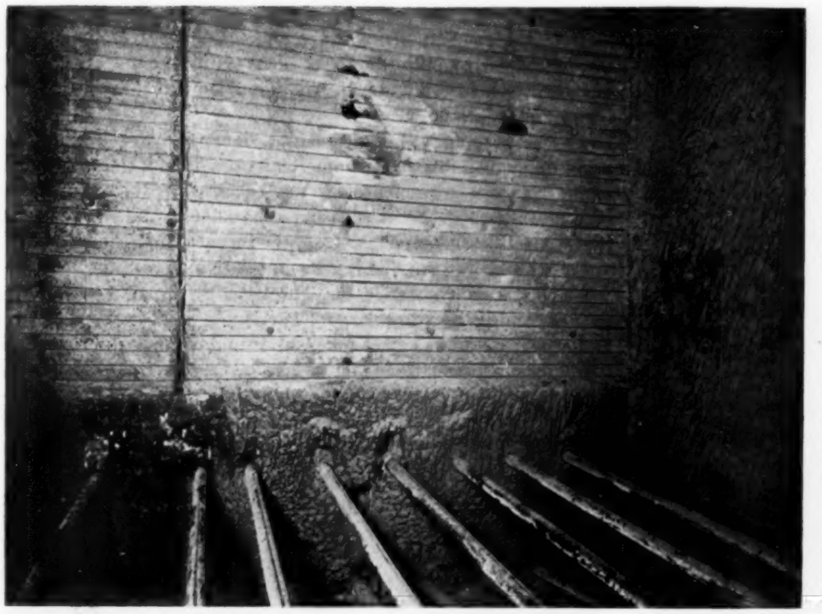

Fig. 2 Installation B; First Application

(A complete new boiler room with 700 deg. fahr. radiant superheaters was a distinct, progressive step in 1924. Installation C, made in the older boiler room to boost the 600 deg. fahr. temperatures also to 700 deg. fahr., was a somewhat similar design applied on another group of eight boilers. A 1927 extension utilized a similar design, as shown in Fig. 3.)

superheated steam was readily available. To supply the want, metal temperatures were measured, and heat-transfer rates to a water-cooled tube nearby, plus furnace temperatures, were observed as well. Chromel-alumel thermocouples, well peened into the tube metal and heat-insulated for a few inches from the tube with porcelains, were employed for the vital measurements. In connection with the second installation of round elements in boiler units 9 to 16, collection of this data was repeated, and the results of both as compared with those calculated from Nusselt's formula are also shown in Fig. 9. Fair agreement is apparent. Internal smoothness of the particular tubes used may affect the calculated values appreciably, and accurate metal-temperature measurement under the difficult furnace conditions is not easily accomplished.

Because of agreement of measured and calculated metal temperatures, it is quite safe to assume that the round superheater elements operate at a temperature not in excess of 950 deg. fahr. It is possible that this temperature may be exceeded sometimes when starting, but the fact that the observed creep was found influenced by steam-flow turbulence (see Fig. 10) shows quite positively that most creep occurs during operation with metal temperatures not exceeding 950 deg. fahr.

Creep

It was realized early that the new-type elements would probably be subject to creep, even though their operating temperature was not over 950 deg. fahr. and the tensile stress due to 300-lb. steam pressure was only 1200 lb. per sq. in. Accordingly, circumference measurements were taken early and frequently, and data shown in the illustrations (Figs. 10 to 13) were obtained.

Chief points and conclusions from these creep measurements were:

1 Rate of circumference increase was found directly proportional to operating hours, indicating that creep was responsible, not infrequent overheating due to improper operation (see Fig. 11).

2 Greatest increase in circumference occurred at the middle of the element, where minimum turbulence from the bends occurred. This also indicated that starting or irregular steam circulation was not responsible (see Fig. 10) for the expansion.

3 Since the first element reached 29 per cent enlargement before failure, it is reasonable to set 20 per cent maximum creep as practical for most superheater installations, providing oxidation does not cause premature failure.

4 Since actual operating values of metal temperature and stress lie considerably under the expected creep curve for low carbon steels (see Fig. 15), it is expected that stresses due to temperature gradient through the tube wall, fluctuation of metal temperatures due to changes in furnace conditions, and slight oxidation of the metal surface are important in correlating laboratory and service results.

5 Creep of Enduro A tubes is appreciable compared with the standard of laboratory results. Fig. 15 shows a wider divergence than with carbon-steel elements. Fig. 16 shows Enduro creep data.

6 Dangers of creep are greatly lessened by the fact that time of ultimate failure can be prophesied early with accuracy. The probable life of elements can be estimated

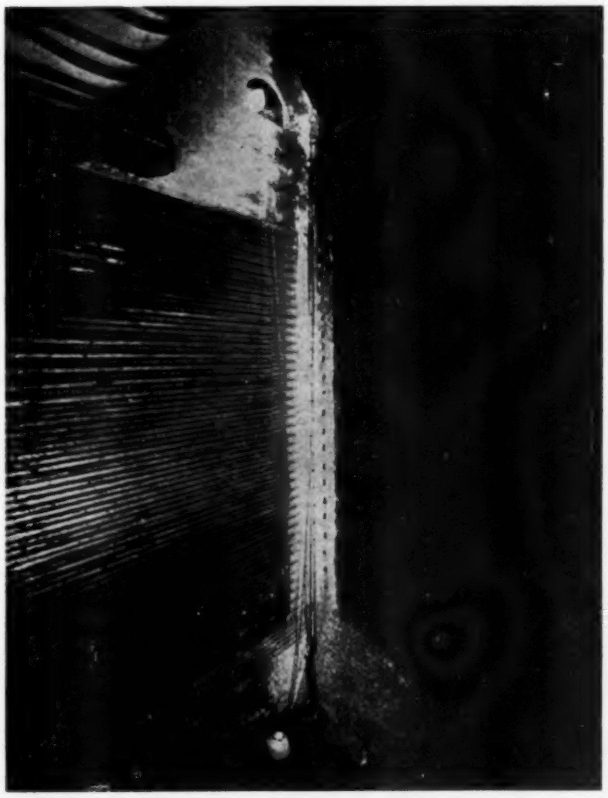

Fig. 3 1300-Lb. Application

(Both superheater and reheater were made radiant in the first 1300-lb. boiler unit. Due to the desirable heat-transfer characteristics of high-pressure steam, no maintenance has been required of the 1300-lb. superheater during its 4 years' service. The superheater is on the left, and the reheater is on the right.)

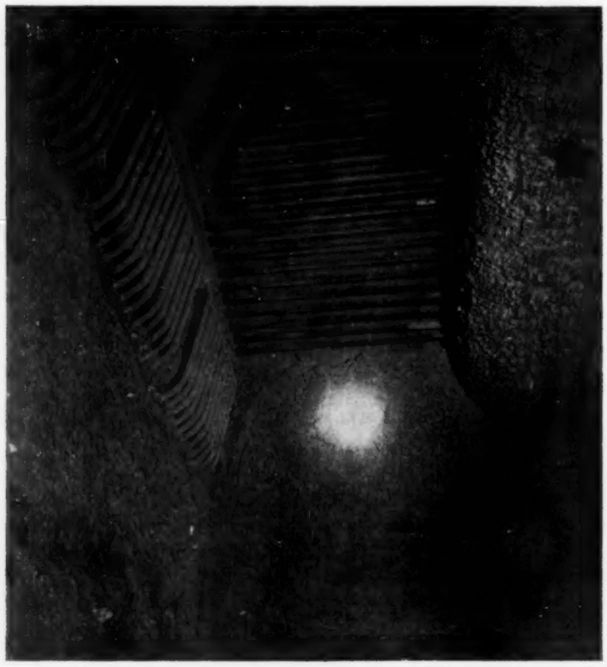

FIG. 4 SIMPLE REPLACEMENT ELEMENTS, INSTALLATION F

(Two years' life of the apparently rugged but actually weak rectangular elements prompted development of less expensive replacement elements. Above, at left, are simple low-carbon steel tubes, and though predicted to serve only a few hours before failure, are partly still in service after 3 years.)

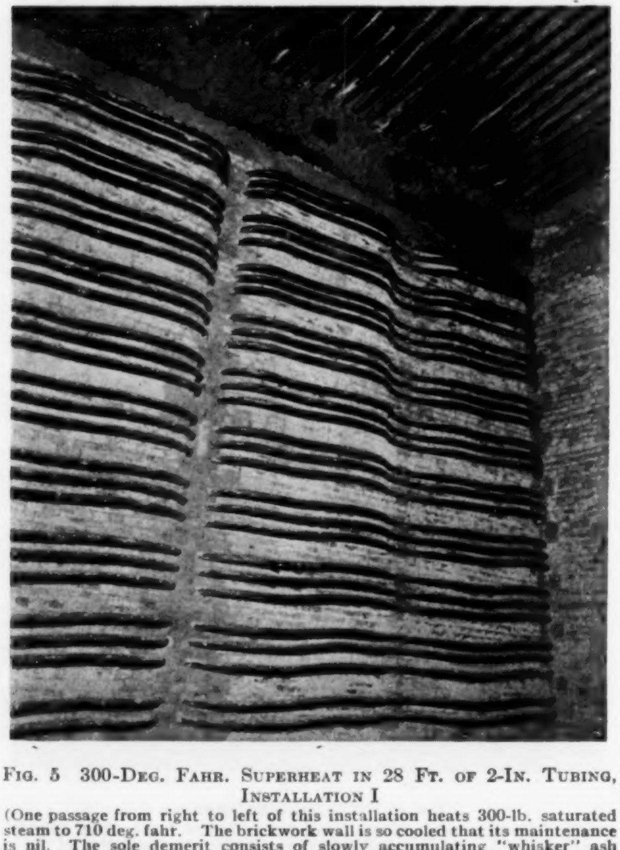

FIG. 5 300-DEG. FAHR. SUPERHEAT IN 28 FT. OF 2-IN. TUBING, INSTALLATION I

(One passage from right to left of this installation heats 300-lb. saturated steam to 710 deg. fahr. The brickwork wall is so cooled that its maintenance is nil. The sole demerit consists of slowly accumulating "whisker" ash deposits on the wall, requiring hand removal weekly or twice monthly. Intermediate supports are required to keep metal stresses very low, for creep occurs easily at 950 deg. fahr.)

within the first few months or years of operation if accurate micrometer measurements are made. Reliance can be placed upon trustworthy performance of tubes subject to measured rates of creep, and forced outages will not occur until estimated life is reached.

7 Use of standard, light-weight, inexpensive tubes having fairly high creep rates are commercially practical if removal every several years is convenient. So few tubes are required to obtain high steam temperatures with radiant surfaces, and renewal as a rule is so easily accomplished from the furnace, that the old standard of 20-year life may be less desirable than 5-year life.

8 Oxidation resistance may prove a principal merit of the high-chromium-nickel steels. Experience with the one superheater using stainless-steel tubes, and similar in all other respects to the other installations, shows higher creep relative to the inexpensive tubes than study of laboratory data would indicate. Reference to Table 3 shows a creep rate of 1.5 per cent per 10,000 hours for stainless steel and 1 per cent for the low-chrome-vanadium material. Published thermal conductivities of stainless steels show them to average only 55 per cent the conductivity of boiler-tube material. Thus, the temperature drop through the metal for same transfer rates and thicknesses is almost double, and temperature stresses are therefore much greater. This actual operating experience suggests that high-chrome-nickel metals are of lesser benefit than laboratory tests indicate them to be, though more experience is desirable to confirm the point.

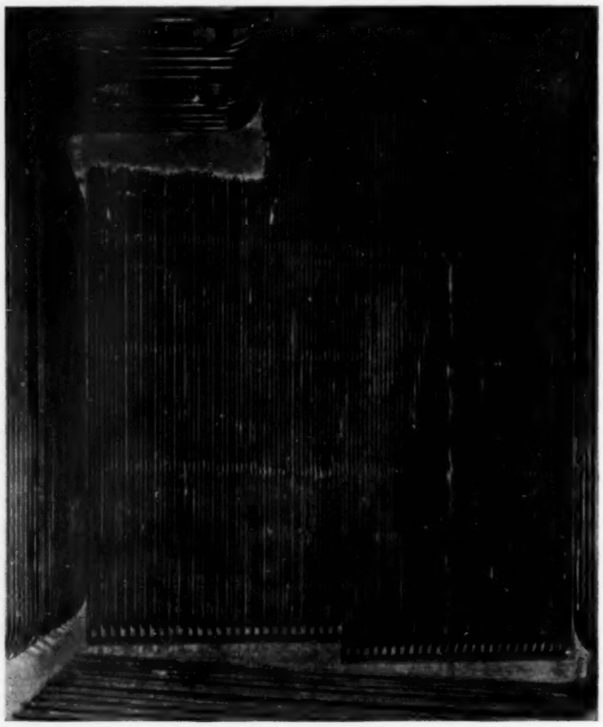

FIG. 6 MOST RECENT INSTALLATION, ONE OF THE THREE 1300-LB. SUPERHEATERS, INSTALLATIONS J AND K

(High pressure assists radiant superheater design markedly, and these superheaters are completely satisfactory after $1^1/_2$ years' service. They have the cleanliness characteristics of fin-tube walls, and have not required a penny's maintenance. They effectively cover both side walls, which is difficult with water walls, and absorb heat with essentially the same effectiveness as bare water tubes.)

9 More experience with creep of metals in service, operating under various conditions of heat transfer and metal temperature, is highly desirable. This particular experience indicates that

TABLE 3 LONG-TIME OPERATING CREEP DATA

Boiler-unit designation	Operating hours	Years of service	Per cent creep: Carbon steel	Per cent creep: Enduro A	Per cent creep: Chrome-vanadium
3	13,840	3.3	...	2.6	..
4	14,366	3.3	...	..	2.2
5	16,020	3.6	7.4	..	..
6	14,728	3.4	..	..	1.25
7	15,834	3.3	...	..	1.0
8	15,400	3.2	...	..	1.8
10	9,249	2.4	...	..	0.6
13	12,163	2.6	...	..	1.2
Summary:					
Creep per 10,000 operating hours			4.6	1.5[a]	1.0
Creep per year			2.0	0.7	0.5
Relative creep rate			4.5	1.5	1.0

(The 400 elements in operation three years were measured to obtain the data. Percentage increase in circumference is reported as "per cent creep." The chrome-vanadium tubing is not much more expensive than high-grade carbon-steel tubing, for it contains insufficient chromium, 1.5 per cent, to class it as a stainless steel and the vanadium is only a fraction of 1 per cent. It appears that the Enduro metal is handicapped by its lesser thermal conductivity, increasing the important temperature stresses. Its external appearance and smoothness, however, is considerably better than the chrome-vanadium elements, indicating possibly longer life because of better resistance to oxidation. Paying 5 cents more per pound for the chrome-vanadium elements than for the carbon ones is certainly desirable, but 50 cents per pound for the Enduro metal is unquestionably unwarranted, even though the weight involved for the entire superheater is small.)

[a] Averaged from Fig. 16.

laboratory stress values for given creep are many times higher than occur in practice unless other than pressure stresses are assumed.

Radiant-superheater experience at the Lakeside Station is best summarized by the following points:

1 Special heavy rectangular elements have been displaced by lighter round elements because (*a*) slow steam velocities and large temperature differences in the front and rear of the rectangular elements caused their failure; (*b*) reasonably high mass-flow rates and uniform circumferential heat absorption of the round elements caused low metal temperature and elimination of thermal stresses.

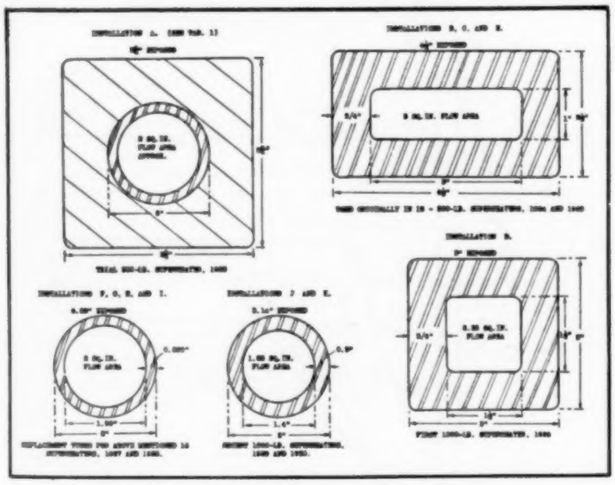

FIG. 7 DEVELOPMENTS SHOWN BY CROSS-SECTIONS

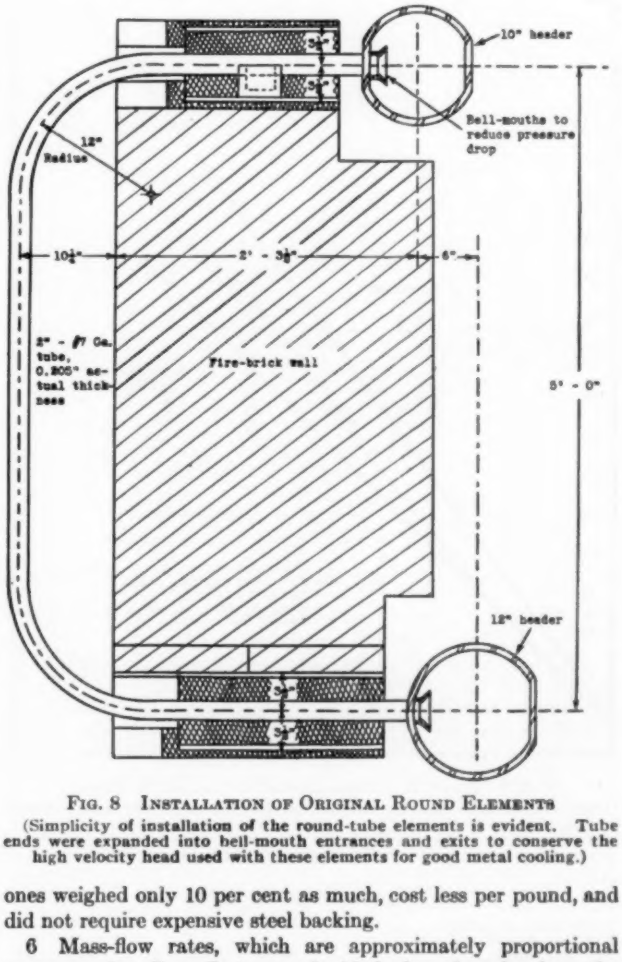
(The simple round-tube sections are greatly superior to the special, heavy elements. The thinnest tube section, lower left, absorbs 20 per cent more heat than the second heavy element, upper right, though it weighs only 10 per cent as much. Its flow area is one-third less, causing desirably higher steam velocities, and effective surface exposed to the cooling steam is about 50 per cent more. Most important of all, enormous and destructive temperature stresses were reduced to almost negligible items by the new design. The square 1300-lb. section, lower right, is successful, but the round section, lower middle, used in subsequent installations is less expensive.)

2 Flush-with-wall position of rectangular elements was discarded for the projecting-tube design of the round elements, until favorable transfer conditions with 1300-lb. pressure steam allowed reapplication of the initial mounting.

3 A refined-steel tube material, containing small amounts of chromium and vanadium, has been found satisfactory for 950 deg. fahr. maximum metal temperature.

4 Round elements set out from a brick wall and with several diameters' spacing absorb heat throughout their periphery at rates closely equal to equivalent flat surfaces in the plane of the wall. Reflection of radiant heat from the brickwork explains this phenomenon.

5 Round-tube elements replacing the unsuccessful rectangular ones weighed only 10 per cent as much, cost less per pound, and did not require expensive steel backing.



10" header
Bell-mouths to reduce pressure drop

Fire-brick wall
5' - 0"
12" header

FIG. 8 INSTALLATION OF ORIGINAL ROUND ELEMENTS

(Simplicity of installation of the round-tube elements is evident. Tube ends were expanded into bell-mouth entrances and exits to conserve the high velocity head used with these elements for good metal cooling.)

6 Mass-flow rates, which are approximately proportional measures of cooling effect, were doubled when changing from the rectangular to round elements. Pressure drop was held down by elimination of connecting nipples and use of bell mouths to diminish entrance and exit losses.

7 Projecting-element design is of maximum efficiency and subjects the tubes to minimum thermal stresses, but has the sole objection that the brickwork backing must be cleaned periodically of ash deposits.

8 Sixteen sets of rectangular-element superheaters were replaced after three years' average life with elements that cost less than 10 per cent as much and that will last at least twice as long.

PART II

RADIANT-SUPERHEATER CHARACTERISTICS

The slope of any superheated-steam temperature versus rating curve is dependent upon so many factors that each particular installation has an individual characteristic, whether the superheater is convection or radiant. Fig. 17 shows the curve for a 300-lb. radiant superheater, Fig. 20 a 1300-lb. one, and the latter shows how the combination of a radiant superheater, a constant-exhaust pressure 1200-lb. turbine, and a convection reheater cause a uniform reheater-outlet temperature.

Much can be learned of radiant-heat-absorption rates in existing installations with water-cooled tubes of known area by metering heat input at various locations and ratings. Metal temperature has little effect upon heat absorption, and the influence can be evaluated accurately.

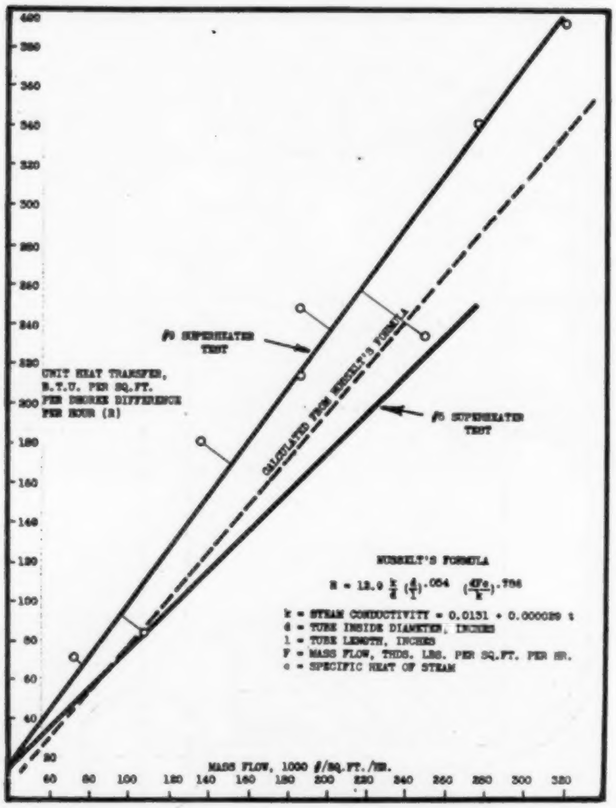

Fig. 9 Heat-Transfer Inside Superheater Tubes

(Metal-temperature measurement by thermocouples peened into elements in operation allowed calculation of the above unit heat-transfer data. Since fair agreement with Nusselt's expression was obtained, maximum operating metal temperatures were concluded not over 950 deg. fahr.)

TABLE 4 METAL TEMPERATURES

1	Pressure, lb. gage....	300			1300		
2	Steam temperature, deg. fahr..........	700			750		
3	Tube thickness, in...	0.2			0.3

	b High-chromium-steel tube....	847	946	1045	853	921	989

(With 1300-lb. pressure, metal temperature averages approximately 100 deg. fahr. nearer the steam temperature than with 300-lb. steam—see line No. 8. High chromium steel nearly doubles temperature drop through the metal—compare lines No. 6*a* and No. 6*b*—and thus greatly increases the important temperature stresses. Temperature drop through 0.3-in. chromium tubes slightly exceeds the temperature drop from metal to steam. Tube temperatures range between 830 deg. fahr. and 1050 deg. fahr., depending upon combinations of conditions.)

---

[a] Following bases: Thermal conductivity of carbon steel, 310 B.t.u. per sq. ft., per hour, per 1 in., per deg. fahr.; of high chromium steel, 170 B.t.u. per sq. ft., per hour, per 1 in., per deg. fahr. Nusselt's formula, shown on Fig. 9, used for calculating values in line No. 7.

With sufficient experimental background, performance of radiant surfaces can be calculated quite accurately for various ratings and furnace types. A method applied with practical exactness is treated in the Bureau of Mines bulletin, "An Investigation of Powdered Coal as Fuel for Power-Plant Boilers," by Messrs. Kreisinger, Blizard, Augustine, and Cross. Simultaneous temperature and heat-transfer measurements have indicated quite consistently a constant of 1300 for the radiation formula:

$$\text{B.t.u. per hour per sq. ft.} = 1300\left[\left(\frac{T_1}{1000}\right)^4 - \left(\frac{T_2}{1000}\right)^4\right]$$

The distinction between radiant and convection superheaters consists principally of location. Fig. 21 shows 75 per cent radiant-heat absorption at the entrance of a convection reheater, and convection superheaters are in service having higher local rates of heat absorption than some radiant installations.

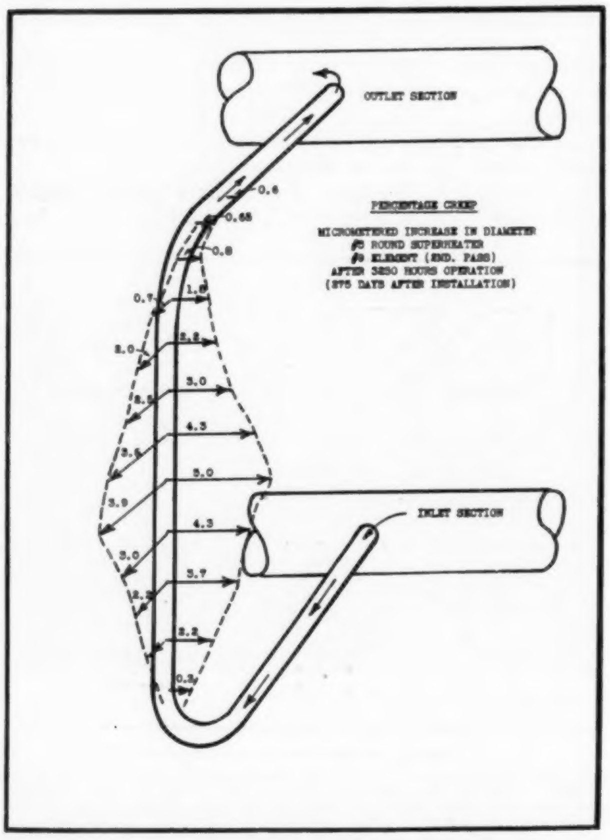

Fig. 10 Turbulence Versus Creep

(That expansion was not due to overheating when starting, but occurred very slowly during operation, is the most important deduction from the above isometric sketch. Turbulence at the bends maintained lower metal temperature than in the middle, and creep values, shown graphed in direction of diameter measured, were correspondingly lower. Higher pressure drop and greater turbulence cause better cooling and lesser creep.)

Fundamental Heat-Transfer Differences, Convection and Radiant Superheaters

For given metal temperatures, pressure drop must increase as rates of heat transfer become larger. The length of steam path decreases, but velocities must increase more rapidly than does heat input rate, and pressure drop varies with the square of velocity. Temperature drop through the metal becomes an important consideration at furnace-heat-transfer rates.

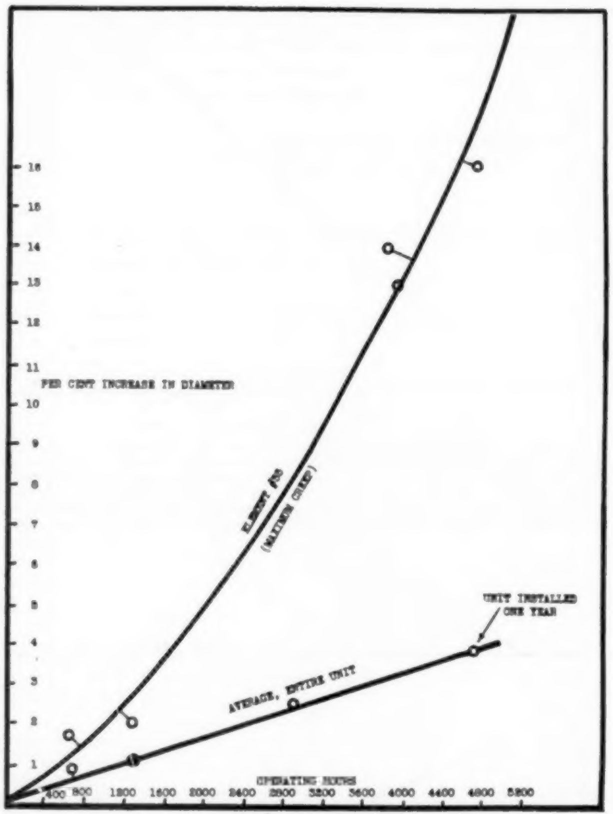

Fig. 11 Creep Rates of Experimental Installation

(That creep is a linear function of operating hours is the most important conclusion from the lower curve. When expansion is so large that the tube walls thin greatly and diameter enlarges appreciably, thus increasing metal-temperature and unit stress due to pressure by several times, the creep curve probably bends upward, as shown by the upper curve. Half of the elements have been removed at convenient times before failure, and half are still in service after 3½ years. They now average 7.4 per cent creep.)

FAILURE OF #35 ELEMENT, NO. 5 SUPERHEATER, SECOND PASS EAST SIDE, WEST EXTREME TUBE. INSTALLED JUNE 10, 1937; FAILED SEPTEMBER 23, 1938 - 6880 OPERATING HOURS

Fig. 12 Creep Failure

(A 37 per cent increase in circumference without failure occurred near the top of the tube, even though expansion around the periphery was not uniform. The original 2-in. tube section could readily be passed through the section shown. Since the effective thickness was only one-fourth of the original, and the inside diameter 60 per cent more, pressure stresses were 6.4 times original stresses. Metal temperature was undoubtedly higher, because of lesser steam velocity. However, temperature stresses were greatly reduced, and the thin tube continued to bear its load. Temperature stresses appear very important, and thin tubes desirable.)

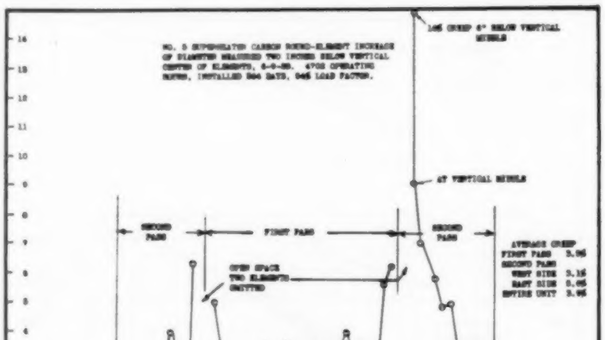

Fig. 13 Creep Variations in an Actual Installation

(Occasional omission of elements, causing higher radiant-heat reflection from the brickwork backing wall, has a marked influence on creep rates. Use of lesser elements in the hotter pass maintained metal temperature about the same as in the first pass. Low-carbon-steel elements increased about 4 per cent in diameter the first year of operation.)

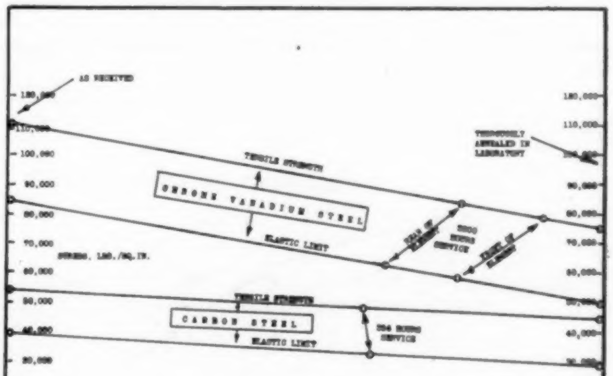

Fig. 14 Annealing Effect of Service at 950 Deg. Fahr.

(That heating to the critical temperature is not necessary for annealing is indicated by the above data. Long-time maintenance at 950 deg. fahr. accomplishes the same results with both kinds of steels. In laboratory testing of metals for creep, it is important that specimens be first thoroughly annealed to simulate ultimate service conditions.)

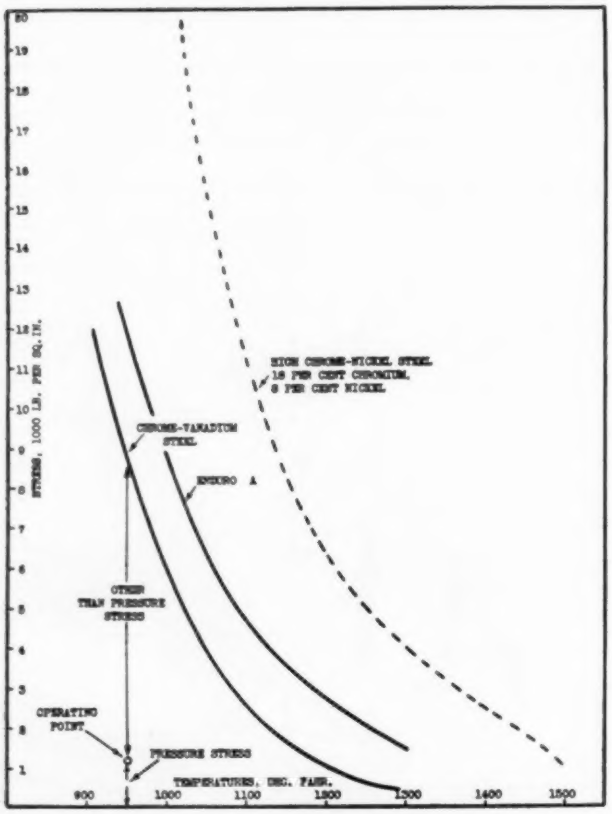

FIG. 15 LABORATORY VERSUS FIELD RESULTS

(Pressure stress is insignificant in producing creep, as study of these curves and operating point will show. The curves are laboratory data, from F. H. Norton, for 1 per cent creep per 10,000 hours. The operating point applies for all 300-lb. steam-pressure round superheater elements. Field creep of the chrome-vanadium elements coincides accurately with that for which the curves were drawn, i.e., 1 per cent per 10,000 hours. Carbon elements increased 4.6 per cent and Enduro A elements 1.5 per cent per 10,000 hours. Additional strength of the Enduro A elements was ineffective because of higher temperature stresses due to lesser metal thermal conductivity. Addition of nickel extends the creep stress considerably, as the dotted curve shows, but thermal conductivity is still lower than that of Enduro A. Obviously, other than pressure stresses are predominant in superheater design.)

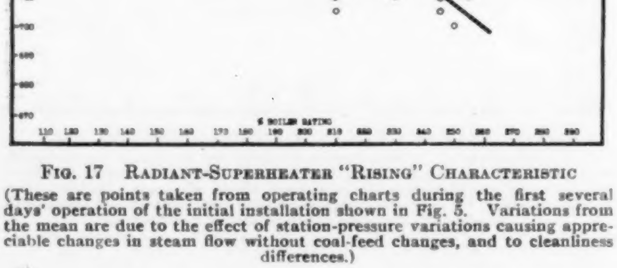

FIG. 17 RADIANT-SUPERHEATER "RISING" CHARACTERISTIC

(These are points taken from operating charts during the first several days' operation of the initial installation shown in Fig. 5. Variations from the mean are due to the effect of station-pressure variations causing appreciable changes in steam flow without coal-feed changes, and to cleanliness differences.)

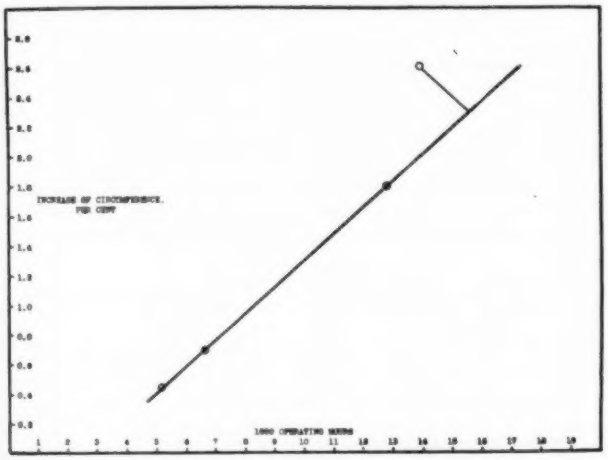

FIG. 16 CREEP OF ENDURO A TUBING

(Four sets of circumference measurements of all 40 Enduro A elements in No. 3 boiler plot against operating hours as shown above. Load factor the last thousand hours has been low, and unreported starting hours high, which possibly explains why the last point is above the curve. Several scattering Enduro elements showed 1.5 per cent creep, while occasionally others with 5 per cent maximums caused the recent average of 2.6 per cent.)

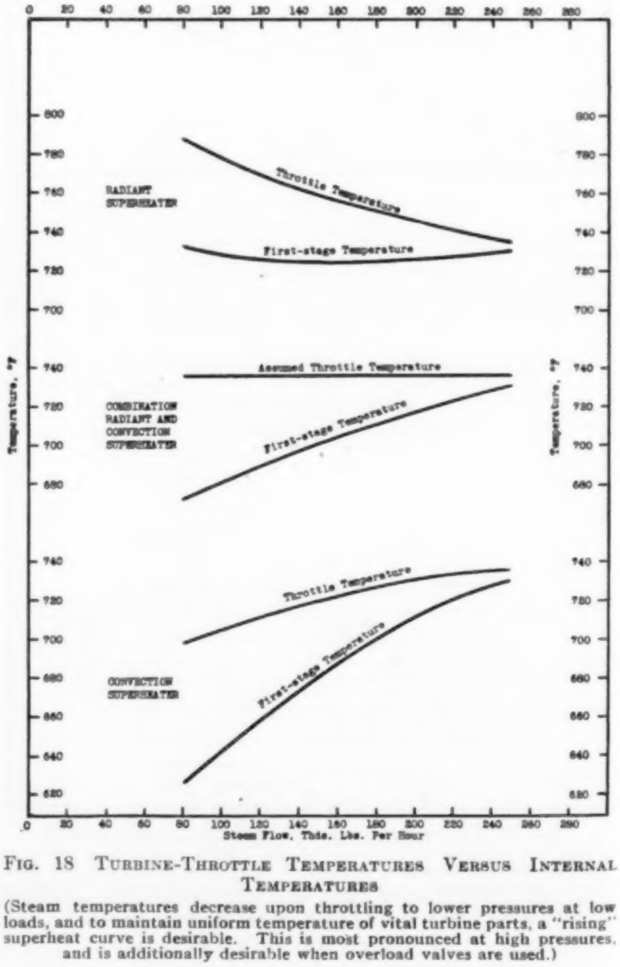

FIG. 18 TURBINE-THROTTLE TEMPERATURES VERSUS INTERNAL TEMPERATURES

(Steam temperatures decrease upon throttling to lower pressures at low loads, and to maintain uniform temperature of vital turbine parts, a "rising" superheat curve is desirable. This is most pronounced at high pressures, and is additionally desirable when overload valves are used.)

The following two major expressions show that cooling of tube metal is not quite proportional to the steam velocity (varies with 0.8 power) and that pressure drop varies with square of velocity. Table 4 solves for metal temperatures under a variety of conditions to illustrate the point that high heat-transfer rates impose a handicap on superheating surfaces.

Heat-Transfer Expression (*Nusselt*):

$$R = 12.9\,\frac{K}{d}\left(\frac{d}{l}\right)^{0.054}\left(\frac{dFc}{K}\right)^{0.786}$$

where

K = conductivity of steam = 0.0131 + 0.000029 t (deg. fahr.)
d = inside tube diameter, in.
l = length, in.
F = mass flow, 1000 lb. per sq. ft. per hour
c = specific heat of steam

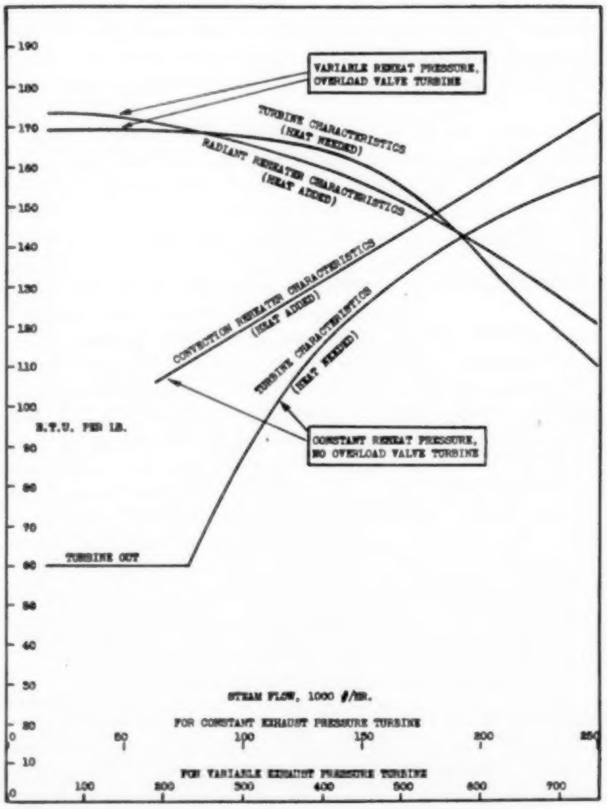

Fig. 19 Contrasts in Reheater Requirements

(Directly opposite reheater characteristics are required for two actual installations A convection reheater suits one well: a radiant reheater fits the other equally well. Turbine type causes the marked difference. Coincidence of the reheater and turbine characteristic curves results in constant reheater-outlet temperature Agreement of slope, at least, is very important.)

The first exponential term $(d/l)^{0.054}$ may be omitted, since for usual length tubes it is very nearly unity, giving

$$R = 12.9\,\frac{K}{d}\left(\frac{dFc}{K}\right)^{0.786}$$

Therefore, the heat-transfer rate varies with 0.786 power of mass flow.

Pressure-Drop Expression (*Fritzsche*):[2]

$$p = \frac{12.8\,v^2Lc}{Vd}$$

where

v = mean velocity, ft. per sec.
L = length of pipe, ft.
c = coefficient, varied by temperature, etc.
V = specific volume, cu. ft. per lb.
d = inside pipe diameter, in.

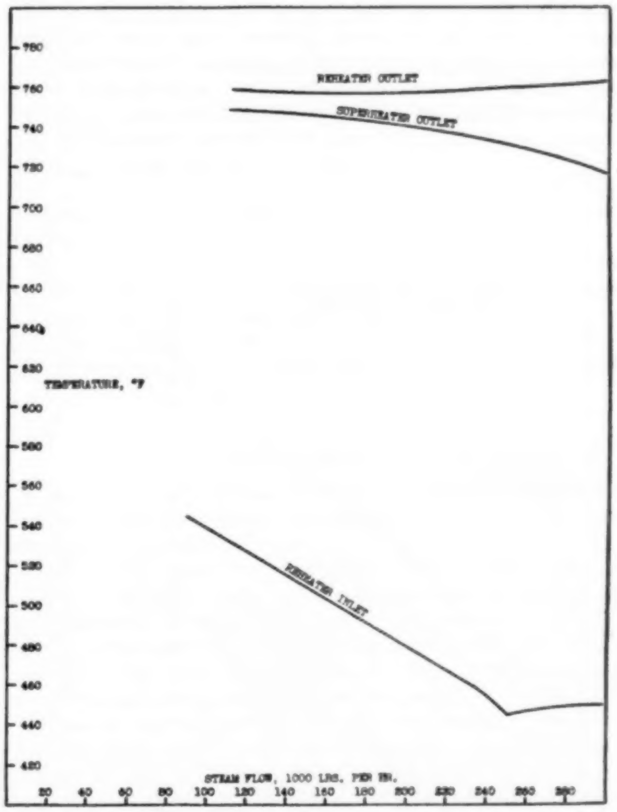

Fig. 20 Where a Convection Reheater Fits Well

(Rapidly increasing exhaust temperatures of a constant back-pressure 1200 lb. turbine as it carries lower loads requires convection-reheater characteristics to result in the flat reheater-outlet temperature curve shown. The rising characteristic of the 1300-lb. radiant superheater is shown. These are actual test data, and were taken with constant excess air in the furnace.)

Thus, from these two expressions,

(1) $R = cF^{0.786}$
(2) $p = c_1F^2L$

Consider two superheaters transferring the same amount of heat, but located in different gas-temperature zones:

$$R = c_2\frac{F}{L} \qquad \text{or} \qquad L = c_3\frac{F}{R}$$

From (1), $F = c_4R^{\frac{1}{0.786}} = c_4R^{1.27}$

Substituting these values in (2),

$$p = c_5\,(R^{1.27})^2\,\frac{R^{1.27}}{R}$$

or, finally, $p = CR^{2.81}$

---

[2] See Marks's Mechanical Engineers' Handbook.

Therefore, pressure loss in superheaters having the same duty and similar design increases rapidly if the same metal temperature is maintained. Doubling of heat-absorption rate requires $2^{2.81}$ or seven times as much pressure drop for the same metal temperature.

Since the time of their initial inception, radiant superheaters have been less likely to cause unscheduled forced outages than many convection installations, merely because uniformity of cooling all tubes has been fortunately dictated by radiant design. Low average steam velocities in the tube banks of many convection superheaters and high header velocities caused velocity heads in the latter to exceed pressure drops across the tubes. Severe tube failures without warning resulted. Later, use of long, continuous tubes between the inlet and outlet headers caused full superheater-pressure drop across each element, and velocity heads in the headers then had little influence in distorting flows through any elements. This principle is naturally dictated in radiant-superheater design, for only a relatively few short tubes can be used, and the pressure drop through each is considerable.

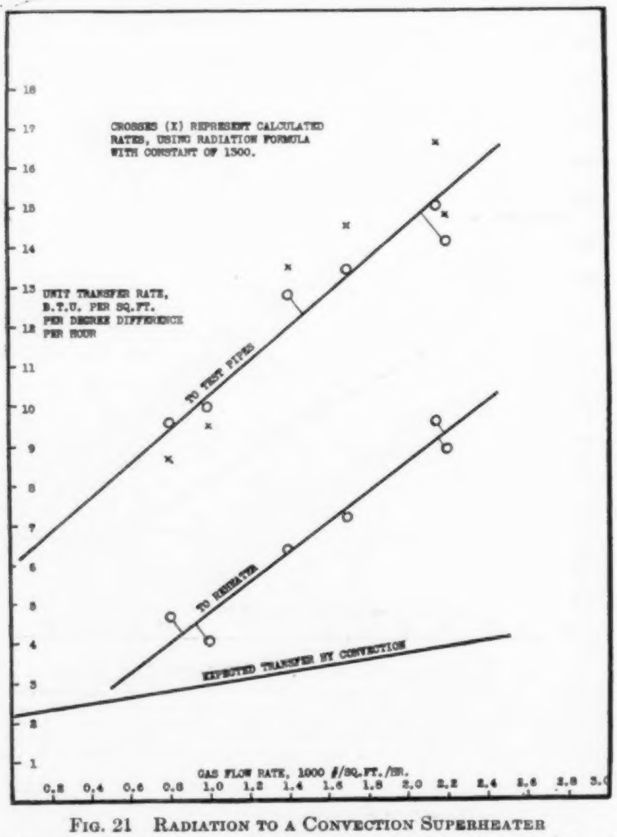

Fig. 21 Radiation to a Convection Superheater

(Test values show 60 per cent average heat absorption by radiation and 40 per cent by convection at high loads. At the entrance of the reheater, where gas temperatures of 1700 deg. fahr. occurred at maximum loads, 75 per cent occurred by radiation and 25 per cent by convection. Single convection superheaters operating in high gas temperatures can have quite desirably flat temperature curves, but as higher steam temperatures and reheat are required, outlet-gas temperatures become so low at low loads that badly "drooping" temperature curves are inevitable.)

Pressure Drop

Uniform heat input throughout the circumference of radiant elements and elimination of all pressure losses not conducive of lower metal temperatures allow minimum pressure drop for given metal temperatures. Round sections are most efficient hydraulically, and use of cores is inefficient. Wherever steam scrubs a tube surface and thus loses pressure, desirable metal cooling should occur. Uniform metal temperature represents maximum efficiency.

The projecting round-tube elements used in the 300-lb. pressure installations are most efficient from the standpoint of uniform peripheral-heat absorption. The flush-with-wall 1300-lb. elements (Fig. 6) are most practical at the higher pressure because of the more favorable heat-transfer characteristics.

Entrance and exit losses, of appreciable percentage with short-length tubes, were diminished by using rounded entrances and discharges in the 300-lb. installations. (See Fig. 8.) A velocity head is conserved, equaling 1 lb. per sq. in.

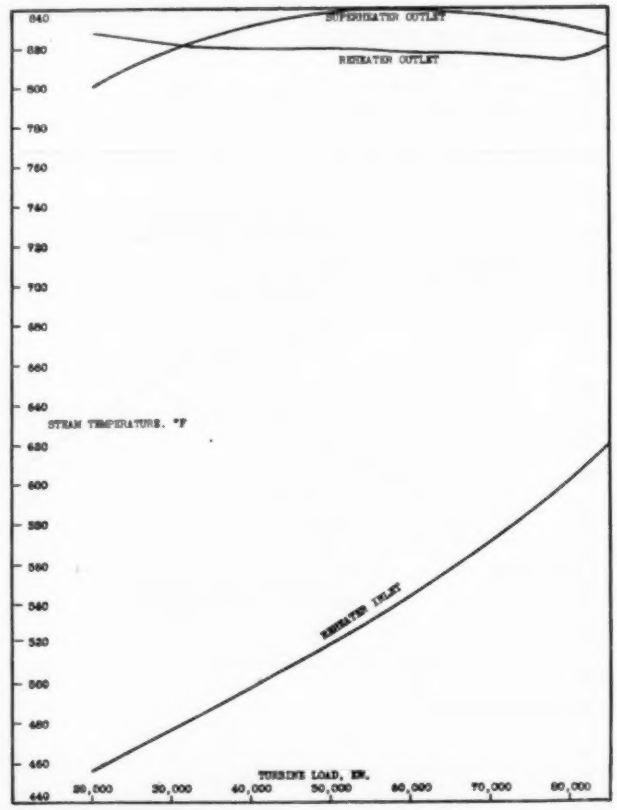

Fig. 22 Uniform High Steam Temperature

(Throttle and reheat-steam temperatures of 825 deg. fahr. throughout a load range of one to four are difficult to average in the case of a single-turbine, single-boiler installation. The above curves, based upon test data, show only 40 deg. fahr. superheat variation and 20 deg. fahr. reheat-temperature variation for this four to one range accomplished by major use of radiant surfaces. Notice the rapidly rising reheater-inlet temperature curve, due to variable reheat pressure and use of two turbine overload valves, which would accentuate the undesirable slope of a convection superheat curve. With simply convection surfaces, the above 20 deg. fahr. reheat-temperature variation would change to 200 deg. fahr.—630 deg. fahr. at 20,000 kw. and 830 deg. fahr. at 80,000 kw. Equipment to give the above results has been purchased for a new station.)

Careful pressure-drop measurements across the initial 1300-lb. round-tube radiant superheater gave surprisingly low results. The usually used Babcock formula gave results nearly twice too large, and the tests were accordingly checked on several occasions. Agreement with Fritzsche's data[3] was found later. Internal tube smoothness probably caused the disparity. Since roughness would probably increase the stationary-film thickness and thus not improve heat transfer, it is important that radiant-superheater tubes be smooth for maximum economy.

Test data and results of application of Fritzsche's formula to the aforementioned superheater follow:

---

[3] As published in Marks's Mechanical Engineers' Handbook, 1916, p. 358.

Data: 212 2-in. chrome-vanadium tubes, 0.30 in. thick, 1128 sq. ft. wall area. Four passes, average length of tube per pass = 31.3 ft. Two bends per tube, 9 in. radius. Headers 7 in. inside diameter.

Steam flow, 1000 lb. per hour	250
Superheater-outlet-steam temperature, deg. fahr	740
Superheater-inlet-steam temperature, deg. fahr	576
Superheater-inlet pressure, lb. gage	1278
Superheater-outlet pressure, lb. gage	1258
Actual pressure drop, lb. per sq. in	20
Calculated pressure drop, Babcock formula	35
Calculated pressure drop, Fritzsche formula	20

CLEANLINESS

Experience with all installations indicates almost 10 per cent decrease of heat transfer the first few days of operation that is never regained. Further temperature loss due to ash accumulations is readily recovered by permanently located soot blowers. The initial surface condition of the unused black elements has apparently a higher radiant-heat absorption coefficient than the slightly roughened brown tubes after service. The Enduro A tubes have been observed to retain their original smoothness longer than the carbon-steel elements and to require less cleaning of ash.

The projecting tube elements installed in the 300-lb. boiler units have the sole minor demerit of necessitating ash removal from the brick backing wall. The 10-in. space fills slowly with fragile "whisker" ash, which requires removal weekly or twice monthly. Because the high-pressure boilers are operated continuously for months without outage, and because this type of hand cleaning would not be convenient, the flush-with-wall installation was used in the later equipment.

The vertical round-tube superheater, using 2-in. tubes on $2^{1}/_{2}$ in. centers and backed with insulating tile, retains its original cleanliness as well as a fin-tube furnace wall. Low-grade coal of 2050 deg. fahr. fusion-temperature ash and 4 per cent sulphur has been burned over long periods with scarcely any soot blowing necessary. Ash particles do not collect on the brick backing, being cooled sufficiently between the tubes to fall downward as dry dust. Radiant-superheater soot-blower steam averages 1/40th of 1 per cent of the high-pressure boiler output.

Internal cleanliness has never been a problem. Outside of finding some water-soluble sodium sulphate in the headers and nipples of the first high-pressure superheater when starting feed-water treatment, no deposits ever have been detected. Steam velocities are high, and bends so liberal that suspended matter cannot collect.

Consideration of the usual radiant-heat transmission expression, which states that heat transferred varies directly with difference of the fourth powers of the absolute temperature between the heating and heated media, shows that metal-temperature differences have practically no influence in reducing heat absorption. A 1000-deg. fahr. tube, compared with a 900-deg. fahr. one operating at a heat-transfer rate of 50,000 B.t.u. per sq. ft. per hour, absorbs only $2^{3}/_{4}$ per cent less heat, and only $11^{1}/_{2}$ per cent less than a 70-deg. fahr. tube.

INSTANTANEOUS STEAM-TEMPERATURE REGULATION

Changing from the heavy rectangular elements to the light round tubes, weighing only 10 per cent as much, distinctly modified the 300-lb. steam-temperature curve because of lesser heat-storage capacity of the latter elements. Rapid and frequent variations, as much as 30 deg. fahr. in a few minutes, occurred due to station-pressure variations. Large boiler-water content ($1^{1}/_{2}$ hours' normal output) caused high or low steam flows without coal-feed variations as pressure changed; and without the great weight of metal of the usual convection superheaters to stabilize temperature, steam-outlet temperatures fluctuated. Good pressure regulation is the only remedy. Instantaneous temperature regulation in the high-pressure boilers is much better due to lesser water content (20 minutes' operation), lesser water-temperature variation with the same percentage pressure variation, and better actual pressure regulation.

When using the heavy rectangular elements, steam temperatures were about 25 deg. fahr. low for the first hour of operation each morning. Storage of heat in metals is important and readily calculated.

INFLUENCE OF STEAM PRESSURE UPON RADIANT-SUPERHEATER DESIGN

Three conditions facilitate radiant design at higher steam pressures. They are:

1 Economic mass-flow rates increase directly with pressure.
2 Specific heat increases.
3 Conductivity of steam increases.

Of course, pressure stress increases, but experiences treated previously indicate that other stresses than that from pressure appear of most importance in causing creep.

At 1300-lb. steam pressure, mass-flow rates equivalent to those in a boiler tube with 3 ft. per sec. water velocity can be obtained economically. The transfer rates may not be as favorable as in the boiler tube due to difference in film conditions, but it is of interest to know that the weight flows can be made equivalent.

PART III

PROPER APPLICATIONS

Quick or unsteady starting and very high rates of furnace-heat transfer render the radiant superheater, in its present state of development, undesirable.

Cooling with steam from extraneous sources, when starting rapidly, is generally futile. Available quantities are so limited that practically no benefit is derived. Calculations, solving for metal temperatures by employing the heat-transfer data given previously, will show that impractically large steam flows are needed to limit metal temperatures within reason.

Minimum starting periods practical with particular installations can be determined fairly accurately by calculation, and checked by test. Maximum water cooling in the furnace walls and minimum water storage in the boiler drums allow quickest starting without overheating uncooled radiant-superheating elements, and in such cases considerations other than superheater maintenance determine the rate of starting.

Heat-transfer rates in excess of 60,000 B.t.u. per sq. ft. per hour have not been averaged in practice. Metal temperatures and temperature stresses increase with higher heat-transfer rates, and a practical limit exists, probably in the region of 75,000 B.t.u. per sq. ft. per hour, depending upon the particular conditions.

Experience with furnace types is needed to prescribe proper radiant-superheater area. Modification of area is not simply accomplished as with convection surfaces. If of the combination radiant and convection type, adjustments can be made in the convection section. If simply radiant, brickwork or water-wall surfaces must be modified if adjustment cannot be made conveniently by flame position or dirtiness. When starting a new radiant installation, low temperatures can be readily insured by partial application of a plastic refractory covering.

INCIDENTAL MERITS OF THE RADIANT SUPERHEATER

Greater furnace-heat absorption and elimination of troublesome furnace refractories have constituted a positive trend of the industry for several years. Higher pressures and temperatures, plus reheat, cause an important trend toward smaller water-cooled surface and larger superheating surface. That some of the furnace cooling surface be for superheating is almost necessary to prevent distortion of designs in the new installations.

Radiant superheaters located on the furnace side walls eliminate many difficult water-wall connections. It is believed that rear-wall and front-wall connections can be made much more conveniently in most installations than can side-wall connections. Greatly fewer outside, inactive tubes are needed, and connections are more direct. Radiant superheaters in the wide walls solve these problems at minimum cost.

Crediting costs of displaced water walls toward the expense of radiant superheaters has an element of fairness. As a rule, additional boiler surface is not expensive after drum water-storage capacity is set, and convection superheaters have thus but a slight credit in reducing boiler cost. Overall costs may be lowest when using radiant superheaters.

Thermally, radiant superheaters are most efficient. Higher steam temperatures reduce radiant-heat transfer but slightly, but they diminish convection-heat transfer greatly, especially at lower loads and in cases where much superheating is done. Heat transfer by radiation is accomplished without draft loss.

Greater excess air (lower CO_2) reduces superheated-steam temperatures from a radiant superheater, but increases them from a convection heater. Exigencies of operation sometimes require an increase of excess air. It increases the safety of an installation to have the radiant characteristics apply.

Temperatures from radiant superheaters can be adjusted by flame position. If they are located in the side walls, changing end-feeder speeds cause a rapid influence at any boiler rating. Radiant-transfer rates vary inversely with the square of distance between the hot and cold bodies. Changing primary-air pressure on all burners, or secondary-air distribution, modifies rear-wall heat absorption.

Uniform turbine-casing temperatures are obtained by the rising radiant-superheater characteristics, as shown by Fig. 18. Even a flat temperature characteristic is less desirable in this respect. Use of overload valves exaggerates the need of higher throttle temperatures at low loads so that more uniform casing temperatures may occur. High temperatures are safest at low loads, since heat-transfer rates through superheater tubes are less, and therefore the important temperature stresses are reduced. Metal temperatures of radiant superheaters decrease slightly with rating in spite of higher steam temperatures. High excess air (low CO_2) need not be used at low ratings to maintain desirable superheat temperatures as in the case of many convection superheaters.

PART IV

Application in Reheat Installations

The following factors show the radiant-superheating surface desirable for reheat installations:

1 Characteristics of turbines arranged for reheat with variable exhaust pressure, and especially those having more than one overload valve, are such that lesser reheat is needed as larger loads are carried. Reference to Fig. 19 shows this condition, contrasting it with that caused by a constant-reheat-pressure type of installation.

2 Use of a separate reheat boiler to obtain uniform reheat temperatures greatly increases boiler-room investment costs and complicates operation. Single-boiler, single-turbine installations are better able to be taken out of service every night, an ultimate requirement of all equipment. Radiant equipment assists single-turbine, single-boiler design.

Use of a separate reheat boiler generally requires two standard boilers. In the case of a recent 80,000-kw. extension, one boiler unit was chosen instead of two because of simpler, equally reliable operation, and of an investment saving in boiler plant of $4 per kilowatt.

3 Convection-superheater characteristics "droop" more at low loads as more superheating surface is installed in regions of lower gas temperature. With a primary convection superheater occupying the standard position, characteristics of a convection reheater following it are of exaggerated undesirability. This is especially true as higher steam temperatures are used, higher feed-water temperatures occur, and steam pressure is high. Heat absorbed in evaporating water so lessens, and superheating duty so increases, that usual practice is greatly distorted. In an installation under construction, 690 B.t.u. per lb. will be added in the boiler and 385 B.t.u. per lb. in the superheaters (56 per cent as much in the latter as in the former). Superheating duty is becoming so high that extensive furnace cooling with water walls cannot be practiced without causing a low temperature head for convection-superheating surfaces.

4 When re-superheating is accomplished with facility, use of two stages of it to obtain greater economies, not simply to reduce moisture in lower turbine stages, may occur. Use of radiant equipment will assist attainment of these additional gains.

5 Regulation by inherent characteristics, not by special control, is a merit of considerable desirability when applied to high steam temperatures. Excessive temperatures for short periods or rapid changes up or down may not cause permanent harm in the boiler room, but great trouble in the turbine room. Relieving the operating force of all temperature-control attention and hazard is certainly desirable.

CONCLUSIONS

1 Developments of the industry toward more superheating emphasize the need of radiant superheaters.

2 Important saving in plant investment costs can be effected by reheating in single boilers serving single turbines. Radiant-superheating surfaces permit this design by insuring practically uniform steam temperatures throughout wide load ranges without any attention.

3 Sufficient experience with simple round-tube superheaters has been obtained to accurately predict their behavior under most furnace conditions. Creep rates have been measured, and metal temperatures are known. For present steam temperatures, they are thoroughly satisfactory, and have been purchased for 850 deg. fahr. steam temperature.

4 High pressures are particularly adapted for radiant superheaters, for pressure stresses appear a minor factor in causing creep. Higher allowable mass-flow rates, higher specific heat, and better steam conductivity more than compensate for higher metal stress due to pressure.

5 Radiant superheaters have incidental merits of facilitating furnace cooling by covering side walls that are not as easily water cooled as front and rear walls, of reducing total heating surface costs because of better transfer efficiency, and of allowing lower CO_2 without excessive steam temperatures when burning unusually poor coals. Temperature adjustment by flame position and more uniform internal turbine temperatures are other merits.

6 Very high heat-transfer rates and quick starting preclude their usage.

7 More and better operating results of metals at high temperatures are needed to extend present upper steam-temperature limits. The experience treated herein suggests that temperature stresses are very important determinants of tube maintenance, and they should be evaluated with exactness. High-chromium steel appears considerably handicapped by its lower thermal conductivity, which greatly enhances the important temperature stresses. Oxidation resistance is needed by low-carbon steels.

8 Frequent and accurate creep and metal-temperature mea-

surements of tubes in service will supply a further development need that the laboratories cannot furnish. Much excellent laboratory creep work has been done, but applying its results with large safety factors is undesirable. The best justification of this paper would develop if it serves as an effective request for more complete operating information.

Discussion

T. McLean Jasper.[4] The general subject of superheating ties up intimately with the strength of metals at elevated temperatures. The most significant thing bearing on the service of materials brought out by this paper is the fact that Enduro steel, operating at only 30 to 50 deg. fahr. higher temperature than the low-carbon steel, due to metal heat-transfer rate, shows a creep rate materially higher than that of carbon steel. The manufacturers of Enduro steels would, the writer feels sure, say that this was not according to their best information based on laboratory tests. This indicates another example in which laboratory tests are not in agreement with carefully made practical tests.

Any one dealing with the practical problem will very properly follow the dictates of the service test.

In Figs. 5 and 6 are shown some superheater elements in place. The writer is wondering if the coefficient of expansion is not largely responsible for the condition of increased creep in the Enduro tubes. Their ends are fairly well fixed, and they will therefore assume a much greater longitudinal strain with increased temperature than will the plain-carbon or chrome-vanadium tubes.

Another significant observation is the confirmation of the value of low-alloy-content chrome-vanadium steel for elevated temperature work. This steel has greater resistance to oxidation than low-carbon steel, and also has a good heat-transfer rate and without any material increase in coefficient of expansion.

N. Artsay.[5] It is a long time since such a good paper on a burning question has been presented before the Society. This story of development in the radiant superheaters is an illuminating lesson.

It is a pity, indeed, that thermal stresses are so little known and understood by the majority of engineers. Every housewife knows the danger of pouring hot water into a thick glass vessel and every foundryman knows the danger of rash cooling, but the mechanical engineers, knowing for a long time the existence of thermal stresses in pipes, rails, and in other obvious cases, and knowing vaguely about such stresses in Scotch marine and Lancashire boilers, had very seldom thought of such in boiler tubes.

The question of stresses in tubes subject to a certain rate of heat transfer has been dealt with theoretically by Lorentz in Germany, as far back as 1907 (V.D.I., 1907, p. 743), later on by Mellanby and Kerr in England (Proc. I.M.E., 1927), by Orrok in the United States ("High Pressure Boilers," Trans. A.S.M.E., 1928), by Munzinger in Germany (Kraftwerk, April, 1930), and by Doucherty (London *Engineering*, April 25, 1930).

From all these sources we may draw a general formula:

$$S = a\eta \frac{Htd_o}{Kd_i}$$

where

S = thermal stress, lb. per sq. in.
a = a coefficient
η = ratio of Young's moduli at actual metal temperature and at 60 deg. fahr.
H = heat transfer, B.t.u. per hour × sq. ft.
K = conductivity, B.t.u. per hour × sq. ft. × deg. fahr. per inch thickness
t = thickness of tube metal, in.
d_o = outside tube diameter
d_i = inside tube diameter

According to Orrok, $a = 130$.

Let us compare thermal stresses in the tubes reported by Drewry.

η = 0.675 and 0.83 at 950 deg. fahr. for open-hearth and alloy steels, respectively
K = 310 and 170, respectively
H = 50,000 B.t.u. per sq. ft. × hour
t = 0.205 in.
d_o = 2 in.
d_i = 1.59 in.

The temperature difference is θ between outer and inner tube surfaces.

$$\theta_1 = \frac{50{,}000 \times 0.205 \times 2}{310 \times 1.59} = 41.6^\circ\text{F., open-hearth steel}$$

$$\theta_2 = \frac{50{,}000 \times 0.205 \times 2}{170 \times 1.59} = 76^\circ\text{F., Enduro metal}$$

Thermal stresses:

$$S_1 = 130 \times 0.675 \times 41.6 = 3650 \text{ lb. per sq. in.}$$
$$S_2 = 130 \times 0.83 \times 76 = 8200 \text{ lb. per sq. in.}$$

Pressure stress is 1200 lb. per sq. in. (original).

Respective total tension stresses in inner fibers are:

4850 lb. per sq. in., plain low-carbon steel
9400 lb. per sq. in., alloy steel.

Thinning down to one-half thickness will increase the pressure stress to 2400 lb. and reduce the thermal stress to 1900 and 4100 lb. per sq. in., respectively, so that the total tension stresses at halving of local thickness are 4300 and 6500 lb. per sq. in., respectively.

These figures indicate that the rate of creep should slow down as time goes on. The author's curve of creep on Fig. 16 for the Enduro tubes indicates, if extended down, almost no creep for the first 3000 hours. For the plain-carbon steel (Fig. 11) the actual points tend to show 0.8 per cent initial creep from the beginning and the slowing down of the creep rate as years of operation go by. Thus the alloy steel shows a peculiar behavior. An assumption could be advanced that while occasional overheatings during starting up periods did not harm the plain-carbon steel, they did change something in the alloy steel, and so it began to creep. The mentioning of irregular creep behavior of Enduro tubing (caption under Fig. 16) seems to support the assumption. Moreover, the annealing effect (Fig. 14) at 950 deg. fahr. is only 17 per cent for plain-carbon steel and 33 per cent for the chrome-vanadium steel; for the Enduro tubes data are not given, but it is reasonable to expect an even greater effect on the higher alloy steel. The author's observation of the difference in the field and the laboratory behavior of steels is very fortunate indeed, and his suggestion of more study and records of this difference should be heartily supported.

European practice with very high steam temperatures (Witkowitz, 932 deg. fahr.) indicates a way for a more economical use of materials. The total steam temperature is achieved in three stages: Saturated steam is admitted into a radiant superheater made of plain-carbon-steel tubes, then into the second (cooler) convection zone, also made of low-carbon tubes, and at last into the final alloy-steel superheater placed in the hot convection zone. In the latter part the molybdenum steels were most successful.

[4] A. O. Smith Corporation, Milwaukee, Wis. Mem. A.S.M.E.

[5] Principal Assistant Engineer of Geo. A. Orrok, New York, N. Y. Mem. A.S.M.E.

The laboratory study of creep should be supplemented by the determination at various temperatures of Young's modulus and of heat conductance for steels under consideration. At present there is felt a woeful lack of this information, while it is as important as the creep curves themselves. Any intelligent use of creep data is impossible without calculating thermal stresses, and so very little has been done to verify the conductance for instance. It seems certain that thermal conductance goes down as metal temperature rises, which aggravates the situation.

Let it be hoped that this excellent work of Drewry will bring more correlation in the present haphazard efforts to analyze the creep. The writer trusts that the necessity of a joint meeting on creep to fix a general program of investigations will soon be realized.

H. J. KERR.[6] The author is to be congratulated on his paper, which combines the application of fundamental principles with a description of scientific operation developed on the basis of the theories used. The design of radiant-heat superheaters is a complicated one if for no other reason than the fact that furnace characteristics vary over a tremendous range. To obtain the full value of the paper, which is certainly a valuable one, the exact conditions which the author started out to meet and which he apparently has well met should be considered, and it should not be assumed that the answers which he has found are applicable to all conditions.

In general the conditions with which the author has dealt are:

1 Low-duty furnaces in which the heat of combustion per cubic foot of furnace volume is not as high as is often called for
2 Coal having a high-fusion-temperature ash
3 Load conditions permitting of careful combustion control, as represented by a starting time of 4 hours
4 An operating personnel that has cooperated with him in securing the best results
5 A maximum steam temperature of 750 deg. fahr.

For these conditions he has apparently developed round-tube radiant-heat superheaters which are meeting the required service conditions, though one might question whether the replacement of tubes at certain intervals as a maintenance problem is entirely satisfactory.

In considering the results, however, from the broader angle of using various kinds of furnaces, some points brought out in the paper may be enlarged upon.

If one takes the radiation formula as given and assumes a transfer rate of 50,000 B.t.u., a furnace temperature of the order of 2100 deg. fahr. is obtained. It would be interesting if the author would say a few words on this, explaining just how this temperature is obtained or just what this temperature actually is. In the majority of furnaces throughout the country it will not be safe to assume either this temperature or this transfer rate as being the maximum to be expected. It is evident, then, that a radiant-heat superheater must be placed in a carefully picked location in the furnace, and where the requirements call for installing the superheater on all walls the problem of meeting higher transfer rates which will surely be obtained locally, at least, must be faced.

Fig. 15, showing the relationship between creep values and the actual pressure stress, is extremely interesting. The author apparently assumes that the major part of the difference between the pressure stress and the creep stress represents temperature stress. Our results do not confirm this conclusion. The apparent discrepancies here would appear to be the result of obtaining on the tubes at some period in the operation higher temperatures than those which are credited to them. In general, our investigation of this matter indicates that we can come very much closer to the creep curve with our pressure stress without obtaining measurable creep over a period of two years.

In comparing square or rectangular tubes with round tubes, it should be borne in mind that the comparison in the paper is on round tubes 0.3 in. thick versus square tubes or rectangular tubes $^3/_4$ in. thick. If this comparison had been made between round tubes and small square tubes of approximately the same thickness, there would not have been the divergence between the tube temperatures obtained. The small square tube, furnishing a flush wall, has advantages, particularly at low ratings where the mass flow is low. In general, the most critical zone for tube temperature is at the very low ratings, particularly where the rising-curve characteristic exists (the rising curve is not characteristic of all radiant-heat superheaters). This is an important factor, particularly where boilers must be placed in service in a shorter time than that permissible at Milwaukee or where firing conditions will not permit of starting up in such a way as to shield the superheater.

With round tubes placed out in the furnace away from the walls, we know from experience that, when dealing with a slagging coal, slag accumulates behind the tubes and around them. It is possible under certain conditions to operate with water tubes located in this manner, but the variation in heat absorption is too great for the satisfactory operation of superheater installations of this type except where the temperature conditions are sufficiently low to insure an absolutely dry ash which will not adhere. If from this type of construction you proceed to the round tube close together, so as to eliminate the formation of slag, then you are back to the condition where only one-half of each tube receives radiation from the furnace, and if the heat head is high enough, the front side of the tube becomes considerably hotter than the rear side, and the tubes tend to bow away from the furnace. In the case of round tubes this bowing will unfortunately not be perpendicular to the wall in all cases, and the tendency is for these tubes to warp out of shape, necessitating a complete wall outside the superheater and a considerable variation in the heat application to the different tubes. In this respect the small square tube, if given an initial bow to the furnace and held, will remain in its proper position for long periods of time. Thus the square tube eliminates the necessity of an outside brick wall.

Fig. 13 indicates clearly how close these tubes are to the limit of overheating when the removal of one tube along the wall will increase the rate of creep on the tube adjoining from about 6 per cent to 15 per cent.

Fig. 17 shows one of the disadvantages of radiant-heat superheaters in general, indicating as it does a variation in steam temperature of some 50 deg. at a given rating during the first several days of operation. Undoubtedly a method of operation has been developed at Milwaukee to eliminate this condition at the present time, but it is nevertheless one of the disadvantages. In our experiments with radiant-heat superheaters we have found that the steam temperature is affected very materially by steam flow, feedwater, and pressure fluctuations.

---

[6] Chief Engineer, Service Department, Babcock & Wilcox Company, New York, N. Y. Mem. A.S.M.E.

This is very noticeable on marine installations when maneuvering the ship.

Dealing now with the question of materials, there is no doubt that some of the low-alloy materials available for superheater use have superior creep values up to approximately 1000 deg. fahr., but in general there is very little improvement above this temperature. Again, as the author points out, an important factor in determining the material to be used is the oxidation rate. In general, at tube temperatures of 1000 deg. fahr. and above, there is little if any gain in using low-alloy-steel tubes in place of carbon-steel tubes. Work by Porter, Fellows, and Rummel shows that when plain steel exceeds a temperature of 950 deg., dissociation of the steam takes place and the hydrogen formation increases fairly rapidly. Therefore a material to be satisfactory for this purpose should not only give an increased stress for a given creep rate at 1000 deg., but should also show a distinct improvement in oxidation rate on the inside of the tubes.

Investigation of and experience with Nirosta KA2 steel with steam temperatures of the order of 1000 deg. and tube temperatures over 1200 deg. fahr. indicates clearly that this material meets this requirement at temperature levels well above those permissible with low-alloy steels.

While it is true that the conductivity of Nirosta KA2 is materially less than that of plain steel, the use of this material should certainly lead to a big improvement over plain or low-alloy steels at heat transfers far above anything contemplated for radiant-heat superheaters, even with steam temperatures as low as 700 deg. fahr. Nirosta-tube superheaters at our Bayonne Works have operated satisfactorily under conditions where plain steel immediately showed signs of failure. One of these Nirosta superheaters has been maintained in operation for endurance tests and has operated for more than a year without any indication of failure, with steam temperatures from 750 to 850 deg. fahr. and metal temperatures as high as 1200 deg. fahr. The higher stress permissible with this material permits of reduction of thickness, which compensates for the lower conductivity.

In general, operators are very much opposed to controlling combustion conditions to meet any other requirements than those of capacity and efficiency, and in general radiant-heat superheaters do not permit this simplicity. The experience at Milwaukee indicates that the control of the combustion can be worked out to quite a satisfactory standard, but it should be borne in mind that this is a necessary requirement of radiant-heat superheaters. How serious a problem this control may be is somewhat affected by type of furnace and again by the mental attitude of those who are to operate it. This last statement might also hold for the regulation of steam temperature by desuperheating. The author feels that such a method is not the most desirable method, whereas it appears to the writer that control of steam temperature by automatically desuperheating the steam at an intermediate position of the superheater represents the most foolproof method for obtaining constant superheat which has been developed.

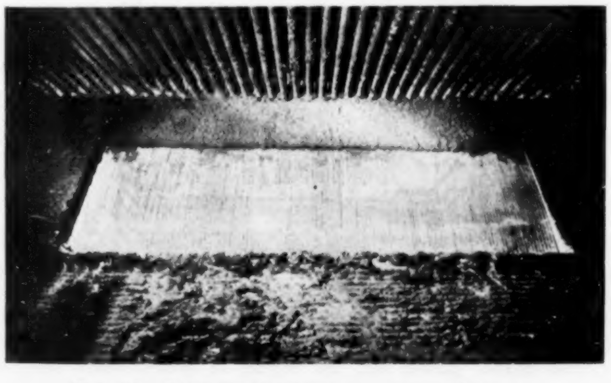

Fig. 23 Calumet Superheater After Service

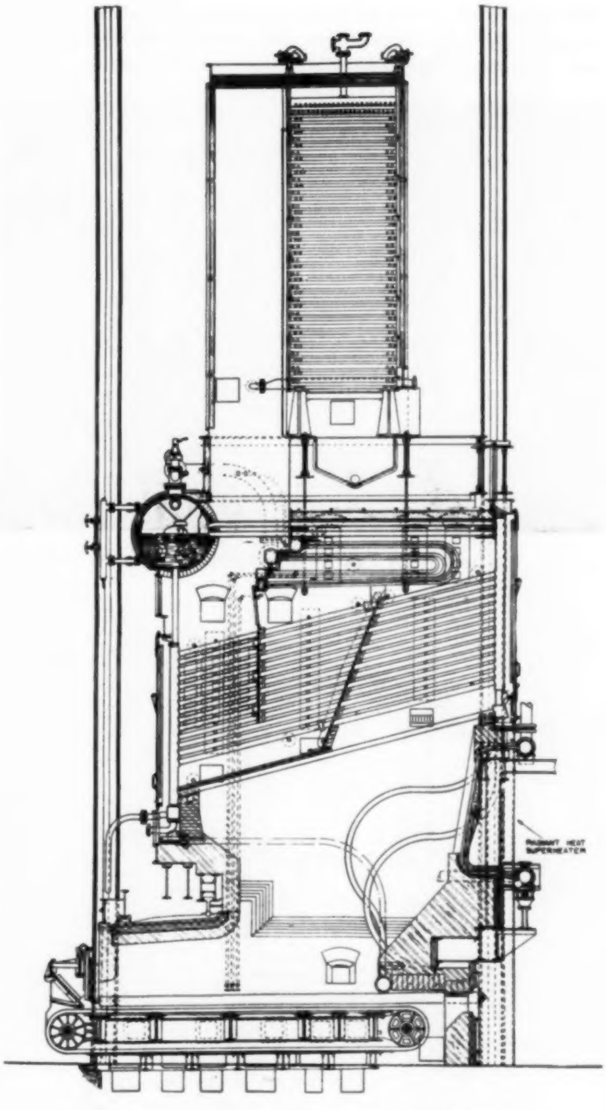

Fig. 24 Boiler and Furnace at Calumet
(Showing location of radiant-heat superheater.)

To show the range of requirements for radiant superheaters, Fig. 23 is a photograph of a small square-tube element superheater installed at the Commonwealth Edison Company's Calumet Station, Chicago. After two years of service with outlet steam temperatures up to 740 deg. fahr., heat inputs up to 58,000 B.t.u. per hour per sq. ft. of wall area, and a pressure drop of 7 lb., with a mass flow of 300,000, this superheater gives every evidence of having an indefinite life. This superheater is set over a forced-blast chain-grate stoker in a furnace having no other wall cooling and a maximum heat release of 40,000 B.t.u. per hour per cu. ft. Fig. 24 is a drawing of the boiler and furnace showing the location of the radiant-heat superheater.

As another example, Fig. 25 shows a photograph of a radiant-heat superheater installed at the Trenton Channel Plant of the

Detroit Edison Company which has been in operation for some two years with final steam temperatures of 1000 to 1100 deg. This superheater has plain-steel tubes at the low-steam-temperature end and Nirosta KA2 at the high-temperature end, the tubes supporting brick liners so as to reduce the heat-transfer rate and give a metal-tube temperature of approximately 100 deg. above max mum steam temperature with a mass flow of the order of 120,000 lb. The writer is expecting that Mr. Van Duzer, of the Detroit Edison Company, will report as to the operating conditions in detail and the present condition of this superheater.

Fig. 25 Radiant-Heat Test Superheater at Trenton Channel Plant

As still another example, there is shown in Fig. 26 a print of the superheater now being installed at the Delray Plant of the same company to heat 90,000 lb. of steam an hour to a maximum temperature of 1100 deg. fahr., with a pressure drop of approximately 25 lb. through the unit and to meet certain efficiency specifications. The flow through this unit is first through a steel-tube superheater, from there through a KA2 superheater, which is parallel flow, and finally through the radiant-heat superheater in the furnace, which is of the same construction as that shown in Fig. 24.

Steam temperatures in the various sections will be, roughly, as follows:

	Deg. fahr.
Inlet	700
Outlet of plain steel section	800
Outlet of KA2 parallel flow section	1000
Outlet of radiant heat section	1100

It might be added that designs are now being made for boilers with superheaters to give a final temperature of 1000 deg. fahr., and such superheaters will be located in a position where they will receive both convection and radiant heat.

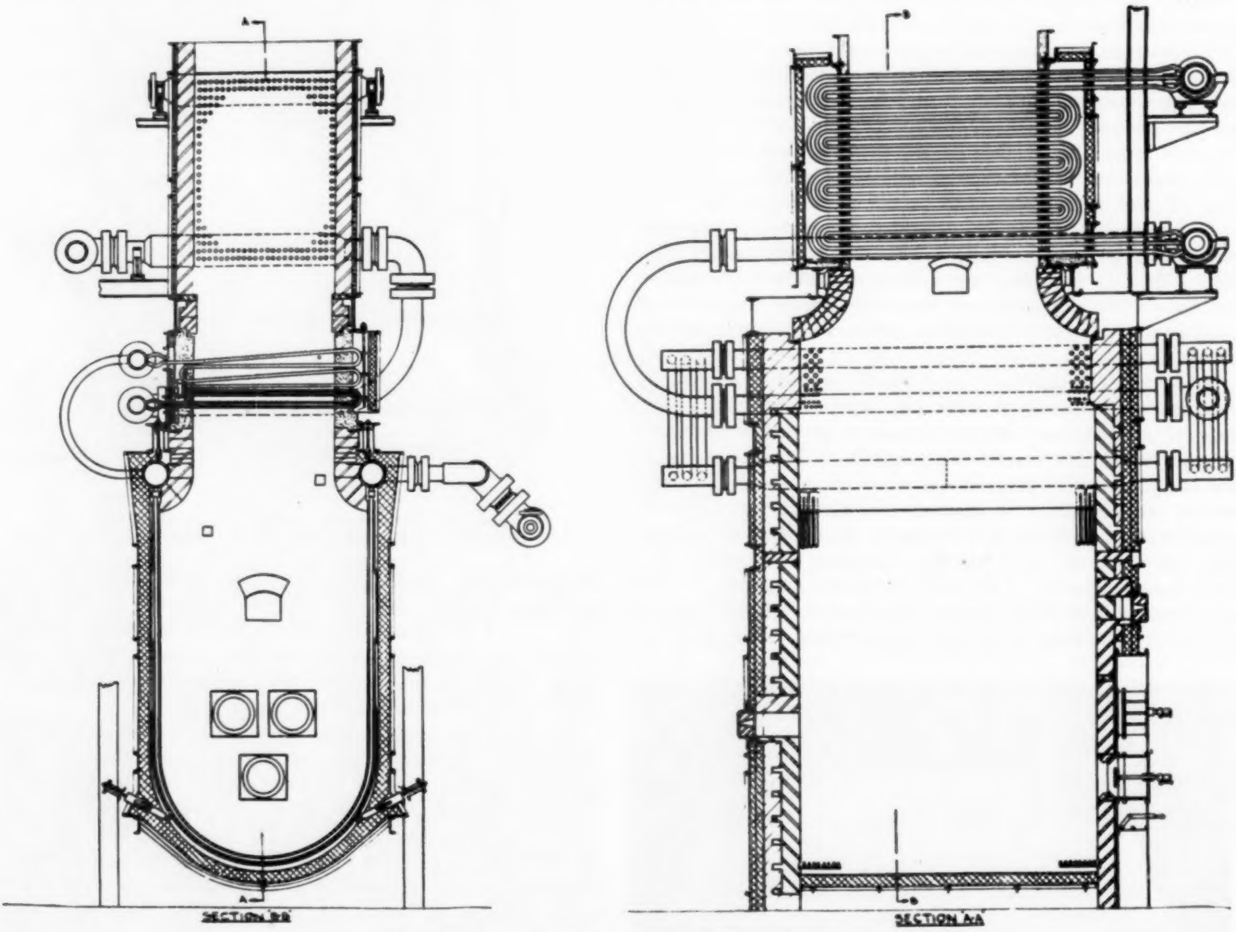

Fig. 26 Superheater for the Delray Plant

The author points out the benefit in heat-transfer rate of increasing pressure up to 1400 lb. The writer is glad to be able to add to this the fact that this benefit continues at higher pressure. We have operated our high-pressure radiant-heat superheater up to 3500 lb. pressure, and at 2500 lb. pressure, with a heat input of 40,000 B.t.u. per hour per sq. ft., we are obtaining a temperature difference between the steam and the outside of tube of only 60 deg. fahr.

R. M. Van Duzer, Jr.[7] The Detroit Edison Company has had in service, since the early part of 1929, an experimental separately fired superheater capable of raising the temperature of 6000 lb. of steam per hour from 700 deg. fahr. to 1100 deg. fahr. The tubes in this superheater, which was supplied by the Babcock & Wilcox Company, were made from a 0.08-C steel and from Enduro KA2. The carbon-steel tubes were installed in the rear wall and the KA2 tubes in the side walls, both of which were covered with protecting tile. Fig. 27 shows the details of this equipment. Steam enters the lower header and flows in four parallel paths to the outlet fitting.

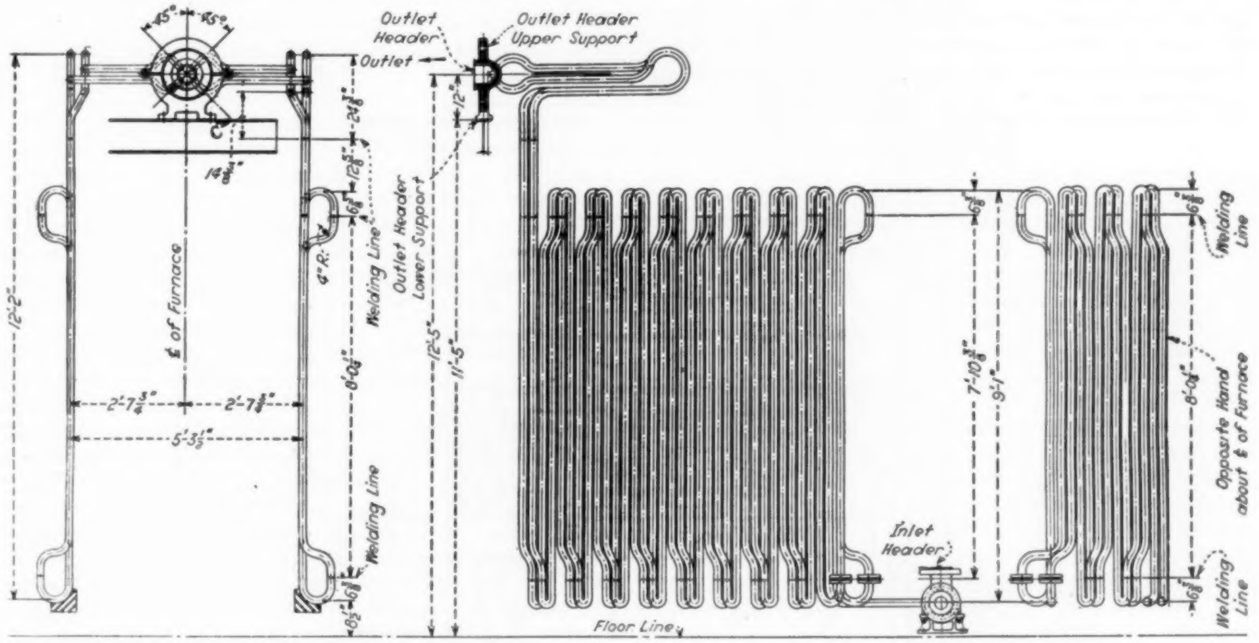

Fig. 27

Table 5 gives a summary of the hours in service to May 25, 1931. No trouble has been experienced with this superheater since its installation.

Table 5

Steam temperature	Hours
Below 900 deg. fahr.	325
900 deg. fahr.	1,458
1000 deg. fahr.	2,398
1050 deg. fahr.	438
1100 deg. fahr.	6,221
Total	10,840

After the superheater, as supplied by the Babcock & Wilcox Company, had been in operation over a year, a section of calorized tubes was added to the outlet, where it was subjected to the hottest steam. This installation was made to determine the effectiveness of the aluminum coating against scaling, and also to find a material that could be substituted for the expensive 18-8 alloy steel. This addition consisted, essentially, of eight $1^3/_4$ in. outside diameter, $^3/_8$-in. wall, 8 ft. long, 0.15-C calorized-steel tube sections, which were placed in the combustion chamber with the lower ends subject to direct flame impingement. No refractory protection was placed on these tubes.

It was realized at the time that the service was rather severe and that use of this material would not be warranted under like conditions in regular operating equipment. The location selected, however, was the best available for securing the information in a short time.

The tubes were removed after 3821 hours of service because of severe growth of two of the forged return bends, located in the flame travel. This growth amounted to nearly 20 per cent. The tubes, themselves, were badly scaled and had increased in diameter from 6 to 8 per cent in the hottest portions. This corresponds to a creep rate of from 16 to 21 per cent in 10,000 hours. The tube metal temperatures varied from 1000 deg. fahr. to 1200 deg. fahr. over the operating range, and the maximum combined stress due to internal pressure and heat flow, from Orrok's equation, was 3100 lb. per sq. in. These creep rates are not to be taken as absolute values, as the measuring points provided on the tubes were affected by the scale formations.

The success of the 18-8 material in this experimental superheater served as the basis of design for the Babcock & Wilcox separately fired superheater which will be placed in service at Delray No. 3 the latter part of this month, supplying steam to the British Thomson-Houston high-temperature turbine-generator. A cross-section of this unit is shown in Fig. 28.

Steam at 700 deg. fahr. is led into the top convection section, which is composed of low-carbon steel. From there, it passes to the middle combined convection and radiant section made of alloy steel; and then on to the lower alloy radiant section. The unit contains approximately 4000 sq. ft. of surface and is designed to raise the temperature of 90,000 lb. of steam per hour from 700 deg. fahr. to 1100 deg. fahr.

The steel used for the two lower sections differs from the material used in the experimental installation in the silicon

---

[7] Detroit Edison Company, Detroit, Mich.

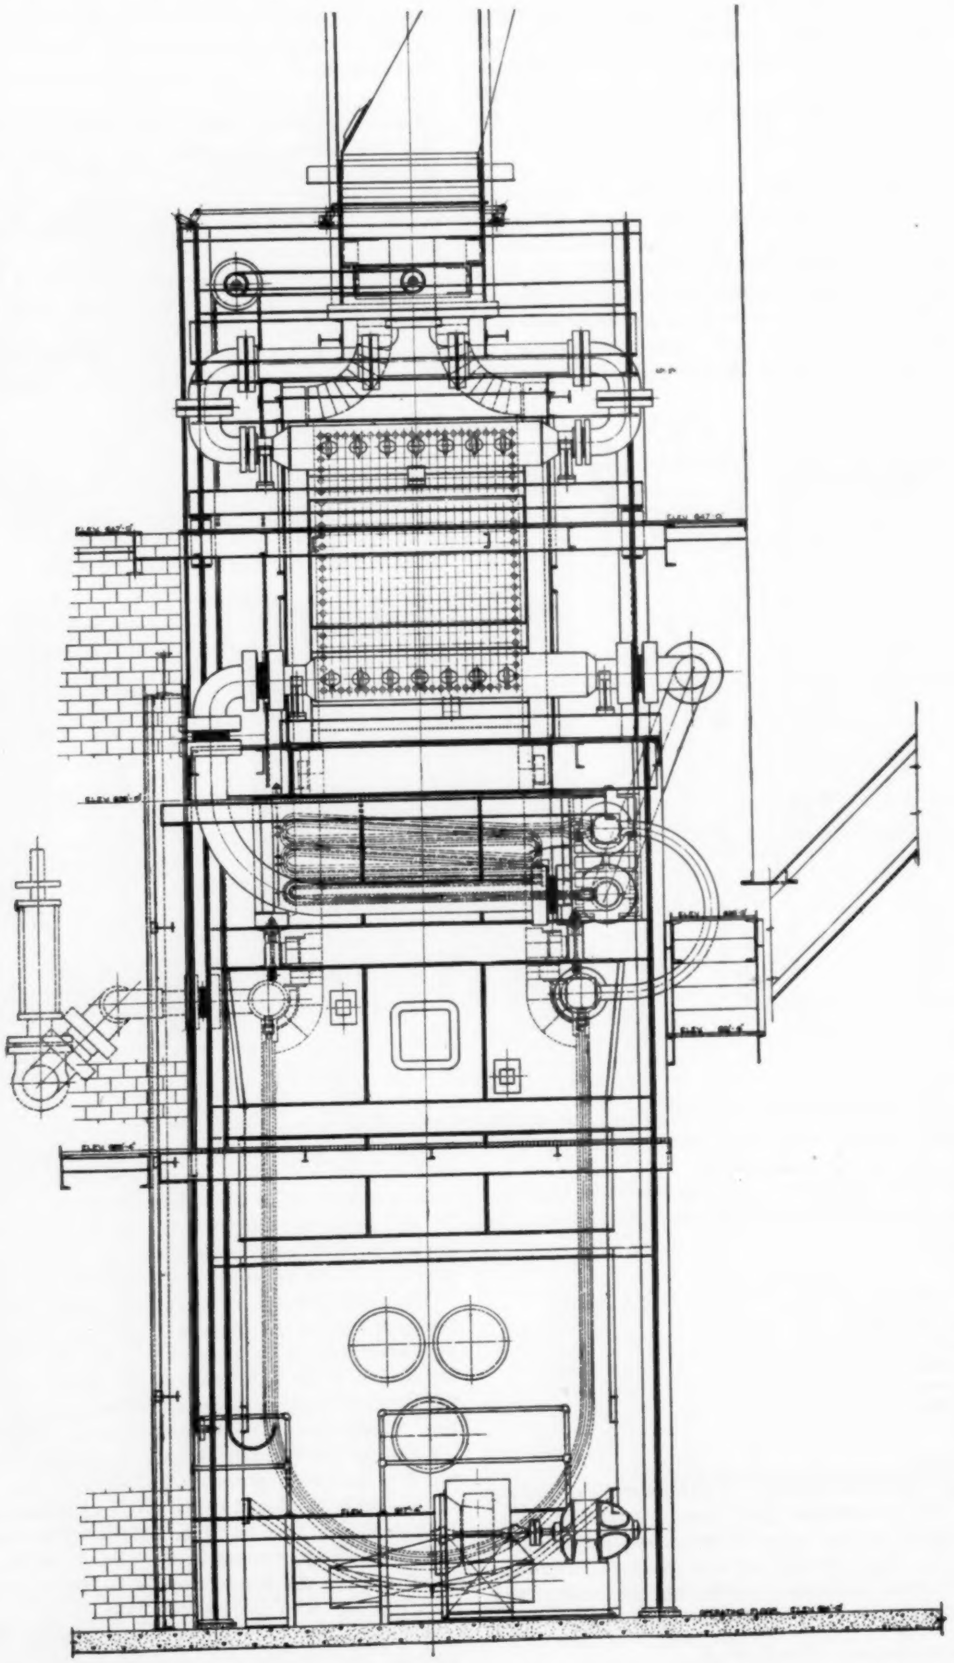

Fig. 28

content. To increase the resistance to sulphur corrosion from the flue gases, 2 to $2^1/_2$ per cent of silicon was added.

A group of high-carbon tubes have been installed in the middle section of the superheater for comparison with adjacent KA2 tubes. Part of this group is calorized, while the remainder has a protective coating of KA2 steel which was applied with a Schoop metal spray gun.

The creep data presented by the author are valuable and reassuring to those who are interested in the development of superheating equipment for higher steam temperatures. It is hoped that additional material will be published in the future on the same subject.

Three other items should receive consideration, together with creep values, in the selection of materials for high-temperature superheater tubing. These are the rate of scale formation, the effect of dissociated steam, and the change in crystal structure indicating a tendency toward embrittlement. Information of this nature concerning the three steels reported in the paper would be of value.

W. E. Caldwell.[8] The paper furnishes a wealth of information on operating experience with radiant superheaters as well as on the operating technique which has been developed in their use and maintenance. The simplicity of the radiant superheater is so attractive that it requires little else to commend it where conditions will permit its use. However, it requires more careful coordination of various related apparatus than does the more conventional type.

Radiant superheaters appear better suited to pulverized-fuel firing than most other methods, since their successful use depends largely on control of furnace conditions and a large furnace which is also desirable for most types of pulverized-fuel firing. The shape of the furnace and the arrangement of the burners are also important considerations, and the latitude in this respect is somewhat limited. The protection of radiant superheaters against unexpected loss of load is a simple problem with pulverized fuel and adequate water cooling in the furnace, since the fire may be quickly extinguished and superheater safety valves depended upon for the final cooling effect.

Paralleling the development of the radiant-type superheater, the conventional type has been making increased use of radiant heat for controlling the shape of the curve. Some years ago a superheater separated from the furnace by only six banks of boiler tubes was considered hazardous, while today a number of successful installations are in use protected by only four banks of tubes and having excellent temperature characteristics. In a revamping undertaking in Hell Gate Station recently a top-bank convection superheater on a stoker-fired boiler was replaced by an interdeck superheater having maximum pressure drop of 15 lb. and located but four tubes above the furnace. The steam-temperature variation normally does not exceed 20 deg. between 80,000 lb. per hour evaporation and 260,000 lb. per hour, the average temperature being 770 deg. With an interdeck superheater on a pulverized-fuel boiler in the same station, the temperature varies from 690 deg. to 710 deg. for a rating of 150,000 lb. to 400,000 lb. per hour and with a pressure drop through the superheater of 19 lb. at the maximum point.

The maintenance problem with interdeck superheaters is largely a question of hanger material and arrangement, but this problem appears to have been satisfactorily solved in recent designs. With the bent-tube type of boiler, the hanger problem practically disappears, since the elements hang from the headers. In the bent-tube type of boiler there is also considerable latitude in the location of the elements with respect to the radiant heat, and the elements receive the protection afforded by the adjacent boiler tubes.

A serious fault in many superheater installations, both radiant and conventional types, is the excessive pressure drop considered necessary for protection. This pressure drop is especially pronounced at high loads, but it influences station performance at all loads, since it establishes the superheater safety-valve setting which, in turn, affects the steam pressure throughout the station. The magnitude of this loss in station performance is not generally appreciated, and in many instances the cost of this superheater protection is far greater than the value of an occasional element which might be required in a less conservative design. While all may not agree that the radiant superheater is susceptible to general application, it appears obvious that the design reported in the paper could never be criticized for being overconservative.

In considering the cost of occasional replacements on the comparatively short life of the elements suggested by the author, it should be recalled that this cost may be offset by a substantial credit on capital savings and on fuel saving from pressure drop alone as contrasted with some other more durable type of superheater.

From the data reported it appears that the pressure loss is less than with most conventional superheaters. In any event if the creep takes place in normal operation rather than during the starting periods it would not seem possible to obtain any further reduction in pressure drop without a corresponding reduction in life of the elements. While in general we are prone to consider occasional replacement as excessive maintenance, maintenance in itself is not always an important measure of the adequacy of apparatus. Maintenance is quite often a manifestation of the far more important consideration, availability, which, in turn, adversely influences capital investment.

Maintenance may be roughly divided into two classes: controllable maintenance, which is subject to scheduling, and unforeseen maintenance, which comes unexpectedly and involves an embarrassing loss of capacity. With the method outlined by the author of predicting superheater-tube life, superheater maintenance may be scheduled so as not to conflict with periods of maximum system demand. Thus one handicap often associated with maintenance is removed.

The substitution of radiant-superheating surface for water walls lessens the quantity of water in the boiler-circulating system. This permits a smaller boiler drum for the same degree of water-level stability.

On the other hand, the radiant superheater and reheater absorbs only about 30 per cent of the total heat absorbed by the complete unit, as contrasted with 50 per cent absorption by some water-wall furnaces reported in recent papers. Thus, for equal furnace size the radiant-superheater installation would result in higher gas temperatures entering the boiler accompanied by increased slagging tendencies in the tube bank. This disadvantage might be offset by increasing the furnace size or by increased depth of slag tubes below the bottom boiler bank.

The reduction in draft loss by the radiant superheater is not clear gain, since it necessitates, by its replacement of water walls, boiler-heating surface elsewhere which may correspondingly increase the total draft loss.

The substitution of radiant superheaters for water walls and consequent reduction of water in the boiler has merit in that it shortens the time required for starting from cold, as indicated by the author. The author refers to re-superheating in two steps to obtain greater economies, not simply to reduce moisture in the lower turbine stages.

There are different schools of thought as to the value of reheat and its purpose, and after all, dry steam results in rather substantial economies besides fuel alone. Turbine maintenance and availability due to water erosion of the lower stage blades is a factor of importance, and there is much room for improvement in this respect. While admitting the complications of certain reheat arrangements, whether radiant or otherwise, the effect of reheat on turbine maintenance should not be lost sight of, quite apart from thermal benefits. Turbine maintenance over the past ten years has been a more serious factor than many realize. To combat this problem more expensive materials are being used in blade construction, and yet wet steam sometimes results in excessive maintenance to other parts of the turbine than moving blades.

---

[8] Research Engineer, United Electric Light and Power Company, New York, N. Y. Mem. A.S.M.E.

It is well known that most turbine erosion is due to moisture, and it is also recognized that corrosion cannot take place in the absence of moisture, even though corrosive gases may be present in the steam. With the use of sufficient reheat stages to maintain dry steam all the way to the exhaust, cheaper turbine materials and workmanship may be employed, which when credited to reheat might give added attractiveness to reheat cycles in new plant designs. Turbine manufacturers in recent years have made great strides in developing blade material to resist the destructive influences of moisture in the lower stages of the machine. The high cost of modern blade materials, together with the greater cost of machining, is not generally appreciated, and the improved resistance to blade erosion in more recent machines is adding more to the purchase price than may users realize. Blade maintenance may be eliminated or reduced either by the use of more expensive blade materials or extensive use of reheat, and it is barely possible that in some instances double reheat cycles may be cheaper in the long run when all things are considered.

In Fig. 20 the curve of superheater and reheater performance for a constant back-pressure turbine seems to indicate that a convection superheater and radiant reheater would have been more desirable, excluding the consideration of temperature strains in the high-pressure cylinder with changing load. That is, the break in the reheater inlet temperature at the 250,000-lb. point would indicate saturated steam from the exhaust of the high-pressure unit. The presence of this moisture might result in ultimate blade erosion at the exhaust end of the high-pressure unit or the accumulation of deposits from the steam which would not adhere in the presence of superheat.

In Fig. 22 reheat is accomplished at a comparatively high point in the expansion range. As a consequence the available range for reheat at the higher loads is comparatively limited. No doubt this arrangement was dictated by careful evaluation of all contributing influences, but it would appear that full advantage had not been taken of the superheat in the initial expansion.

The desirable shape of the superheat or reheat curve is influenced largely by the choice of the control arrangement of the main turbine, which in most instances is dictated by nature of load, cost of capital, fuel and labor, as well as limitations of manufacture.

A superheat curve which might be attractive for multi-nozzle control might be less desirable for throttle control or bypass control, and the radiant superheater for use alone offers little opportunity for change in the natural shape of this curve. It would seem that for the initial superheating certain types of interdeck superheaters lend themselves more readily to obtaining the desired shape of curve than the radiant type alone. It would also appear that for the initial superheating a single interdeck design might be more economical than a combination of radiant and convection superheaters used together, due to the duplication of piping and headers. For reheating the natural characteristics of the radiant reheater are very attractive.

Radiant superheaters under some conditions are also subjected to convectional influences within the furnace, and it is possible that in time the arrangement of apparatus and control of the furnace may be so governed as to widen the control of the temperature range even for the radiant superheater.

In 1924 six pulverized-fuel boilers were installed in Sherman Creek Generating Station to provide additional capacity. The boilers were comparatively small (650 hp.) and were provided with water-cooled side walls and radiant superheaters on the rear walls. These boilers, by the way, were the first pulverized-fuel boilers ever equipped with water walls. The radiant superheaters are of the round-tube return-bend type and are held against the rear wall by clamps made of a high-heat-resisting material. The six boilers are practically identical, but each furnace is fired by a different combustion system or different burner arrangement. Four of the boilers are fired by the bin and feeder system, while two are fired by unit mills. Several different burner combinations have been used on some of the boilers, and a great mass of data and experience obtained.

The experience with creep of the superheater elements has been much the same as that reported by the author, except at an accelerated rate with some of the units. One of the problems with these superheaters was the anchorage to the wall and also the impinging effect of the flame in certain furnaces, due largely to burner arrangement. The pressure drop through these superheaters is about 15 lb. at a maximum flow of 60,000 lb. per hour, and at the average rating the pressure drop is about 8 lb. The temperature range is between 500 and 600 deg., which varies for the different units. The shape of the curve of some of these radiant superheaters practically parallels the usual convection type, due probably to convection heat or flame impingement with increasing rating. With the burning away of the supports some of the elements would lean toward the furnace and result in much shorter life than the average. Visual inspection through observation openings indicated when attention was necessary, and in the early days of this installation micrometer measurements would have been superfluous.

The creep took place not only circumferentially but longitudinally as well, causing bowing between supports which, unless corrected, subjects the units to very severe conditions. On one furnace in which impingement was especially severe a protecting water screen was installed in front of the superheater, which gave complete protection. A curious effect of this water screen was the change in the shape of the superheat curve. Previous to the installation of the screen the curve exhibited the characteristics of a convection superheater, while after the installation the shape resembled more closely what would be expected from a pure radiant superheater, due perhaps to the water screen intercepting the convection effect of the turbulent furnace gases.

From time to time the superheater elements unprotected by a water screen are removed, straightened out, replaced, and used in this manner until they are unfit for further use, due to excessive reduction in the wall thickness.

In the early days of this installation the appearance of the superheaters indicated the path of the gases and temperature distribution almost as clearly as could be determined by more precise investigations. The straightening of these tubes was accomplished by a device made from a large valve yoke and stem clamped to a building column, so that by means of the hand wheel, pressure could be applied through the stem to force the tube into shape.

The failure of a superheater tube in service is much less destructive than many would imagine and less serious usually than the failure of a boiler tube or water-wall tube. The opening in a failed superheater increases the steam flow and cooling effect, which protects it against further distress. In a pulverized-fuel furnace a major failure of a superheater element usually extinguishes the fire and is not extremely hazardous if adequate safeguards are provided on the combustion system. The unexpected failure of a superheater element might be embarrassing to boiler capacity, but otherwise it is not ordinarily serious.

A problem with some conventional superheaters is pressure-drop limitations established by the boiler width or space available for the installation. In recent installations this has been overcome by the use of elements in parallel, vertical as well as horizontal, thus making up the deficiency in width by an increase in height. While there are a number of conventional superheaters which come within the 20-lb. pressure drop referred to in the paper for the radiant superheater, the majority of installations greatly exceeds this pressure drop and as a result would suffer by comparison with this figure. From a consideration of adiabatic heat drop, 1 deg. of superheat is equal in value to about 3 lb. pressure, and in evaluating superheater performance both temperature and pressure loss are major considerations in striking a balance with the many other factors.

Various types of superheaters are sensitive to different influences which are difficult to predict in the design stage. Besides the influence of the ratio of gas to fuel, some superheaters are sensitive to change in the ratio of products of combustion to steam resulting from changes in the feedwater temperature and similar influences. What is needed is a low-cost superheater or reheater, the temperature from which may be adjusted for sufficient range to take care of changing conditions which frequently arise. The design reported on by the author seems to meet some of these conditions in an admirable manner.

Some plants are so situated that slight changes in market conditions may render any one of the three fuels, coal, fuel oil, or gas, available for economical use. This range of fuel renders the choice of a superheater design very difficult and becomes an important consideration at the time of purchase.

Among the lessons which may be drawn from the paper might be mentioned the indicated durability of ordinary carbon steel used for steam piping. From the observations of creep and temperature presented by the author, it appears probable that the steel piping in use today would probably be satisfactory with steam temperatures up to 850 deg., with a creep rate so low as to cause no particular concern.

As our knowledge and experience with the limitations of various materials advance we will be able to design and operate apparatus much more economically than was possible with some of the earlier "rule of thumb" standards which had been established. One of the difficult problems of the present day in evaluation procedure is to strike a rational balance between physical life and obsolescence. The author's paper deals in a fine way with a design of apparatus which but a few years ago would have been considered radical, but which on close analysis appears more rational than some of our earlier efforts with conservative designs.

H. DAHLSTRAND.[9] Only too seldom is there given complete, detail information concerning the behavior of machinery in actual operation. In a paper such as this, where all the details have been closely studied, the information will be of the greatest value to designers of boilers and superheaters and also of other machinery operating at high temperatures. Experience has shown that data gathered during the actual operation are of great value. Coordinating these data with laboratory tests is of particular value to the designer of machinery in working up detailed designs. This is particularly important when making designs for the high temperatures now used in power plants.

One of the interesting sections of this paper is that covered by complete creep data on the material used in the superheat tubes. Very little has been published concerning the creep under actual operating conditions, and information on this subject will enable us to make up designs with greater confidence. From the results it is shown that the creep is appreciably more than that shown by standard laboratory methods. This, of course, can be expected, as it is impossible to duplicate the operating conditions in the laboratory work. In exposing material to changing temperatures, while these changes may not be great, they will be sufficient to materially increase the stresses in certain parts of the sections, and when the temperature changes are reversed, other parts of the sections may be stressed higher than that calculated in the design. This obviously should increase the rate of creep over that shown by laboratory tests.

One of the important facts for steam-turbine designers brought out by the paper is the importance of maintaining, as far as possible, uniform temperature at various ratings. Naturally it is of importance when starting any unit to bring up the temperature slowly so that no dangerous stresses are set up at that time. Sudden changes in temperature as far as steam turbines are concerned may cause dangerous distortions.

The writer thoroughly agrees that complete operating information on equipment operating at high temperatures is of the greatest importance and should be emphasized in all high-temperature installations.

GEO. A. ORROK.[10] Papers dealing with operating experiences in the development of power are among the most valuable which the Society publishes, and when one of these papers, covering years of operating experience, has included in its scope, scientific discussions along research lines, which show the connection between theoretical and practical viewpoints, the members of the Society are to be congratulated.

The paper deals with over seven years of experience with radiant-heat superheaters where the entire problem has been worked out to a successful solution under severe operating conditions of pressure and temperature.

Perhaps the outstanding statement in the paper is that the pressure stresses in a radiant-heat superheater are so small as to be of only minor importance. The really important thing to consider is the heat stresses, and therefore the thinnest section of metal which will stand the punishment is the best and most economical thickness to use. In the writer's own experience he had recommended as the safest and best solution that thickness of tube which makes the pressure stresses and the heat stresses equal in numerical value. The author's observations on creep and on the values due to creep but duplicate those of other experiences where similar apparatus has been used. Increases of the outer diameter of the tube amounting to from 15 to 20 per cent are common in 18 months of service. The inner diameters of the tube may in the same time increase as much as 45 per cent.

The most serious condition occurs when there is tuyere action from a stoker where the point of the flame actually impinges on the tube surface or where the oil flame or powdered-coal flame impinges in a similar way. Here the tube oxidizes very rapidly, creep and bulges occur at a very much faster rate, and failures similar to those shown in Fig. 12 almost invariably happen. When the flames do not impinge on the tubes, the useful life of course is much longer, but creep does take place, and the life of a superheater tube under these conditions when made of open-hearth steel may be upward of three years.

---

[9] Engineer in charge, Steam Turbine Department, Allis-Chalmers Mfg. Co., Milwaukee, Wis. Mem. A.S.M.E.

[10] Consulting Engineer, New York, N. Y. Mem. A.S.M.E.

The heat conductivity of open-hearth steel with approximately 0.12 carbon is nearly twice that of high-carbon steels and perhaps $2^1/_2$ times that of alloy steels. The conductivity of wrought iron is about the same as of high-carbon steel. Why these variations occur is not known, and this would appear to be a fruitful field for research, since apparently the best metal for heat conductivity and therefore for the lowest outside temperature and lowest heat strains is the standard open-hearth tube steel which has been so largely used. High steam velocities through the tube also reduce the outer surface temperatures, and the operator should be willing to take quite a drop through his superheater in order to take advantage of the increased heat transfer and lower outer surface temperature.

The author's statement of the advantages of the combination of the convection and radiant-heat superheaters is most striking, and in general this paper merits the closest attention.

AUTHOR'S CLOSURE

Mr. Orrok's discussion of tube thicknesses suggests the point that thin tubes have an important investment credit when metals of the 18–8 class, costing 50 to 60 cents per pound, are employed. Mr. Orrok is to be commended on his early advocation of reasonable tube-wall thicknesses.

As both Mr. Orrok and Mr. Caldwell point out, radiant-superheater failures occur as small, unharmful steam leaks. Ability to continue operation until convenient maintenance occurs is a vital merit. Forced outages and scheduled maintenance are widely separated procedures.

Mr. Kerr's liberal discussion is a valued addition to the subject. The considerable interest and work of his company in radiant superheaters appears another confirmation of the point that these superheaters warrant serious attention of the industry.

The furnace temperature of which Mr. Kerr asks is obtained at the point of heat-absorption measurement. It is the equilibrium temperature which a thermocouple assumes, and which when applied in the radiation formula indicates a constant of 1300. Tests have shown the validity of the method throughout a heat transfer range of 10,000 B.t.u. per sq. ft. per hour to 125,000 B.t.u. per sq. ft. per hour.

Other points suggested by Mr. Kerr's discussion are:

1 Low ash-fusion temperature does not preclude use of radiant superheaters. A 4 per cent sulphur coal of 2050 deg. fahr. ash-fusion temperature was burned in Lakeside boilers for several months last fall without a suggestion of dirtiness trouble from the flush-type round-tube superheaters. Reasonable-temperature, bare-tube furnaces are not subject to the wide temperature and transfer variations that Mr. Kerr mentions.

2 As the paper mentions, side-wall locations are preferable for radiant superheaters to facilitate boiler design. They would not be advisable for most front walls, for heat-absorption rates exceed the prescribed 60,000 B.t.u. per sq. ft. per hour and are not as nearly proportional to steam-flow rates.

3 Regarding temperature stresses: The paper gives considerable experimental information indicating their probable importance. Good reasons are advanced showing that the tubes were not occasionally overheated. Moreover, the relatively stronger Enduro tubes actually expanded more because of their poorer thermal conductivity and therefore higher temperature stresses. It seems prudent to concede the existence of these temperature stresses.

4 As the paper infers, radiant superheaters are impractical for hydro-plant or transmission-line standby when cold boilers must be put into service in a few minutes. Very heavy elements with great heat-storage capacity would most nearly meet this requirement. Reasonably good reliability of other power-plant equipment and proper load scheduling can easily tolerate four-hour starting from cold, and the plant in general will benefit thereby.

5 The paper states that metal temperature is lowest at low ratings, assuming of course that coal feed and steam flow are in reasonable equilibrium. Both test data and calculations confirm this point.

6 Mr. Kerr referred to the initial and only experimental installation of carbon-steel tubes when he stressed the point of a tendency of certain elements to expand unduly.

7 Operators will agree that low CO_2 is occasionally necessary during exigencies. Convection superheaters then give high temperatures, but radiant superheaters afford low, safe temperatures during the emergency. No other regulation by combustion changes is necessary in a properly designed installation.

8 Superheating to high temperatures and then continuously desuperheating at and above normal rating, so that good economy and reliability can be obtained occasionally at low ratings, does not seem efficient nor reliable.

It is pleasing to know that Mr. Kerr's company has had favorable experience with 18–8 material at metal temperatures as high as 1200 deg. fahr. That experience insures boiler-room success with 1000 deg. fahr. steam, and the industry will be very glad to get the report. The Babcock & Wilcox Company is doing an excellent thing in obtaining experience with new equipment in its own plant rather than trying it on a large scale for the first time in the customer's station. Mr. Kerr is commended for his valued statements of his company's experiences.

Mr. Caldwell suggests that reversal of the types of superheater and reheater treated in Fig. 20 might be advisable for prevention of moisture in the turbine exhaust. The text is incomplete in not indicating that partial bypassing of the high-pressure turbine occurs above 250,000 lb. per hour to obtain higher steam flow from the high-pressure boilers. The exhaust is superheated at all times.

The 20 lb. pressure drop of the 1300 lb. pressure superheater is equivalent to only 5 lb. pressure drop at 300 lb. steam pressure, which better illustrates the low pressure drop of an actual radiant-superheater installation. Mr. Caldwell's discussion in all aspects of superheater economics merits much application.

Mr. Jasper's remarks of the greater thermal expansion of high chromium alloys are important. In installations where only a portion of the tube periphery is exposed to the furnace, greater stresses tending to cause bowing will occur than in the case of carbon-steel tubes. It is understood that expansion of chrome steel is 60 per cent greater than that of carbon steel.

Mr. Artsay's discussion is valued for its calculations of temperature stresses and correlation of existing expressions of these stresses. He is right in stating that accurate laboratory creep knowledge is only a small portion of a designer's needs. His theoretical contribution will be used in attempts to still further improve installations.

Mr. Dahlstrand's statements properly suggest that turbine design for higher temperatures will be more difficult than boiler-room and piping design, and that therefore turbine equipment should be given the benefit of as uniform temperatures as possible. Whereas 1 per cent creep per 10,000 hours is permissible in the boiler room, less than 0.01 per cent creep per 10,000 hours may be permissible in the turbine room. This latter rate corresponds to 0.002 in. elongation in 20-in. casing bolts per 10,000 hours. The bolts should still exert compressive force on the casing joint, and possibly may need tightening yearly to compensate for creep.

When 1000 deg. fahr. superheat and reheat are used in high-pressure installations, then more heat will be added in the superheating equipment than in the boiler for evaporation. Higher feedwater temperatures and higher boiler pressures are decreasing boiler duty at the same time that superheating duty is increasing.

These changes result in an important distortion of present designs.

Water-cooled furnace walls are a present trend of the industry, but the future high-temperature installation cannot afford them since they absorb too much heat and would leave insufficient heat for superheating. If retrogression to refractory walled furnaces is assumed, heat capacity of flue gases after passing a few rows of boiler tubes is also insufficient for efficient superheating, especially at low ratings. Detroit is leading the way toward temperatures of 1000 deg. fahr., and the time that 1000 deg. fahr. reheat will also be used is probably not far away. It seems appropriate that the industry receive general acquaintance with radiant superheaters at this time so that liberal experience may be had with them before they are positively necessary.

Summarizing, it is felt that the discussions far excel the paper in value, representing, as they do, widespread experience instead of limited application. Appreciation is expressed to the discussors on behalf of the Society and the power industry.

FSP-54-15

Performance of Modern Steam-Generating Units

By C. F. HIRSHFELD[1] and G. U. MORAN,[2] DETROIT, MICH.

C. F. Hirshfeld

This paper is based on data collected upon the operation of 244 large steam boilers over a period of three years. A paper was presented at the 1929 Annual Meeting of the A.S.M.E. covering one year's records, but it was thought advisable to continue for at least two years in order to obtain more conclusive results. The primary object was to study boiler outages with special attention given to causes, frequency, and duration, and the effect of such factors as severity of use, design, fuels, and methods of firing on boiler reliability. This paper gives a general summary of the data and a short discussion of results. It will be followed by a more complete analysis of the individual records in the near future.

G. U. Moran

At THE request of the Power Division, the authors presented a paper under this title at the 1929 Annual Meeting of the A.S.M.E. It was based on boiler-operating data obtained from steam-power stations well distributed throughout the United States. These data covered experience with 186 boiler units. The primary purpose was to evaluate the reliability of modern steam-generating equipment, particularly as affected by the severity of use, the type of design, and other nameable variables.

In that paper only tentative conclusions were drawn, because it was evident to the authors that for many reasons the numerical values could not be regarded as inclusive or conclusive. The number of boilers studied was comparatively small, and the time period of one year did not serve to give a true picture of the performance of any single unit. The personal factor also served to distort the findings to an undesirable extent, because different individuals had obviously placed different interpretations upon the items of performance recorded.

The results reported did, however, appear to be of such value as to justify the Power Division in asking that the study be continued on a larger scale and for a longer period of time and that the results thereof be reported in a second paper. It was thought that the experience gained in the first year would increase the reliability of data collected during subsequent years, both through more exact definition of the data desired and through greater skill in their interpretation.

It was decided to continue the study for two more years and to add as many boiler units as possible so as to obtain more representative results. The present paper is based on the records of 244 boiler units for periods varying from one to three years. The data in hand fall within the period July 1, 1928, and July 1, 1931, except for variation of a few weeks in the case of a small number of units.

Printed log sheets were furnished to each operator reporting. The logs were so arranged that each day's operating data were reported for each boiler. Every factor that might have a bearing on the unit's performance was included in the log. Complete instructions and definitions were furnished so as to make the records as nearly as possible directly comparable. The log sheet used is shown in Fig. 1. Design data necessary for a proper interpretation and coordination of the results were obtained by means of a separate questionnaire of conventional type.

As in the first study, information was gathered only on boilers operating at pressures above 200 lb. gage and containing over 10,000 sq. ft. of saturated heating surface, except that a few units with smaller surface but operating at very high ratings were included.

The following definitions were given the operators for guidance in filling out the log sheets and were used by the authors in working up the data:

1 A "steaming" unit is one which is passing steam to the line.

2 A "banked" unit is one in which a pressure approximately equal to line pressure is maintained, but from which there is no flow of steam to the line.

3 A "reserve" unit is one which is cold and in which the pressure is at or near atmospheric, but which may be put on the line in the time that it normally takes to lay and light the fire and bring the steam pressure up to that in the line.

4 A "crippled" unit is one which is in such condition that it is incapable of being put on the line within the time that is normally required to bring a boiler from cold to steaming.

5 The "availability factor" is the ratio between the time during which the unit is not crippled and the total time reported.

6 The "use factor" is the ratio between the time during which the unit is not crippled or in reserve and the total time reported.

The figures submitted by the different operators reporting indicate that in most cases they have interpreted the definitions

NOTE: Actual time to the nearest hour to be indicated for each job. The total for each day will exceed the total crippled time when jobs are done simultaneously. The job causing the shutdown should be indicated each day by an asterisk, thus—*3.

Fig. 1 Log Used in Collecting Boiler-Operating Data

in the way in which they were intended. In a few cases there appears to have been a different interpretation of the meaning of "crippled" from that intended. In these cases the operators appear to have reported the boilers in "reserve" condition where the majority would have reported them as crippled. Where such interpretations appear to the authors to affect the average results reported herein, the fact has been noted and the necessary corrections have been indicated.

Due to the large mass of data collected and the short time available between the receipt of the last records and the date of preparation of the paper, it has been impossible to complete all the studies contemplated. This paper is therefore only a preliminary report. It gives certain high-spot values which may be compared with those published about two years ago. Study of the data received will be continued, and the authors hope to present a comprehensive treatment within the next few months. The presentation of the completed study will end this endeavor, as it is not believed that any worth-while purpose would be served by continuing the collection of information on this subject.

A summary of the data collected during the three-year period is given in Table 1. The units are grouped according to steam pressures and firing methods, as was done in the first paper. In addition, each class is now subdivided according to the length of time represented by the operating records reported.

In some cases boilers were reported as "crippled" for long periods of time from causes not directly chargeable to the units themselves. We have here a question of definition or interpretation which is troublesome. For example, if a reheat boiler is in condition to operate but cannot be operated because the turbine to which it is connected is shut down, it is certainly fair to regard the boiler as not crippled. On the other hand, if a boiler which is in condition to operate is shut down while the stack to which it is connected is being painted, one might logically take the stand that while the boiler itself was in operative condition the complete steam-generating equipment of which it formed a part was crippled. The authors intend to make a detailed study of the causes of boiler outage as reported and to work up complete records with respect to such causes. Pending the acquisition of the necessary information and until they have had time to digest the data now in hand and supplementary information now being acquired, they have been forced to adopt the interpretation of "crippled" that was used by each operator reporting.

In the present paper they have therefore assumed that when an operator reported a unit as crippled for causes outside the unit, this represents the fact. They have, in such cases, subtracted these hours from the total number of hours reported as crippled and from the total hours covered by the report. This is recognized as a makeshift, but is the best that can be done at present.

The figures given in Table 1 under the heading "Group performances" correspond to those given in the previous paper as "Averages." They were obtained in the same way in both cases; the designation has been changed because experience has shown that the use of the word average for these values is confusing to some readers.

The method of deriving the figures is best explained by reference to the table. The first two units reported are stoker-fired and operate at pressures between 500 and 700 lb. There were 14 for which there were records extending over three years and 10 for which there were records for two years—24 boilers in all.

The figures given in columns 4, 5, 6, and 7, opposite the group of 14, were obtained by totaling the total hours reported for these boilers, totaling the hours reported in each of the four conditions indicated by column headings, and expressing the latter totals as percentages of the total hours reported for the group of 14 boilers. The same thing was done for the group of 10 boilers.

The figures given under "Group performances" were then obtained by totaling the hours reported for the group of 24 boilers, totaling the hours reported under each heading (i.e., steaming, banked, etc.), and then expressing the latter as percentages of the total hours.

The figures given for the class, as for example those indicated as "Performance of stoker-fired class," are not the averages of those given above them in the table. They are obtained by totaling hours for all boilers in the class and handling, as described, for single groups.

TABLE 1 SUMMARY OF OPERATING RECORDS

Period covered in years	Number of units in group	Pressure class, lb. per sq. in.	Percentage of total period				Use factor	Availability factors			Group performances[a]					
			Steaming	Banked	Reserve	Crippled		Individual High	Individual Low	Group	Percentage of total period: Steaming	Banked	Reserve	Crippled	Use factor	Availability factor

[a] Certain numbers given in Table 1 are followed by a question mark. Inspection will show that they represent extraordinarily low values for crippled hours. It is believed that the low values either result from an unintended interpretation of definitions or that the age of the units is not sufficient to have brought about a representative average performance.

The performance figures obtained in the present study are entered, with those reported in 1929, in Table 2. It is interesting to note the similarity between the results of the two studies. The stoker-fired, pulverized-fuel-fired, and oil- and gas-fired units maintain approximately the same relative positions in both cases, but the availability has decreased slightly in all cases in the study extending over the longer period. This seems to indicate that some outages are not annual occurrences and are not necessarily encountered in so short a period as one year. It might be interpreted as indicating a decreasing availability with age, but while this would be a natural expectation, it is not believed to have had much influence in this case because of the fact that boilers of radically different ages were considered in both the short-time and long-time studies.

The 400-to-499-lb. stoker-fired class continues to show the lowest availability. Certain facts known to the authors lead them to believe that while the figures reported represent the facts, at least for the first three entries in the group, they should not be regarded as truly representative on a national basis. There is really no reason why this group should be poorer than the groups above and below, it if equally well designed, constructed, and operated.

The fact that the availability of this group is so much lower than that of any of the other stoker-fired groups naturally leads one to suspect that the lower availability for the stoker-fired class in comparison with that of other classes may result from the inclusion of the low-availability group in obtaining the figure for the class. The inclusion of this group does have an effect upon the class figure, but not so great an effect as one would expect. It happens that the total number of boiler years represented by the low group is comparatively small. The omission of the group in obtaining the class figures would raise the availability factor from 0.831 to 0.837, an almost negligible variation.

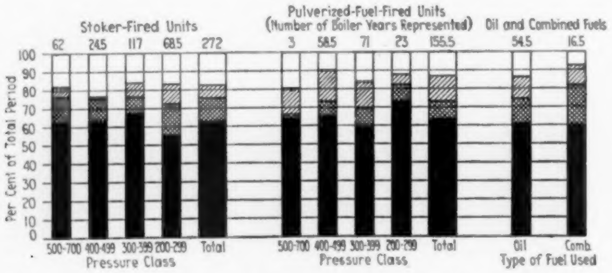

FIG. 2 PERFORMANCE OF STEAM-GENERATING UNITS BY GROUPS
(Legend: White space, crippled; single-hatching, reserve; double-hatching, banked; black, steaming.)

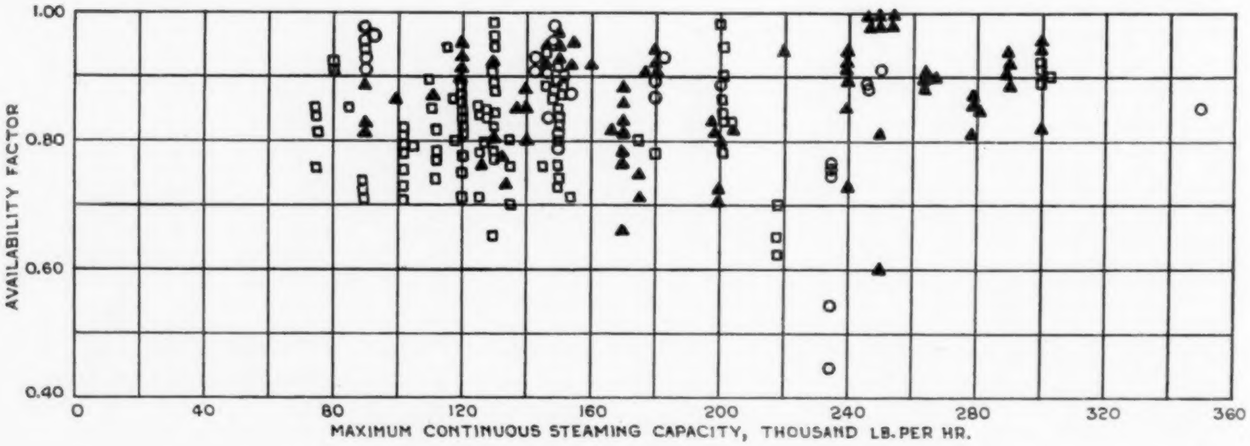

FIG. 3 EFFECT OF UNIT SIZE ON AVAILABILITY
(Legend: Squares, stokers; triangles, pulverized fuel; circles, oil.)

Comparison of either figure with the value 0.869 obtained for the pulverized-fuel-fired class might be assumed to indicate a slightly higher degree of reliability for pulverized-fuel-fired equipment. To draw such a conclusion one must be willing to concede that the number of boilers studied, the length of the period covered, and the methods of collecting and compiling data are all such as to justify the drawing of such fine distinctions. The authors are not prepared to say that this is the case. They are, however, making more detailed studies of the causes of outages in the two classes for the purpose of determining whether any real difference directly chargeable to the firing method can be found.

An attempt to determine the effect of size upon the availability factor of boilers resulted in the production of Fig. 3. Availability factors were plotted against the maximum continuous steaming capacities as given by the operators. Steaming capacities were used in an effort to eliminate the effects of different distribution of heating surface between boiler, economizer, and preheater, as well as the effects of radical differences in boiler design.

It is reasonable to suppose that larger units can more often be given greater reliability within economic limits than can smaller units. The figure appears to show some justification for such an assumption. The smaller units appear to average availability factors in the neighborhood of 0.83 to 0.85, whereas the larger units appear to give values averaging more nearly 0.90. However, it should be noted that some of the smaller units give performances substantially equal to the best of the larger units. It is only the greater spread in the case of the smaller units that results in the figures just given. One is driven to the conclusion that skill in design, construction, and operation, or the economic possibilities of individual cases, are in fact more controlling than the size of the unit.

An interesting study was made possible by the fact that the man-hours used on crippled boilers was reported for 43 units. The number of boilers is rather small, but it is thought worth while to present the results obtained. This is done in Fig. 4 and in Table 3. In the table the units are classified only as to method of firing, and they are arranged in the order of availability factors. For convenience, work done during crippled periods has been expressed in terms of maintenance man-hours per million pounds of water evaporated during the total period studied. The column headed "Regular overhaul" refers to all repair work done during those periods which are set aside for regular inspection and overhaul. The following columns include all work done during crippled periods outside of those regular periods of overhaul.

If we ignore a few points in the figure which are probably abnormal, the trend is probably in favor of the large units as shown by the dotted line. The large capacity unit thus appears to possess advantages with respect to repair and maintenance costs as well as with respect to space requirements and operating personnel. It is to be noted, however, that the greatest part of the possible gain appears to be obtained in going to capacities of the order of about 120,000 to 140,000 lb. of steam per hour; the gain obtained by doubling such sizes is negligibly small.

In the 1929 paper data were given with respect to each unit reported on so that the reader could note variation between units and appraise their significance for himself. It is planned to do the same with the data now in hand for inclusion in a later and greatly enlarged paper. At that time the authors expect to be able to present the results of a number of different types, such as the effects of rate of driving, the effects of different features of design, etc. They regret that it has been impossible to do all

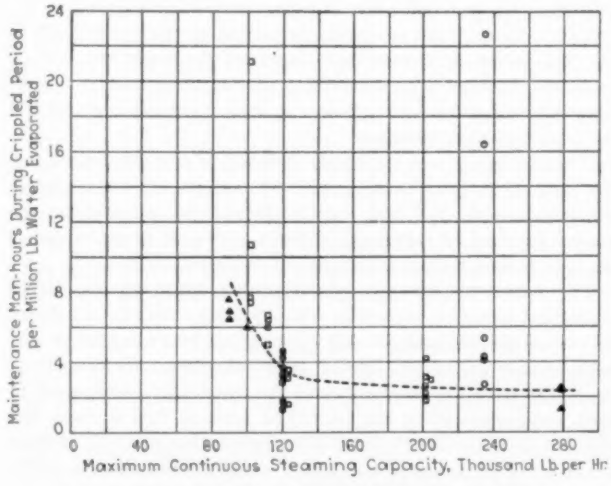

Fig. 4 Effect of Unit Size on Maintenance Labor

(Legend: Squares, stokers; triangles, pulverized fuel; circles, oil.)

this work in time for the presentation of a more complete and comprehensive paper.

As a matter of interest, Table 4 has been presented to show the availability and use factors of steam turbines as reported by the Turbines Subcommittee, Prime Movers Committee of the N.E.L.A. These data were presented in the subcommittee's report of August, 1931.

In concluding, the authors desire to express their thanks to the operators who furnished the performance records upon which this paper is based. Without their kind cooperation the work would have been much more arduous and of far less value to all concerned.

TABLE 4 TURBO-GENERATOR AVAILABILITY

Discussion

A. G. Christie.[3] This paper presents facts regarding the availability of boilers that have heretofore been lacking. In studying the data presented, one finds that both use factors and availability factors presented in the 1931 figures are slightly less than the 1929 figures. The use factor may have been influenced by the lesser loads and greater reserve capacity in the stations during the last two years. The availability factor is modified to some extent by the age of the units. There has been little new construction during the last two years, and it is probable that the average age of the units covered in the 1931 figures exceeds that of the 1929 figures. Age also may have had something to do with the lower figures for the 400-to-499-lb. class of boilers.

Fig. 2 indicates that the stoker-fired units tend to be crippled to a greater extent than pulverized-coal-fired units. This is also shown by the figures in Table 1. It would be interesting to know the reason for this and whether stokers of recent designs have shown any improvement in this respect over older types.

The data presented in Fig. 3 show a trend toward higher availability factors for units with the larger steaming capacities. One deduces from this that boilers operated at these higher outputs are more reliable than smaller units. This is a highly significant result, for it indicates that there is no detriment on the score of reliability to the construction of properly designed boiler units of even greater continuous steaming capacities than at present. Since boiler and turbine availability factors are not greatly different, one can therefore plan on future power stations with one boiler per turbine, even with turbines of larger capacity than the average size now used.

---

[3] Professor of Mechanical Engineering, Johns Hopkins University, Baltimore, Md. Mem. A.S.M.E.

Encouragement toward the use of larger boilers may also be derived from Fig. 4, which indicates the trend toward lower maintenance costs with steaming capacity of boilers. Hence the use of large boiler capacities not only reduces the unit cost of the station, but at the same time lowers the operating cost.

A comparison of Tables 1 and 4 indicates that the availability factors of turbines still exceed those of boilers. If the unit boiler-turbine system is to become standard practice, further study and care must be given to the boiler plant to bring its availability factor on a par with that of the turbine plant.

D. W. Flowers.[4] The writer is struck with the care used in preparing the data and with the need for such data by operators and designers in discovering whether the investment dollar is being used in the boiler plant to the best advantage.

There is a considerable difference in availability factor between the best and the worst boiler, and it is hoped that the further analysis planned by the authors will give a review of the causes for the various units being "crippled," in such a way that designers in the future may avoid the troublesome construction.

The authors note that the availability of these boilers has slightly decreased over the figures for 1929. The writer has noticed the same thing in our plant (Comal Station, New Braunfels, Texas) in 1931 as compared with 1930. The cause of this decrease is the reduced demand for electric generating capacity. In 1930 when we could use all of the higher efficiency boilers to good advantage all the time, routine inspections and necessary repairs were carried on with as large a crew as could be worked efficiently, and were carried on at night with overtime labor at increased rates. In 1931, when at least one boiler is idle all the time, we are saving total expense by doing maintenance work with reduced crews and all on a straight time basis, but this practice is slightly reducing the availability factor of the boilers. Perhaps the business depression has set similar conditions to work in the stations under investigation and inspection in this paper.

Ollison Craig.[5] The authors are again giving figures of availability of units classified as to methods of firing. Table 1 shows the average availability of pulverized-fuel-fired units to be greater than that of stoker-fired units.

The figures given in Table 3 offer a clue to the difference in availability. The total maintenance in terms of man-hours per million pounds of water is somewhat greater for stoker-fired units than for pulverized-fuel-fired units, as an average. Of the actual maintenance expended in each case, change of equipment accounts for 16 per cent in the case of stoker firing, but only 4 per cent in case of pulverized fuel firing. Maintenance of fuel-burning equipment accounts for 14 per cent of the total in the case of stoker firing, but only for 4.7 per cent in the case of pulverized-fuel firing. Furnace maintenance percentage is about the same for each.

It would be interesting to know why fuel-burning equipment maintenance for stoker firing is about three times that for pulverized-fuel firing. The log shown in Fig. 1 provides means for determining temperature of preheated air in cases when air preheaters are used. Data are apparently available for determining the relation between fuel-burning equipment maintenance and temperature of air preheat. This would probably offer the clue to the higher maintenance for stokers and indicate an economic limit of air-preheat temperature applied to stokers.

In the case of stoker firing it would be interesting to know how availability is affected by the average rating carried on the unit.

Vern E. Alden.[6] The immediate objective of the work which the Power Division requested the authors of this paper to undertake four years ago is the centering of the attention of operating and designing engineers on the importance of keeping the outage or "crippled" hours for large steam generating units down to a minimum. The reduction of outage hours is, however, only a means to an end, and that end is the limiting of the power-station investment for carrying the system load to the lowest possible figure from year to year, as the load grows. This broader conception of the problem introduces additional factors. Outage or "crippled" hours fall into two classes:

(1) Those which can be foreseen and, to a considerable extent, scheduled so that they will not cause embarrassment in the handling of the system peak load or appreciably affect the overall fuel consumption for the system.

(2) Those outages which come unexpectedly and will conceivably take the boiler unit out of service at the time when its capacity is needed most. It is believed that considerable progress has been made by the operating and designing engineers in reducing the percentage of total outage hours which cannot be scheduled in advance. It would be most interesting if the authors, in their later paper, would present such figures as are available, indicating the progress which is being made in this direction.

A reduction in the maximum available steaming capacity is only less serious in degree than outage of the boiler unit. It is probable that many steam-generating stations are more handicapped by reductions in steaming capacity of the boiler units than they are by actual outages.

It would have been extremely difficult, if not impossible, for the authors to have made a critical analysis of this factor in connection with 244 boiler units distributed in, perhaps, 80 generating stations. It is not difficult, however, to make such a study in connection with a single generating station.

The trend toward the use of boiler units having larger individual steaming capacities which has its origin in the desire to reduce the investment and the cost for operating labor and maintenance per unit of station send-out, makes it necessary to study the record of availability of the boiler-plant equipment in each steam-generating station. The kind of fuel burned, the water conditions, and the type of equipment installed will present a new set of problems in connection with each installation. The objective in all cases will, however, be substantially the same—the insurance that the maximum amount of steaming capacity expressed in thousands of pounds of steam per hour will be available at the time of maximum system needs. The accomplishment of this end result is in part the work of the designing engineer and in part that of the operating engineer. The designing engineer can, if he has as a background a complete understanding of operating problems, accomplish much by the careful working out of the details of design. The operating engineer can make his contribution through the careful planning and scheduling of regular inspections and preventive maintenance work and through the working out of the most improved methods of operation.

[5] Consulting Engineer, Riley Stoker Corporation, Worcester, Mass. Mem. A.S.M.E.

[6] Power Engineer, Stone & Webster Engineering Corporation, Boston, Mass. Assoc-Mem. A.S.M.E.

Some of the major causes for the outages of boiler units are the following:

(1) The formation of slag on the boiler tubes at the inlet to the first pass.

(2) Inability to maintain a uniform fuel bed and the formation of clinkers in the fuel bed.

(3) The failure of refractories.

(4) The formation of scale or the occurrence of corrosion inside the tubes of the boilers, water walls, and economizers, all resulting from inadequate feedwater treatment.

(5) Improper feeding of the fuel and improper mixing of the fuel with the air, coming as the result of shortcomings or the deterioration of the coal feeders or of the burners, either in the case of pulverized coal or oil firing.

(6) Failure of certain of the component parts of the stoker to function properly.

(7) Difficulties incident to the removal of ash and clinkers from a stoker installation or ash and slag from a pulverized-fuel-burning installation.

(8) Troubles with superheaters which may be either leaks in the rolled joints or at the handhole caps, failures of the individual elements incident to improper steam distribution, or failure of the supports due to overheating.

(9) Direct or indirect troubles with soot blowers.

(10) Troubles with economizers.

(11) Troubles incident to improper water circulation in the water-cooled furnace walls.

(12) Troubles incident to air-preheater corrosion.

(13) Troubles incident to the erosion of induced-draft-fan impellers.

It would be of considerable value to operating and designing engineers if the authors would include as a part of the paper they have promised to present in the near future, a more complete list of the various causes of boiler outages which their studies have disclosed. In general, it has proved to be necessary only that we clearly define a problem, in order that we very definitely insure its solution by the steam-station operating and designing engineers of this country. The real progress which has been made over a period of the last ten years in reducing the outages of turbine-generators is the proof of this statement. The authors certainly deserve the thanks of the Power Division and of the Society for the work which they have done in defining this problem and in stimulating further study of the individual situations by the responsible designing and operating engineers.

R. C. Vroom.[7] The unusually low availability factors for the last two oil-fired units of Table 3 raise a question as to exactly what caused the large amount of outage. As both the boiler and furnace maintenance are high, it would appear that these units are operating regularly at high rates of heat liberation in the furnace and at high rates of evaporation per square foot of heating surface. Pertinent data in regard to the operating conditions would be of interest.

A. J. German.[8] Nearly all of those that have commented on this paper have suggested that the authors should include the various causes of boiler outages, thereby possibly locating the weakest link. The writer is of the opinion that this is too much to expect of the authors. Had the writer been asked by the authors to answer their questionnaire for a few years back, he would have had to answer that the first year our stokers were by far the principal cause of boiler outages, and undoubtedly would have given reasons for it. If he had answered the questionnaire the following year, he would have answered something as follows: "We are sorry that our answer to the question last year must now be changed; namely, we have installed new stokers and they have not been the cause of any interruption in boiler performance, but due to the fact that with these stokers we now could operate the boilers at a higher rating, and do the same work with one less boiler, we are now experiencing refractory trouble; hence that has now become the weakest link and the principal cause of boiler outages."

Again, if he had answered the third year's questionnaire, he would be compelled to again change the answer; namely, he would have to inform them that our furnaces had now been redesigned, air cooled, etc., and since then we have been able to again increase the boiler rating, and tests have proved that it could be done with a better over-all efficiency, but it required us to operate the forced-draft fans at a capacity which had never been necessary up until then. This is now the weakest link.

The writer is of the opinion that nearly all plants that have been built for some years and designed for a considerably lower capacity than was later attempted to get out of them, have had somewhat similar experiences, for the reason that all of us want to keep up with the latest improvements.

If the writer is correct in the foregoing statement, then it seems that this would be proof that we could not expect to have anyone collect such data and have it of any use.

Authors' Closure

The authors are highly gratified at the interest aroused by this preliminary report. They are particularly indebted to the discussors for their many suggestions relative to the further and more detailed presentation of the data at hand. The final paper is being prepared with these suggestions in mind, so it is thought unnecessary to go into more detail at the present time.

Influence of Inlet Boxes on the Performance of Induced-Draft Fans

By LIONEL S. MARKS,[1] CAMBRIDGE, MASS., and E. A. WINZENBURGER,[2] WALTHAM, MASS.

L. S. Marks

This paper presents experimental results of tests to ascertain the effect of inlet boxes on the performance of induced-draft fans. The tests showed the magnitude of the changes in performance that can be expected and emphasizes the need for testing fans with their inlet boxes attached. The conclusion drawn from the tests is that it is not sufficient for the fan user to know the characteristics of a selected fan with free inlet, but he also should know the characteristics when the inlet box is attached.

E. A. Winzenburger

IT IS well known that the performance of a centrifugal fan may be influenced considerably by the direction and velocity of approach of the air to the inlet. In induced-draft fans the direction and velocity of approach of the gases are determined by the form and dimensions of (1) the inlet box that is furnished with the fan and (2) the inlet ducts leading the gases to the inlet box. The performance of an induced-draft fan with open inlet will in general be different from its performance with inlet box attached. The performance on the test block of an induced-draft fan with inlet boxes attached may be quite different from the performance of the same fan when installed, if the inlet ducts are not well designed.

The object of the tests described herein is to ascertain the effect of the inlet boxes on performance. Certain types of inlet box in fairly common use were selected for investigation. The actual dimensions and forms of these boxes are not standardized, so that the results obtained must be recognized as applying only to the particular conditions of the tests. The tests were intended to bring out the magnitude of the changes in performance which might reasonably be expected and to emphasize the necessity of testing fans with their inlet boxes attached. If the particular ducts to be furnished in the actual installation give an inlet flow different from the ideal, straight, symmetrical flow of standard test practice, the fan performance will be affected, and in such cases testing should be carried out, not only with inlet boxes attached, but also with inlet ducts in position.

The tests were carried out at the Gordon McKay Laboratory of the Harvard Engineering School with the assistance of W. A. Abrahamson and H. D. Watson. The fan used was a double-inlet, Turbovane, induced-draft fan supplied by the B. F. Sturtevant Company. The wheel, Fig. 1, is double-inlet, 38 in. diameter, $23^5/_8$ in. wide, and has radial tips. It is provided with curved aluminum inlet rings of the form shown in Fig. 2.

The boxes used are shown in Figs. 3, 4, and 5. Fig. 3 is a simple rectangular box. Fig. 4 is a rectangular box modified by sloping part of the top and bottom sheets as indicated. Fig. 5 is a scroll-inlet box provided with vanes for guiding the air into the fan wheel. The rectangular and modified rectangular boxes were tested also with a vertical guide sheet about 6 ft. long in the center of each duct and extending up to the locations shown in Figs. 3 and 4. It was thought that some guidance of the air stream might improve the fan performance. The scroll-inlet boxes were tested also with the guide vanes removed.

This, it was recognized, would impair the performance of the fan, but would make evident the importance of proper design of the boxes.

The Standard Test Code for Centrifugal Fans of the National Association of Fan Manufacturers and the American Society of Heating and Ventilating Engineers was followed closely except in one minor particular. The inlet ducts were about 4 diameters in length instead of the 6 diameters specified, but they were provided with rounded inlets as indicated in Fig. 6. The inlet-air measurements were made at the specified location of $1^1/_2$ diameters from the inlet boxes. This modification gives a more uniform flow in the inlet ducts by avoiding the *vena contracta* that is inevitably formed at the entrance to the standard type of duct. The influence of this modification on the fan performance is not measurable.

The power input was determined by an electric dynamometer on the fan shaft. In order to eliminate insensitiveness due to frictional resistance in the weighing system of the dynamometer, the weighing levers were removed and the dynamometer was balanced by weights hung through a single knife edge from the short arm projecting from the dynamometer shell. The only frictional resistance remaining is that of the ball bearings

supporting the shell. Both the dynamometer arm and the dead weights were easily measurable within an accuracy of 0.1 per cent. The power input was determined also by measurement of the electrical input to the dynamometer corrected for electrical losses. With carefully calibrated instruments and with daily measurements of stray power (following the method detailed by C. L. Dawes, "Electrical Engineering," Second Edition, Vol. I, pp. 423–426) and armature resistance, the power developed by the dynamometer is determinable with an error not exceeding a small fraction of 1 per cent.

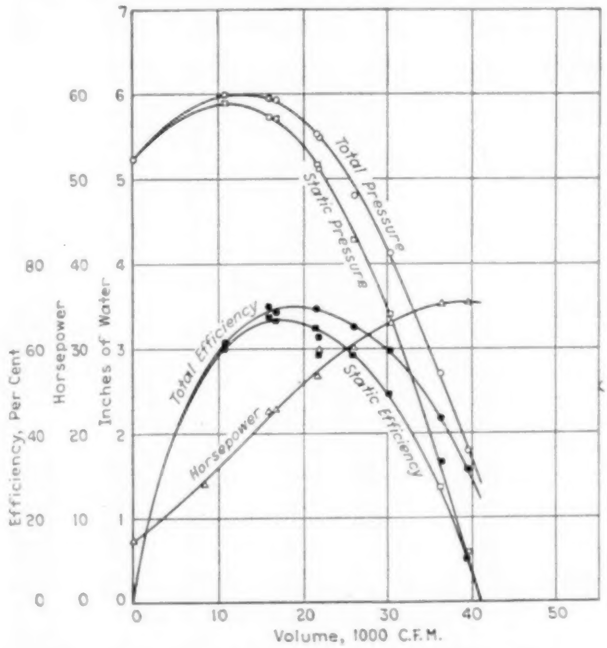

FIG. 8 RECTANGULAR INLET BOXES WITHOUT GUIDE SHEETS

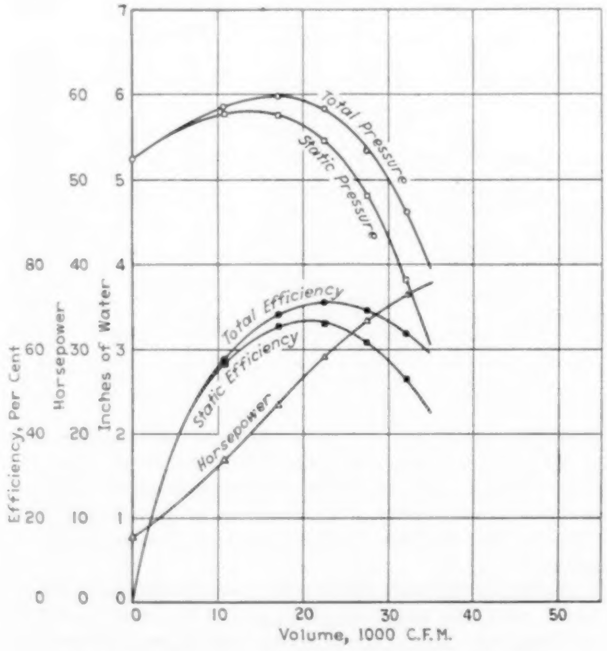

FIG. 9 RECTANGULAR INLET BOXES WITH GUIDE SHEETS

It was found that the agreement between the electrical and mechanical measurements of power was not as close as the apparent individual accuracies of the two methods would suggest. The electrical measurement was from 1 to 2 per cent greater than the mechanical measurement. The frictional resistance of the ball bearings may be partly responsible for this difference. The electrical measurements have been used in the tabulations and curves of this report, both because they are

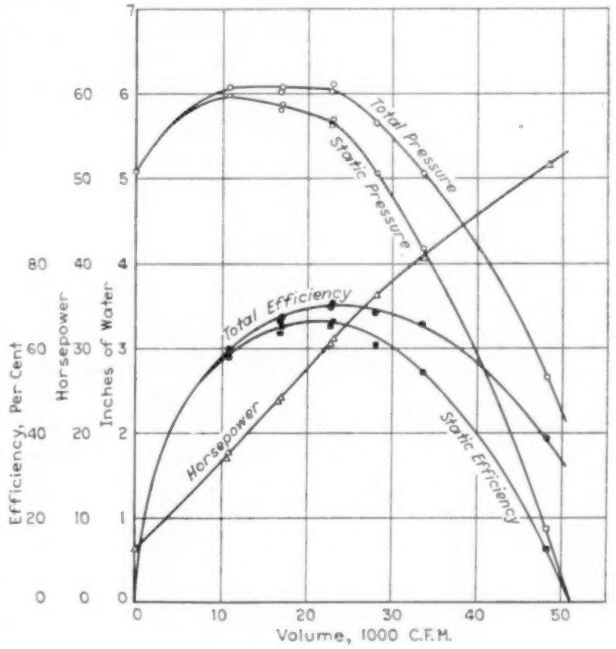

FIG. 10 MODIFIED RECTANGULAR INLET BOXES WITHOUT GUIDE SHEETS

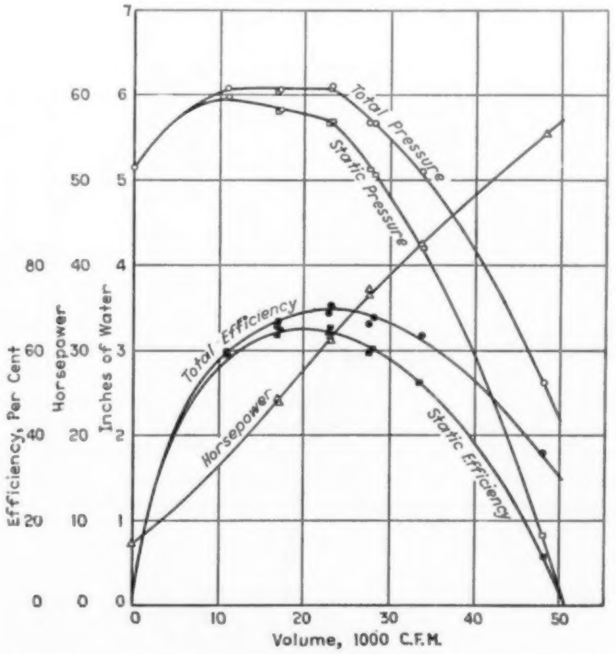

FIG. 11 MODIFIED RECTANGULAR INLET BOXES WITH GUIDE SHEETS

the higher values and also because it is thought that they have a greater accuracy. It was found that horsepower and efficiency plotted on the basis of the electrical measurements lie more closely on a smooth curve. For accurate testing, the direct readings alone of an electrical dynamometer cannot be considered satisfactory and should always be checked by electrical readings.

Pitot tubes were used in the standard method and locations for the determination of static and total pressures. Since it is known that, with some fans, this standard method does not yield accurate results, a Moss nozzle was attached to the end of the discharge duct during one of the tests, and readings were taken of the total pressure at the nozzle in addition to the usual pitot-tube readings. The discharge volumes determined by the two methods agreed closely at three speeds of operation and gave evidence that for this fan the pitot-tube measurements were accurate.

The tests were made at 800 r.p.m., except with the scroll-inlet boxes, when the speed was 900 r.p.m. The conditions during each test were steady, except for the rectangular air boxes without guide sheets. For this condition, with volumes of 22,000 c.f.m. and over, the performance was unstable. The fan would develop periodically a roaring noise which coincided with a power increase of 10 to 15 per cent, but without noteworthy change in the discharge volume. The addition of guide sheets in the inlet ducts improved this condition notably.

The usual procedure in a series of tests was to start with blocked outlet and then to test with 20, 30, 40, 50, 60, 80, and 100 per cent openings. Tests were then repeated at some of the smaller openings as a check.

The principal results of these tests, reduced to 900 r.p.m. and an air density of 0.075 lb. per cu. ft., are presented in Table 1. Characteristic curves for the seven sets of tests are given in Figs. 7 to 13. A comparison of the static pressures for various volumes discharged is shown in Fig. 14. Comparisons of horsepowers and of static efficiencies are shown in Figs. 15 and 16, respectively.

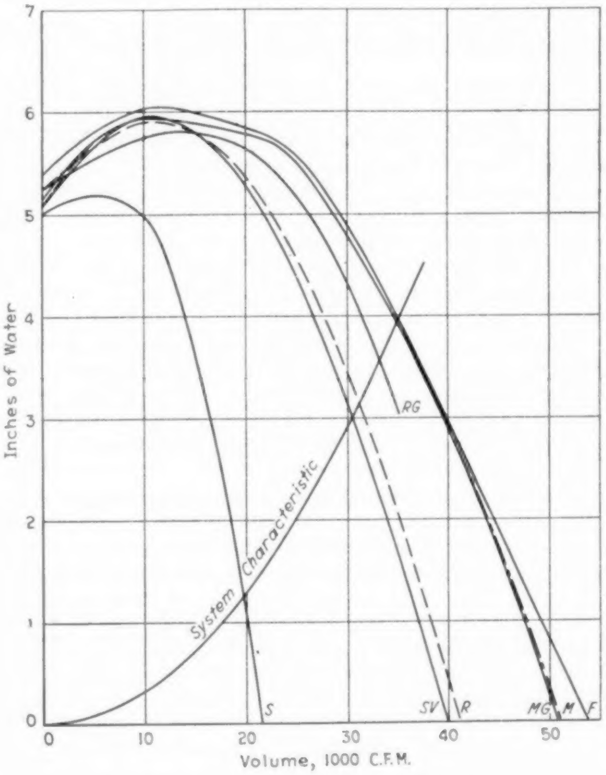

FIG. 14 COMPARISON OF STATIC PRESSURES

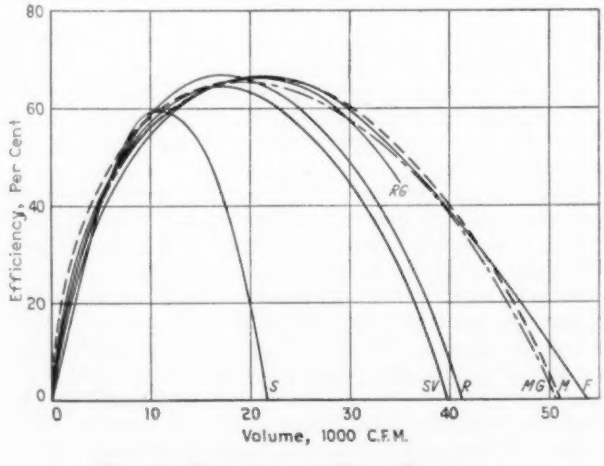

FIG. 16 COMPARISON OF STATIC EFFICIENCY

It is immediately evident that the modified rectangular boxes, both without guide sheets *M* and with guide sheets *MG*, give performances practically identical with that of the free-inlet fan *F*.

A comparison of performance may be on the basis of static pressure at a given volume, volume at a given pressure, volume at a given efficiency, or efficiency at a given volume. Judged in any of these ways, the order of merit for the remaining boxes is (1) rectangular boxes with guide sheets *RG*, (2) rectangular boxes without guide sheets *R*, (3) scroll-inlet boxes with vanes *SV*, and (4), far below all the others, scroll-inlet boxes without vanes *S*. As indicated previously, this last condition is not one which would be used by any intelligent fan manufacturer and is consequently left out of consideration in the discussion that follows.

A quantitative appraisal of the inlet boxes may be made at some selected capacity and static pressure by comparing the necessary speeds and the power consumptions with those of a free-inlet fan. With a discharge volume of 35,000 c.f.m. and a static pressure of 3.96 in., the speed of the free-inlet fan is 900 r.p.m. and the power consumption is 43 hp. Table 2 shows the percentage change from these figures for the other boxes.

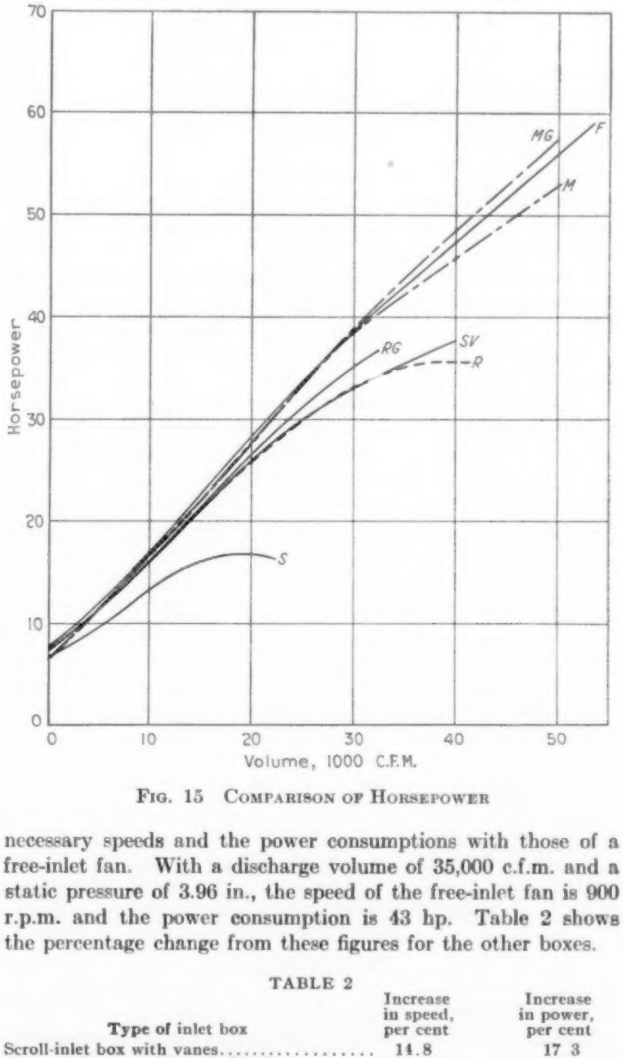

FIG. 15 COMPARISON OF HORSEPOWER

TABLE 2

Type of inlet box	Increase in speed, per cent	Increase in power, per cent
Scroll-inlet box with vanes	14.8	17.3
Rectangular box without guide sheets	12.2	10.5
Rectangular box with guide sheets	5.3	0.7
Modified rectangular box without guide sheets	0.3	−1.2
Modified rectangular box with guide sheets	0.3	3.0

It should be recognized that the increased power consumptions of the scroll-inlet and rectangular boxes result from the fact that at the selected capacities the efficiencies are lower than for the free-inlet fan. Fig. 16 shows that the maximum efficiencies of all the fans (excluding *S*) are substantially the same. If a larger fan is used with the scroll-inlet boxes and rectangular boxes, the operating point for a given capacity will be higher up on the efficiency curve, and the power consumption consequently will be decreased.

A comparison on this basis has been made for a static pressure of 5 in., a volume of 29,250 c.f.m., and a power consumption of 37.5 hp. This performance, which is that obtained from a 38-in. wheel with free inlet at 900 r.p.m., corresponds to a static efficiency of slightly over 60 per cent. From Fig. 16 the capacities with the various inlet boxes at the same efficiency can be measured, and from Fig. 14 the corresponding static pressures can be ascertained. To find the size and speed of fans to give the same performance as the free-inlet fan, use is made of the relations existing between geometrically similar fans: namely, (1) the volume of discharge is proportional to the square of the linear dimensions and to the first power of the tip speed, and (2) static pressures are proportional to the square of the tip speed. Table 3 shows the fan sizes and r.p.m. necessary for each type of inlet box to give the same performance as the free-inlet fan at the selected point.

TABLE 3

Type of inlet box	Wheel diameter, in.	Speed, r.p.m.
Scroll-inlet box with vanes	42.8	812
Rectangular box without guide sheets	40.0	900
Rectangular box with guide sheets	37.7	944
Modified rectangular box without guide sheets	36.9	952
Modified rectangular box with guide sheets	38.65	884

The addition of guide sheets in the inlet ducts results in a marked improvement in the performance with rectangular boxes. With the modified rectangular boxes, no improvement is found or is to be expected, in view of the excellent results obtained without the guide sheets.

The outstanding conclusion to be drawn from these tests is that it is not sufficient for the fan user to know the characteristics of a selected fan with free inlet. He needs to know also the characteristics when the inlet box is attached. With a rectangular inlet box, which is probably the most common form in use, in order to obtain the same performance which the fan gives with free inlet, it is shown that it is necessary to speed up the fan 12.2 per cent and the power input is increased 10.5 per cent. If the user wishes to obtain the free-inlet pressure at the rated volume without the increase in power input, he would have to select a 40-in. fan instead of a 38-in. fan. The instability which characterized the performance with rectangular boxes may be regarded as an indication of the unsuitability of these particular boxes.

It is noteworthy that the comparatively minor difference between the modified box and the straight rectangular box resulted in a considerable change in performance. The mere provision of sufficient cross-section for the approaching air is not sufficient to ensure good performance; it also is necessary to consider the direction of flow in the vicinity of the inlet and to form the boxes in such way as to provide appropriate guidance.

Discussion

W. A. Rowe.[3] This paper brings out forcibly the reasons which prompted the revisions in the code in respect to exhausting fans with inlet boxes. The exception cited by the authors to this standard-test-code set-up, while contemplated at the time of the carrying out of these experiments, is not true with the code as finally revised and adopted. The code does not now provide an inlet duct having a length of 6 mean diameters, as it was found that a short duct with an entrance nozzle produced a more uniform velocity gradient and more accurate reading. The form as adopted is as follows:

> Centrifugal fans with inlet boxes shall be tested with inlet boxes in place. A duct (or a duct for a double-inlet fan) of the same size and form as the inlet-box opening shall be connected thereto as shown on plate G. The inlet test duct shall be not less in length than the mean of its two sides. The open end shall be provided with a nozzle inlet formed of cylindrical sides curved to a radius of not less than one-half of the short dimension of the duct and not less than a 75-deg. arc. Readings shall be taken in said ducts at a point one-half of a mean side from the open end, exclusive of the length of the nozzle. The readings are to be taken in accordance with plate G and calculations made in accordance with the calculation sheet for centrifugal fans exhausting; see plates A, B, and C.
>
> Ratings based on such tests shall be clearly stated as applying to centrifugal fans with inlet boxes and include the loss in the boxes.

As a result of this action, fan rating tables are now available showing the operation of the fans with the boxes in place. However, these rating tables are based on the particular proportioned box provided with the fan, and the authors very properly point out the reason for this. The results they have obtained apply not only to the particular conditions of the test made by them, but to the particular fan or type of fan used in the test.

While the results of this test show the effect on the fan performance in the case of rectangular inlet boxes of certain dimensions as affecting the aspect ratio and area of the inlet to the box, it will be found that with other proportions and areas the effect may be greater or lesser. It is possible by trying out various combinations to determine a box of such proportions as will provide a minimum change in the characteristics of the free fan without excessive width overall, which on induced-draft fans determines the span between bearing centers. Sometimes an apparently minor change makes a very material difference in the performance of the fan, as mentioned in the last paragraph of the paper, and it is necessary to cover wide ranges of proportion and design before arriving at the best combination of all factors.

C. S. Messler.[4] These tests confirm in general the results that we have obtained in investigations along the same lines.

In the case of rectangular boxes the authors have used a box with a ratio of height to width of 2.78 to 1. We think this ratio is too large for best results with this type of inlet box. We have obtained much better results using a plain rectangular box having a ratio of 2 to 1. These tests were made using a fan of the same type as that used by the authors, but with a wheel 52 in. in diameter. At 75,000 c.f.m. and a static pressure of 9.8 in., corresponding to an orifice 65 per cent of wide open, the speed of the free-inlet fan was 1000 r.p.m. and the increased speed for the rectangular boxes is 1.5 per cent.

We have made no tests on a box that would be comparable to the modified rectangular boxes used by the authors, but this design seems to have some decided advantages over the plain rectangular type.

In the case of the scroll inlet boxes, our investigations have proved conclusively that without vanes or baffles the air reaches the fan inlet with such a whirling motion as to form a vortex at the center of the inlet, so that the effective area of the inlet is reduced by about one-half. Under some conditions we found air flowing into the inlet around the outside area and out from the inlet at the center. The volume handled by the fan under these conditions was less than one-half that handled by the fan with free inlet. This confirms results obtained by the authors. It is therefore imperative when using scroll inlet boxes to provide vanes or baffles to direct the flow of air into the fan inlet. The fan performance can be varied over quite a wide range, depending on the design of vanes or baffles used.

A. A. Criqui.[5] The paper states that the standard method of fan testing does not in some cases yield accurate results, although the Moss nozzle test results checked very closely in this case with the standard fan-testing-code results. It would be interesting to know what criticism the authors make on the standard method.

[5] Buffalo Forge Company Buffalo, N. Y.

It is stated that when tested with rectangular inlet boxes without guide sheets the fan developed a condition of instability with periodic recurrence of a roaring noise and an increase in power, and without corresponding change in the volume of air delivery. The addition of guide sheets in the inlet ducts improved this condition. This condition no doubt was caused by a combination of the fan characteristics and the inlet box, and can easily be corrected in the box design.

The tests conducted by the authors show that the modified rectangular inlet box was the most efficient of those tested.

Results of the writer's tests agree with those of the authors in that rectangular inlet boxes should be modified for best results.

It is not thought that the authors wish to claim that the figures given in their conclusions may be regarded as general. Obviously the results apply only to the particular proportions of boxes tested. Rectangular boxes could be made of sufficient area so that results would be practically the same as with free inlet. Such large boxes would not be economical, however, and it therefore becomes a problem in which it is necessary to make the box design as efficient as possible in as small a space as possible to keep both the power consumption and the cost of the unit within economical limits. This can be accomplished by the use of rectangular boxes with proper modifications.

H. F. Hagen.[6] The opening paragraph of the paper might well have been emphasized by italics. Fans, particularly induced-draft fans, more often than not, are selected and bought only after the power house has been designed and the necessary space has been allotted to all the other equipment. The fans and the required flue work have to go into the space that is left; and it sometimes seems to the fan engineer that his most difficult problem is dodging beams. Many power-plant designers believe that directions of flow do not matter, so long as the flue areas are large enough to give a low velocity. While it is true that disappointment in boiler output is sometimes due to inaccurate fan guarantees, yet in still more cases reduced output is due solely to beam-dodging flues. The authors' tests demonstrate authoritatively the large variations in performance that result from careless inlet-box design.

Consider a fan bought from a standard test-code performance with free inlets, as in Fig. 7, and then being provided with boxes, as in Fig. 3, with an unexpected reduction in capacity, as shown in Fig. 8. The cross-sectional area of the boxes is nearly double the fan inlet area, but in spite of this the performance has been materially reduced. Suppose the fan had been bought for 29,250 c.f.m. at 5 in. static pressure, from the performance of Fig. 7. When installed according to Fig. 8, at 29,250 c.f.m., the static pressure would be only 3.6 in. This reduction is in proportion to the differences between expected and actual conditions that are found in so many modern power plants.

A fan is, as shown by these tests, decidedly susceptible to changes in inlet flow, and this change in performance occurs whether the change in inlet flow is caused by different inlet boxes or different duct connections.

An apparently minor modification of the box of Fig. 3 to that of Fig. 4 brought the performance back to that of Fig. 10, which is substantially equal to the original.

However, it must be remembered that in these tests the inlet duct gave a straight flow to all the boxes. And, as the authors state in their first paragraph, the performance may be again affected "if the inlet ducts are not well designed." It was for this very reason that the design of Fig. 5, a spiral box with vanes, was introduced. This is an expensive construction, and, because of smaller capacity, requires a larger fan to do the same work efficiently, again increasing the cost. Table 3 shows that to secure the same volume at the same efficiency a wheel 42.8 in. in diameter is required as against a 36.9-in. wheel for the simpler modified box.

However, if the effect of the spiral box is allowed for and the fan is sold from the curve of Fig. 12, the design might reasonably be expected to give more consistent performance, less affected by poor flue design than any of the others. Its higher cost would then be justified by insuring exactness of performance in actual service. The design has been successful in that it has greatly decreased complaints and has in general given the consistent performance expected of it.

The careful testing and checking of results, as mentioned in the paper, show an attitude worthy of general imitation. The standard test code was followed, but with extra precautions. The code provides that the horsepower shall be determined by an electric dynamometer or a calibrated electric motor. The authors used both methods and secured satisfactory checks, incidentally finding that more than usual precautions were necessary in using a dynamometer. Volume measurements were made with the pitot-tube traverse, the method preferred in the code; but a nozzle determination, also a well-recognized method and described in the code, was secured as a check.

The authors are to be congratulated on the completeness of their presentation of results and for their use of the readily intelligible, customary forms of plotting.

From more general considerations the writer believes that the fan industry and fan users should feel encouraged at this evidence of interest in fan problems displayed by a competent laboratory. A complete series of comparative tests, such as that described in the paper, is difficult to prosecute in the habitually harassed commercial laboratory, even when the technical skill may be available. And unless the particular work planned is followed through to completion, one reaches no conclusions. The results of the tests will be of direct help to the writer and will serve as valuable guides to other designers. They will tend to promote confidence between user and manufacturer. There are many problems before the industry at the present time whose solution and demonstration will necessitate just such painstaking and accurate investigation, and preferably by an independent laboratory. It is hoped that this paper indicates an interest in fans on the part of Professor Marks and his colleagues that will continue.

L. Menkin.[7] It has long been recognized by ventilation engineers that the performance of a fan, when installed, will be quite different from that obtained on the test floor of the manufacturer. The actual conditions of the air flow, prior to entering the fan and after leaving it, are of primary importance in determining the fan characteristics. The velocities of approach of the air flow to a fan inlet are such as to give it a condition of turbulence, with a high Reynolds number. The degree of that turbulence, as the air flow changes its direction to enter the fan and acquires a rotational motion, is bound to have a strong influence on the fan characteristics.

In comparing the merits of the various inlet boxes tested by the authors, it is rather unfortunate that no conclusions can be reached as to the exact factors responsible for the various differences in fan performance. For instance, in the tests of the rectangular and the modified rectangular inlet boxes, the better performances of the latter may be attributed to any one of the following factors or to a combination of them:

---

[6] B. F. Sturtevant Company, Boston, Mass.

[7] Ventilation Designer, Board of Transportation, New York, N. Y. Assoc-Mem. A.S.M.E.

1 The sloping of the top and bottom sheets
2 The fact that there is a collar box between the fan housing and the inlet box
3 The inlet box is offset from the center of the fan
4 The entrance area of the modified inlet box is larger than that of the regular rectangular box.

For proper comparison, it would be interesting to see the performance of the same fan with a simple rectangular box, but which would be provided with a collar box of the same size as was provided for the modified rectangular box, and which would be offset from the center of the fan the same amount as the modified box, and would have the same width and height at entrance as the modified box. Under such conditions it would be an easy matter to determine the effect of sloping the top and bottom sheets of the box. Similarly, by varying any one of the other factors, one at a time, their comparative values could be determined. It would be especially interesting to get valuable data for an accurate comparison of the merits of a scroll inlet box with vanes with those of the modified rectangular box. The scroll inlet box has been advocated by some manufacturers, but if it could be conclusively demonstrated that the modified rectangular box is better and that a saving of 10 per cent on the wheel size can be effected for the same results, a considerable economy would have been attained by reducing the size of fans, and thereby the size of the buildings housing them. This would be of especial importance in very large ventilation installations, such as the exhaust system of a vehicular tunnel.

Joseph M. Barnes.[8] The writer would ask the authors if they made any tests as to the effect of installing fixed baffles horizontally in the inlet boxes, at right angles to the direction of gas flow, in an attempt to more accurately distribute the flow over the entire cross-sectional area of the box, and if so, whether this detail had any marked effect on fan efficiency.

Authors' Closure

The authors are glad to know that the recently revised, but as yet unpublished, standard test code prescribes the practice which they are advocating, of testing induced-draft fans with inlet boxes in place. This practice will force manufacturers to investigate more carefully the influence of the inlet boxes and will result in better fan performance. Such information as that supplied by Mr. Messler on the desirable proportions of rectangular inlet boxes is a case in point.

In reply to Mr. Criqui, the standard test method may give results which are considerably in error when the flow is pulsating. This condition occurs particularly in certain fans with a small number of blades. The pitot-tube reading under the circumstances will inevitably indicate a volume which is too large. The error may be considerable.

Mr. Hagen justifies the use of spiral inlet boxes by the statement that they give more consistent performance independently of the inlet-duct design. This belief seems reasonable to the authors and is now under investigation by them.

The further investigation suggested by Mr. Menkin would be interesting and valuable. The investigations now recorded are preliminary and exploratory. The authors hope to carry out a more systematic investigation at some future time.

In reply to Mr. Barnes, the only attempt at distributing the flow of inlet air was by the use of vertical guide sheets.

Solubility of Calcium Salts in Boiler Water[1]

By FREDERICK G. STRAUB,[2] URBANA, ILL.

The purpose of this investigation has been to determine the behavior at elevated temperatures of the various chemical compounds found in boiler waters. This includes a study of the solubility of the various compounds under conditions simulating those found in high-pressure boilers. Such a study involves the determination of the solubility of the more insoluble compounds such as calcium carbonate and calcium sulphate separately and combined, as well as in the presence of the more soluble salts such as sodium carbonate, sodium sulphate, and sodium hydroxide. These results should aid materially in determining the proper water treatment for high-pressure-boiler operation.

IN THE operation of high-pressure steam boilers the prevention of scale receives first consideration since it is realized that the deposition of scale on the heating surface of high-pressure boilers operating at high ratings is very undesirable. The question of concentration of soluble salts also receives consideration since it influences scale deposition, carry-over, turbine-blade deposits, etc. There has been a tendency to predict scale in higher-pressure boilers unless phosphate treatment is resorted to above 200 lb. Thus, Hall[3] states:

> The formation of adherent anhydrite scale on the evaporating surfaces of a boiler operating at 185 deg. cent. (150 lb. gage pressure) is prevented by using soda ash to maintain the following conditions in the boiler water:
>
> $$CO_2 \text{ p.p.m.} > 0.0883\ SO_4 \text{ p.p.m.}$$
>
> It is evident from the expression
>
> $$CO_3 > K \text{ (at operating pressure } p) \times SO_4$$
>
> that the maintenance of scale-free conditions depends upon keeping a definite supply of CO_3 in the boiler water. In case conditions arise such that the necessary CO_3 concentrations cannot be maintained, then it is no longer feasible to use soda ash as the conditioning chemical.... Thus higher operating pressures are characterized by more rapid decomposition of CO_3 and at the same time by the necessity for maintaining higher CO_3 concentration, as the value of K is greater at higher than at lower operating pressures....
>
> A satisfactory and practical answer to the complete conditioning of water for high-pressure operation may be given as follows: If the make-up water is evaporated, and the only impure water entering the boiler consists of the condenser leakage, then conditioning the boiler with phosphate is the only chemical control necessary. If the make-up water is not evaporated, and is of some magnitude, then economy may demand a pretreatment (with lime and soda ash for any water, or by a base exchange process if the water does not contain temporary hardness) followed by the final conditioning of the boiler water with phosphate.... In any event, however, the final control of the boiler water must be based on the use of a stable substance such as phosphate.

If the A.S.M.E. Boiler Code recommendation for the prevention of embrittlement is followed, the amount of sulphate becomes too high for the carbonate and scale would be predicted by the older theory. However, in many instances ratios of over 3 are being maintained in plants at higher pressures, calcium is entering the feedwater in various amounts, phosphate is not being added, the amount of CO_3 is decidedly low, and yet scale is not a problem.

TABLE 1 ANALYSES OF BOILER WATERS FROM PLANTS NOT HAVING SCALE DIFFICULTIES

Plant	A	B	C	D	E
Pressure, lb. gage	700	700	400	225	160
NaOH	103	79	144	90	200
Na_2CO_3	8	5	42	29	26
Total alkalinity	144	109	233	148	291
Na_2SO_4	1130	415	3350	5030	3100
NaCl	190	43	1240	692	125
$\frac{Na_2SO_4}{\text{Total alkalinity}}$	7.8	3.8	14.4	34.0	10.6
$\frac{CO_3}{SO_4}$	0.0059	0.01	0.011	0.0047	0.007

The composition of typical boiler waters from several such plants is given in Table 1. The feedwater conditions at these plants are as follows:

Plant A. 98 per cent condensate returns; 2 per cent zeolite-treated water make-up; condenser water about 12 grains hardness; condenser leakage low.

Plant B. 98 per cent condensate returns; 2 per cent evaporator make-up water lime-soda softened prior to evaporation; condenser water about 12 grains hardness; condenser leakage low.

Plant C. 80 per cent condensate (process) returns; 20 per cent make-up; hot-process softener used for treatment; untreated water about 16 grains total hardness with about 7 grains sulphate hardness.

Plant D. 80 per cent condensate returns; 20 per cent make-up water about 17 grains total hardness with 9 grains sulphate hardness; internal treatment, sodium carbonate and organic.

Plant E. 80 per cent condensate returns; 10 per cent make-up water. The make-up water is treated by a cold-process lime softener and has about 3 grains residual hardness, with 3 grains excess soda ash leaving the softener.

According to existing theories, all of these plants should form scale. The carbonate-to-sulphate ratio according to Hall should be greater than 0.0883 in all of these plants. However, in them, some operating at 700 lb. pressure with calcium present in varying amount, the operators are not bothered with scale troubles.

These discrepancies between theory and operation may be readily explained on the basis that we do not have sufficient data available to formulate theories which hold at the higher pressures. Thus, Hall's figures were calculated using the solubility product, and not having exact values for the solubility of calcium carbonate

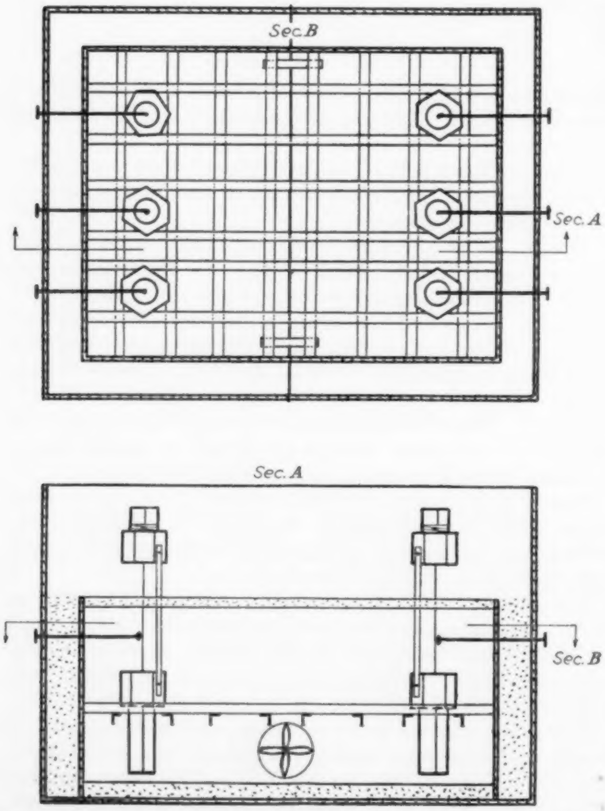

Fig. 3 Constant-Temperature Box, Showing Position of Bombs

his determination of the solubility of calcium sulphate was only made up to about 225 lb. pressure. Partridge[4] has checked Hall's figures on the solubility of calcium sulphate, but he also stopped at about the same pressure. Neither Partridge nor Hall determined the influence of additional salts on the solubility of calcium sulphate. In order to obtain further data in respect to the solubility of the various calcium compounds occurring in boiler waters and to study the influence of soluble salts, research has been conducted along these lines. This work has not been completed; however, sufficient data have been collected up to 1500 lb. pressure to show the general trend of the results.

In order to obtain the desired data an extremely large number of solubility tests had to be run. The procedure in the majority of the previous investigations conducted along this line at lower pressures has involved the operation of a small boiler. Naturally the results obtained from such tests were few in number since so much time had to be spent in obtaining equilibrium conditions. The present investigation had departed from this method of testing in that a large number of small steel bombs were used for the solubility determinations. Four constant-temperature boxes were constructed to hold these bombs. With each box at a different temperature and with six bombs in each box, twenty-four separate solubility tests were run simultaneously, thus obtaining results much faster than possible by the older procedure.

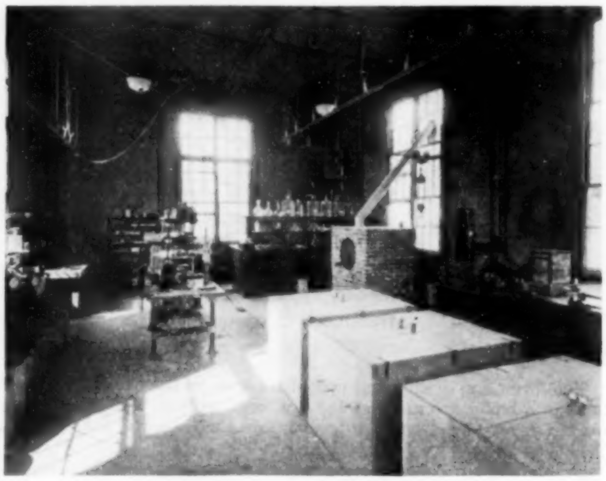

Fig. 4 View of Laboratory Showing Three of the Heating Boxes in the Foreground

The details of construction of the steel bombs are given in Fig. 1. Fig. 2 shows a photograph of the testing bomb completely assembled. Fig. 3 shows how the bombs are assembled in the heating box, while Fig. 4 shows three of the heating boxes in the foreground. The boxes are electrically heated by means of resistance wire. Constant temperature was maintained by means of automatic potentiometer temperature regulators. The accuracy of the temperature control was ± 3 deg. fahr.

The procedure involved in these studies was to put the desired solid phase in the larger or bottom bomb. The desired solution was then added boiling hot and the bomb closed by screwing the top on. The smaller or top bomb, previously cleaned and closed, was then attached by means of the connections on the capillary copper-lined steel tubing to the lower bomb. The valve between the two bombs was closed. The assembled bomb was put in the heating boxes and held at the desired temperature until equilibrium was obtained. In these tests the time in the furnace

to reach equilibrium was found to be rather short—about 6 to 10 hours. However, the furnaces were run about 72 hours. Consequently, plenty of time was given for equilibrium conditions to be established.

When it was desired to sample the bombs, the valve was opened by means of the handle extending through to the outside of the heating boxes. The steam pressure in the lower bomb forced the solution through the filter and the capillary tube into the upper bomb. After the top bomb was filled with the solution, the valve was closed and the complete bomb was removed from the heating boxes. When cool, the top bomb was removed, and the volume of solution accurately measured and completely analyzed.

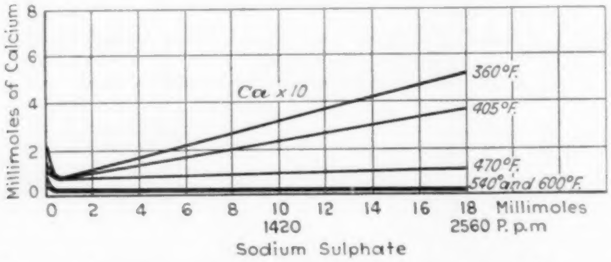

FIG. 11 SOLUBILITY OF CALCIUM: SOLID PHASE ADDED, CALCIUM CARBONATE; SALT ADDED, SODIUM SULPHATE

The solubility tests reported were run at 360, 405, 470, 540, and 600 deg. fahr., corresponding approximately to 150, 250, 500, 1000, and 1500 lb. gage. The solubilities of calcium sulphate and calcium carbonate were determined in distilled water separately and combined. The influence of soluble salts such as sodium carbonate, sodium hydroxide, and sodium sulphate upon each of these calcium compounds was also studied. The results of these tests are given in graph form in Figs. 5 to 14, inclusive.

The solubility of calcium sulphate at 360 deg. fahr. is approximately the same as that determined by Hall and Partridge. As the temperature increases the solubility decreases. A much larger decrease in solubility takes place between 360 and 470 deg. than between 470 and 600 deg. Thus, for 100 deg. fahr. increase in temperature above 360 deg. there is a decrease of 0.54 millimole, while 130 deg. increase above 470 deg. causes a decrease of only 0.12 millimole.

The solubility of calcium carbonate is rather difficult to determine since it is largely influenced by the partial pressure of carbon dioxide over the solution. Thus, at room temperatures as the partial pressure of the carbon dioxide increases the solubility of the calcium increases. The influences of the partial pressure of carbon dioxide on the solubility of calcium carbonate at elevated temperatures has not been determined. However, some work is being done in the author's laboratory along this line. In determining the solubility of calcium carbonate, water free from carbon dioxide and pure Iceland spar crystals were used. The partial pressure of carbon dioxide over these solutions would be a function of the decomposition of the calcium carbonate and would depend on the temperature. Under these conditions the solubility of calcium carbonate was found to decrease with increase in temperature. This is in accord with the work of Frear and Johnston,[5] who show that the calcium carbonate decreases in solubility with increase in temperature.

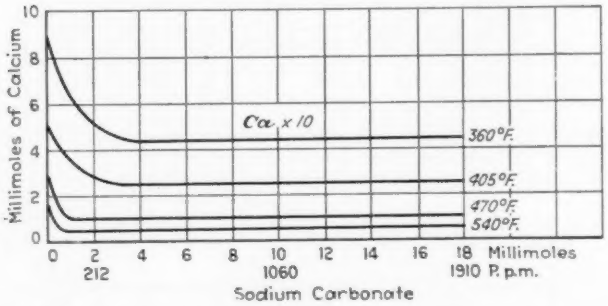

FIG. 12 SOLUBILITY OF CALCIUM: SOLID PHASE ADDED, CALCIUM CARBONATE AND CALCIUM SULPHATE; SALT ADDED, SODIUM CARBONATE

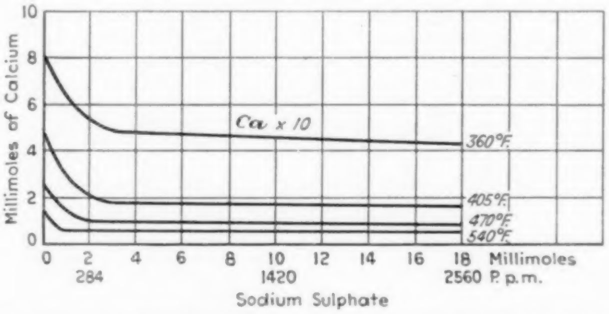

FIG. 13 SOLUBILITY OF CALCIUM: SOLID PHASE ADDED, CALCIUM CARBONATE AND CALCIUM SULPHATE; SALT ADDED, SODIUM SULPHATE

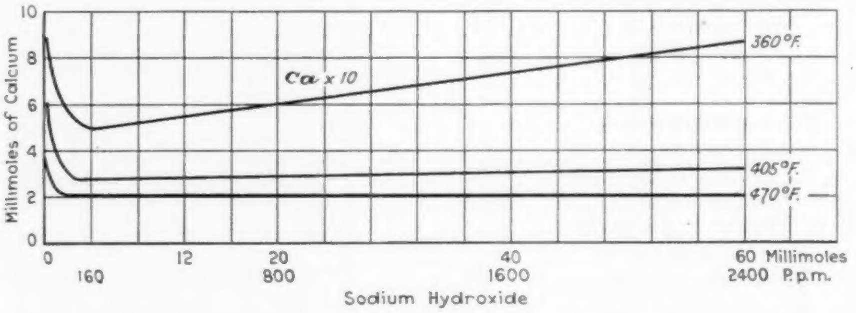

FIG. 14 SOLUBILITY OF CALCIUM: SOLID PHASE ADDED, CALCIUM CARBONATE AND CALCIUM SULPHATE; SALT ADDED, SODIUM HYDROXIDE

However, if these determinations which were made below 212 deg. are used to calculate the solubility at the higher temperatures, the results so obtained will be lower than those actually found. Hall has based his calculations on the assumption that calcium carbonate increases in solubility with increase in temperature.

If calcium sulphate and calcium carbonate are added as a solid phase, the solubility of the calcium, as shown in Fig. 7, is very similar to that of calcium sulphate alone, being a trifle lower at practically all temperatures reported.

---

[5] *Jl. Am. Chem. Soc.*, vol. 51 (1929), p. 2082.

When sodium carbonate is added to calcium sulphate, the solubility of the calcium drops rather rapidly until about 300 parts per million of sodium carbonate have been added. The addition of sodium carbonate up to 2000 parts per million does not have any additional effect on the calcium solubility. In these tests there was always an excess of calcium sulphate present. When sodium sulphate was in solution with calcium sulphate added as a solid phase, the results were almost the same as when sodium carbonate was added. This may readily be seen by comparison of the curves in Figs. 8 and 9.

The addition of sodium hydroxide with calcium sulphate as the solid phase also gave results much similar to those obtained when adding sodium carbonate or sulphate. After a small amount of hydrate has been added, putting in more has no further influence on the calcium content of the solution.

The results obtained from adding sodium carbonate and sodium hydroxide solutions to calcium carbonate as the solid phase have not been plotted. This is due to the fact that upon the addition of as little as 0.25 millimole of either salt the solubility of calcium dropped to zero and stayed at that point as more was added. Thus the solubility of calcium was zero in the presence of sodium carbonate or sodium hydroxide when calcium carbonate was the solid phase added.

When calcium carbonate was the solid phase added the addition of a small amount of sodium sulphate decreased the calcium solubility, but as more was added the calcium content increased at 360 and 405 deg., but remained constant at 470 deg. and higher temperatures. This is shown in Fig. 11.

When both calcium carbonate and calcium sulphate were present in the solid phase, the addition of Na_2CO_3 gave results similar to those obtained when calcium carbonate was not added. In these tests there was always an excess of sulphate. The addition of sodium sulphate or hydrate to this mixed solid phase gave similar results, as shown in Figs. 12 and 13.

In all these tests there was an excess of solid phase added. Tests were run starting with a solid phase of calcium sulphate and adding an excess of sodium carbonate. At the end the calcium solubility was equal to zero at all temperatures, which was the same as calcium carbonate with sodium carbonate present.

In attempting to determine the CO_2/SO_4 ratio for the conversion of calcium sulphate to calcium carbonate, the sulphate content of the solution was determined. It was assumed that if 100 per cent of the carbonate reacted with the sulphate the calculated sulphate would be equal, mole for mole, to the carbonate added.

The results obtained are presented in Table 2 and show that practically 100 per cent of the carbonate reacts with the sulphate at 360 deg., and even at 600 deg. only a small percentage of carbonate is not accounted for as sulphate.

In actual boiler water there will nearly always be free hydrate available. Therefore, the foregoing tests were repeated with hydroxide present. The results of these tests are given in Table 3. The calculated sulphate is obtained as before. The tabulated differences show that the determined sulphate agrees with the theoretical within the experimental error. Thus, when an excess of calcium sulphate is present in a solution containing hydrate alkalinity, practically all of the sodium carbonate reacts with the sulphate to form sodium sulphate and calcium carbonate. The retarding influence of the sodium sulphate, even up to concentrations of 3000 parts per million or 170 grains per gallon and at 1500 lb. pressure, can practically be neglected, and the presence of a measurable amount of sodium carbonate should convert the calcium sulphate to calcium carbonate. When sodium carbonate exists in the solution, the solubility of the calcium drops to extremely low values due to the fact that the calcium sulphate has been completely converted to calcium carbonate.

TABLE 2 RELATION BETWEEN CALCULATED SULPHATE AND DETERMINED SULPHATE WHEN SODIUM CARBONATE SOLUTION WAS ADDED TO $CaSO_4$ AS SOLID PHASE

(Results in millimoles per liter)

Temperature, deg. fahr.	Na_2CO_3 added	SO_4 at end	Difference
360	3.75	3.70	—0.05

Discussion of Results

The results which have obtained are still incomplete, and the effect of other salts such as chlorides, silicates, and phosphates and the influence of higher temperatures are now being studied. However, they should help in determining the desirable water conditions for higher-pressure boilers.

The solubility of calcium carbonate, being practically zero at the temperatures studied when sodium carbonate or hydrate is present, illustrates why calcium carbonate scale does not form in boilers operating with an appreciable alkalinity. The calcium is all thrown out of solution as insoluble calcium carbonate, and forms the finely divided solid or sludge.

The solubility of calcium sulphate decreases rather rapidly up to 500 lb. pressure, and somewhat slowly above this pressure. The amount of soda ash necessary to prevent the reconversion of calcium carbonate to calcium sulphate in solutions having free hydrate present is decidedly low, even at the highest temperature studied and in the presence of large amounts of sodium sulphate. This shows that with measurable amounts of sodium carbonate and hydrate remaining in solution the calcium sulphate is entirely converted to calcium carbonate, which in turn has an extremely low solubility under these conditions. Thus, if equilibrium is maintained, calcium sulphate cannot exist as a solid phase with sodium carbonate and hydrate in the liquid phase. The influence of the sodium sulphate in solution on the formation of calcium carbonate is practically negligible at the concentrations studied.

The interpretation of boiler-water conditions in terms of these data must be done somewhat conservatively. The data are equilibrium data, and it is entirely possible that such conditions are not reached in all parts of the boiler. At the same time the rate of steam generation at the heating surface may have more to do with scale formation than the question of relative solubility. However, these results should indicate with a fair degree of accuracy whether or not scale should form. They will explain why scale is not a factor in the boiler waters referred to in Table 1.

All of these waters have sufficient carbonate and hydrate to cause the precipitation of calcium carbonate in the boiler water and prevent calcium sulphate from forming.

Research is in progress which will attempt to correlate the solubility equilibrium data with scale prevention.

The conclusions which may be made at this time are as follows:

1 The solubility of calcium carbonate decreases with increase in temperature

2 The solubility of calcium carbonate in the presence of sodium carbonate of hydrate is practically zero at the temperatures studied

3 The solubility of calcium sulphate is not directly proportional to the sulphate in solution

4 Calcium sulphate as a solid phase cannot exist in equilibrium with solutions containing sodium carbonate, even at pressures up to 1500 lb.

5 The old calculated ratios of CO_2/SO_4 to prevent calcium sulphate formation as a solid phase are extremely high.

Discussion

Cyrus William Rice.[6] The writer would like to offer some comments, as we find this solubility to be influenced by other constituents in the formation of structural deposits of calcium under operating conditions.

Our experience has clearly indicated that the increasing concentrations of the sulphate ion through the addition of sodium sulphate to the boiler concentrations have a decided influence on the deposition of calcium as calcium sulphate where calcium is the predominating hardness constituent in the feedwater; that sodium sulphate under similar conditions causes deposits of calcium silicate where silica is contained in the feedwater in a form unknown to us. These effects have all followed the addition of sulphate for the purpose of increasing the sulphate to carbonate ratio.

In cases of zeolite operations this addition of sulphate has often proved so troublesome that the practice had to be discontinued.

Under either of these circumstances the quality of the feedwater and the operating pressures remained the same, and the only change that brought about the troublesome deposits was the increasing concentrations of the sulphate radical. These same deposits of calcium sulphate and calcium silicate have also followed the excessive use of sodium hydroxide.

The solubility of calcium in the boiler concentrates is also influenced by organic matter and some of the silicates. This has been such in a number of cases as to cause sulphate deposits with soda concentrations in excess of 1000 p.p.m. and in a few instances objectionable silica deposits have occurred with soda concentrations approximating 2500 p.p.m. $CaCO_3$.

A review of many complete laboratory analyses of boiler concentrates compared with similar analyses of deposits from fire-exposed boiler tubes has also indicated that deposits of calcium sulphate do not take place within boilers in most of the treatments with sodium carbonate, where the product obtained by dividing all the SO_4 into the CO_3 in the boiler concentrates exceeds 0.0883.

While this is the case, there are exceptions to this, as we know that ratios as low as 0.01 do not cause scale deposits and that a ratio several times the 0.0883 has been accompanied by very troublesome formations on the evaporating surfaces.

Because of this, rules of this character have no definite value in controlling the chemical conditioning of boiler feedwaters.

In referring to the various examples given by the author where the ratio of 0.0883 did not apply, the writer can see why Plant A, because of its zeolite supply, did not scale. Plant B may also fall in this class because of the small amount of make-up and possibly too low calcium content in the feedwater and boiler concentrates to cause deposits.

In either Plants A and B the leakage of calcium into the condensate from the cooling water would also have to be small in amount. Plants C, D, and E, because of the low percentage and character of the make-up, are different, and according to our experience under similar conditions should cause structural deposits of calcium.

In that the amount of dissolved calcium in the boiler concentrates has an important influence in causing deposits, a complete analysis of these, including the calcium and magnesium, should prove interesting reading in all the cases cited.

Getting down to the basic facts in treating feedwaters, it is the manner in which dissolved calcium is removed from the boiler concentrates and the extent to which this takes place that is really the important issue in the conditioning of feedwater.

With calcium to the possible minimum, magnesium is no consideration, although complete analyses of the boiler concentrates invariably show more dissolved magnesium than calcium in a water that has proved itself non-scale-forming with soda treatments.

As stated, the manner in which calcium is removed is most important. This is not mentioned in any part of the paper, and the charts this gives may prove misleading to those who do not have a clear understanding of the subject.

For instance, the charts show about the same amount of calcium with either sodium carbonate or sodium sulphate in use, yet the addition of the carbonate in the treatment of a feedwater produces an insoluble sludgy material, and treatment with sodium sulphate causes hard, adherent structural deposits. In either case, the amount of calcium remaining, as it is indicated by the charts at the various temperatures, is enough to cause objectionable deposits under similar conditions within boilers.

To prevent structural deposits, calcium must be practically eliminated from the boiler concentrates. This can be effected only through the treatment of such concentrates with chemicals that will precipitate calcium as an insoluble non-adherent material.

The index of the calcium concentration in the boilers is therefore one of the best guides for controlling structural deposits, and the writer believes that experiments for determining its solubility with different treating chemicals under different concentrations of the treating agents and in the presence of the many different salts common to feedwater will prove very interesting. Experiments for the removal of calcium and silicate from waters with soda treatments of all kinds, including phosphates and in the presence of hydroxides, sulphates, chlorides, and carbonate of soda, will also be valuable and interesting, because of the great number of industrial waters in which silica has proved itself so troublesome.

Joseph D. Yoder.[7] The method the author describes for sampling water is ingenious and should be satisfactory for the purpose if large enough to give as large samples as required for accuracy in determinations of substances with low solubilities.

He shows a great similarity of chemical reactions at 1500 lb. to those prevailing at 150 lb. pressure. This knowledge should be reassuring to designing and operating engineers as evidence that the prevention of scale offers no obstacle to the installation of high-pressure boilers, regardless of whether the percentage of make-up is large or small.

[6] President, Cyrus William Rice & Co., Inc., Pittsburgh, Pa. Mem. A.S.M.E.

[7] Manager, Water Purification Department, Cochrane Corporation, Philadelphia, Pa. Mem. A.S.M.E.

That the investigation of chemical equilibria at the high pressures is to be extended to include other salts, particularly silicates and phosphates, is of interest and promises to be of further value.

In the consideration of these data, it is necessary to keep in mind that the prevention of adhering deposit is not solely one of relative solubilities. Consideration must be given to the fact that some precipitates possess less tendency to adhere to surfaces than others, and furthermore that with different conditions the same precipitate offers different tendencies to adhere. As an illustration, if calcium carbonate in the absence of excess CO_3 radicals as sodium carbonate crystallizes from solution, the tendency will be for the calcium carbonate to adhere to the evaporating surfaces, whereas sodium carbonate in excess causes the calcium carbonate to precipitate as a non-adhering sludge. Within reasonable limits the higher the excess of CO_3 radical the less tendency will there be for the deposits to adhere to the evaporating surfaces. As there are practical objections to the high concentrations of sodium carbonate or other soluble solids in the boiler, the goal of feedwater treatment is to prevent adhering deposits and to let remain the smallest quantity of soluble salts.

The author reports that the solubility of calcium carbonates decreases with increase in temperature and that at the temperatures investigated, 360 to 540 deg. fahr., the solubility of calcium was zero with as little as 0.25 millimol or 13 p.p.m. sodium carbonate in solution.

That calcium should have zero solubility under these conditions is surprising and does not seem consistent with other observed facts. Samples of treated water withdrawn from boilers at 250 lb. pressure, 405 deg. fahr., invariably show the presence of some calcium carbonate in solution and generally as much as 8 to 13 p.p.m., with appreciable quantities of sodium carbonate and sodium hydrate. This may be partially accounted for in that some of the calcium carbonate in suspension dissolves at the lower temperature before filtration of the sample preliminary to making the analysis.

There are other indications that the solubility of calcium carbonate is not zero at boiler pressure. An illustration of this is that if a boiler contains some calcium-carbonate deposits when the feeding of sodium phosphate is begun, the phosphate reacts with the calcium-carbonate precipitate to form calcium phosphate, which signifies that the calcium phosphate has a solubility somewhat less than the solubility of calcium carbonate.

Mr. Straub establishes that the ratio of sulphate to carbonate may be very much higher than Hall believed and that a ratio of sodium sulphate to sodium carbonate of 3 to 1 can be carried at the higher boiler pressures without the formation of calcium-sulphate scale.

In the treatment of feedwater, the writer has observed but little tendency to form calcium-sulphate scale with the 3-to-1 ratio. He does, however, advocate the use of phosphate to supplement lime and soda or zeolite treatment of water for boiler pressures higher than 250 lb., and for certain water supplies finds it desirable for pressures as low as 100 lb. The demonstrated value of the phosphate treatment is not so much to prevent a calcium-sulphate scale as to prevent a calcium-silicate-carbonate scale which may contain a small percentage of calcium sulphate and also to make possible carrying lower alkalinity and therefore less sodium sulphate in the boiler water.

Owing to the greater dissociation of sodium carbonate to sodium hydrate at the higher boiler pressures, it obviously becomes necessary to carry higher sodium alkalinity at higher pressures. When it becomes necessary to maintain three times as much sodium sulphate in the boiler water as sodium alkalinity, the result is higher solids in the boiler than is desirable with the natural inclination of the operators to reduce the alkalinity below that required to prevent the calcium-silicate-carbonate deposit. This same tendency to reduce the alkalinity may lead to the formation of calcium-sulphate scale, particularly if the chemical treatment is not always uniform.

The feeding of phosphate makes it possible to keep a very low alkalinity in the boiler and has the further advantage that the calcium-phosphate precipitate offers less tendency to adhere to the evaporating surfaces than calcium carbonate. From the practical standpoint, the feeding of phosphate insures a cleaner surface of the boiler metal, for which reason it is fed regardless of what may be the exact theory involved. The writer's opinion is that its effectiveness is primarily due to the very low solubility of calcium phosphate, the stability of the PO_4 radical, and the physical structure of the precipitate, which is not favorable to crystallization.

Hall[8] and Partridge[9] have advanced the theory that calcium carbonate does not form scale, because its solubility increases at higher temperatures and therefore it becomes insoluble in the main body of the stream of water and not at the surface of the metal, whereas calcium sulphate is less soluble at the higher temperatures and therefore it becomes insoluble at the evaporating surfaces and forms scale. This theory never seemed tenable, and on a previous occasion the writer cited a number of reasons why it did not give an adequate explanation of scale formation. It is pertinent that Straub now finds that the calcium carbonate becomes less soluble with increase in temperature, which completely undermines the theory of scale formation advocated by Hall and Partridge in that he demonstrates their basic premise to be false.

It will be interesting to have determined the solubility of calcium phosphate at increasing temperatures, for it also does not produce scale in the boiler if the PO_4 radical is in excess. There are some indications that, like calcium sulphate and calcium carbonate, it also becomes less soluble with increase in temperature, although the writer has no knowledge of its solubility having been determined at temperatures corresponding to boiler pressures.

R. E. HALL.[10] The paper furnishes data on solubilities of some calcium salts at the temperatures characteristic of present-day boiler waters that are of great interest and that are certain to be of great usefulness. Up to a dividing line of the boiling temperature of a solution under normal atmospheric pressure, a wealth of exact solubility data exists; at pressures above that of the dividing line, there is a great dearth of data of any accuracy commensurate with modern methods of determination. For instance, the solubility of the common gases, oxygen and carbon dioxide, at these higher pressures (temperatures) is not known. Dependable determinations on the solubility of sodium carbonate above 212 deg. fahr. are of recent date. The data on sodium sulphate at elevated temperatures ought to be reviewed.

The varying phases and the solubility of calcium sulphate up to the temperature of 430 deg. fahr. have been given careful consideration by Boyer-Guillon, Melcher, Hall, Robb, and Coleman, and Partridge and White. The work of Professor Straub extends the solubility data to 600 deg. fahr. and brings out the important fact that anhydrite is the stable phase at these temperatures. Thus no complications from phase relationships are involved in considering the problem of calcium-sulphate removal from boiler waters to be used at high operating pressures.

While the presentation of solubility data in the form of curves only, best meets the needs of the present paper, they are of such importance that it is hoped that eventually the values of all of the individual determinations will be presented.

---

[8] Hall, R. E., Carnegie Institute of Technology Bulletin No. 24, 1927.

[9] Partridge, E. P., University of Michigan Engineering Research Bulletin No. 15, 1930.

[10] Director, Hall Laboratories, Inc., Pittsburgh, Pa. Mem. A.S.M.E.

In a boiler water the solubility of any one salt is largely influenced by the other salts that are present. The author considers a number of cases, among others the effect of sodium sulphate upon the solubility of calcium sulphate, and finds that up to a concentration of 2560 p.p.m. of sodium sulphate the solubility of the calcium sulphate is considerably decreased by the presence of the sodium sulphate. Our own work on this effect of sodium sulphate on the solubility of calcium sulphate, carried out at a temperature of 360 deg. fahr., was reported in Bulletin 24 of the Carnegie Institute of Technology and the U.S. Bureau of Mines. When sodium sulphate was not present, the solubility of calcium sulphate was found to be 120 p.p.m.; when 1370 p.p.m. sodium sulphate was present, the solubility was lowered to 81 p.p.m., but began increasing as more sodium sulphate was added, so that there were 83 p.p.m. of calcium sulphate when the sodium-sulphate concentration was 4250 p.p.m., 86 p.p.m. when sodium sulphate was 7550 p.p.m., and 103 p.p.m. when sodium sulphate was 14,900 p.p.m. Bulletin 24 states:

> The decrease followed by an increase in solubility of the calcium sulphate, with increasing concentration of the sodium sulphate, points to an increase in the concentration of complex ions and molecules, and an increasing disturbance of the simple equilibria existing in the pure solution. A limit would be reached when equilibrium becomes established between the solution and Glauberite, $Na_2Ca(SO_4)_2$, as solid phase.

The author has not considered the influence of sodium chloride on the solubility of calcium sulphate or calcium carbonate. The effect is very striking. Thus, at 360 deg. fahr., at which temperature the solubility of pure calcium sulphate is 125 p.p.m., when 1000 p.p.m. of sodium chloride are in the solution the solubility of the calcium sulphate is approximately 250 p.p.m., or twice as much; for 2000 p.p.m. of sodium chloride is 300 p.p.m., and for 5000 p.p.m. of sodium chloride has increased to 410 p.p.m. These data are found on page 64 of Bulletin 24. Doubtless before the author completes this work he will determine the effect of the addition of sodium chloride on the calcium-carbonate solubility relationships.

Basing their calculations upon the data of Johnston and Frear, which became available in 1929, both Mr. E. P. Partridge and Professor Straub find by extrapolation of these data that the solubility of calcium carbonate decreases with increase in the temperature of the solution. Professor Straub's experimental data also point to this conclusion. This is contrary to the data of Kendall, whose values were the most accurate available prior to publication of the work of Johnston and Frear. The fact that the solubility curve of calcium carbonate has a negative slope with increasing temperature explains what apparently has been an anomaly in boiler-scale formation. A boiler with any considerable percentage of make-up, and treated with sodium carbonate, usually becomes covered with a thin coating of true scale, which ordinarily keeps flaking or peeling off, and which moving by gravity to the mud drum or the blowdown header is largely removed by blowdown at that point, but of which some considerable mass is usually left at the time when the boiler is opened. The fact that the temperature-solubility curve of calcium carbonate has a negative coefficient places it in the class of the truly scale-forming substances, such as calcium sulphate or calcium hydroxide, and thus explains this formation of scale. The slope is slight, and hence the tendency for scale formation is not so marked as with a greater negative slope, but is none the less real.

The data now available therefore point to a negative solubility-temperature coefficient of the calcium-carbonate curve. As brought out by the equilibrium calculations of Partridge and as indicated in the experiments of Straub, in which static equilibrium is derived in experimentation in bombs, the ratio of carbonate to sulphate in the water necessary to repress formation of calcium sulphate is considerably less than the values we arrived at some years ago on the basis of the solubility data of Kendall. It will therefore be interesting to review the results when ratios of this type are applied to the conditions of dynamic equilibrium as they exist in the boiler waters.

In our earliest experimental work (1922), we ran a 42-day test on a boiler operating at 150 lb. pressure and using practically complete make-up of South Pittsburgh filtered water without treatment. We analyzed everything going to and coming from the boiler, and on this basis arrived at the fact that 89 per cent of all calcium sulphate going to the boiler was deposited there as scale.

At that time the fundamental theorem of scale prevention—namely, suitable control of the chemical equilibria at the evaporative surfaces—was unknown, and hence any maintenance of carbonate-sulphate ratios for the elimination of scale formation was not considered. Our next move, therefore, was to maintain a definite slight (5 to 15 g.p.g.) alkalinity in the boiler water. Under those conditions considerable sludge developed in the boiler water, but on the surfaces of the tubes calcium-sulphate scale was deposited. It contained very little carbonate and very little silica.

In the fall of 1923 and winter of 1924, on the basis of data then available, the carbonate-sulphate equilibrium ratios were worked out. They demonstrated that both sulphate concentration and operating pressures must be considered in any decision on the amount of chemical required for conditioning the water.

Treatment was then set up at the plant in question on the basis of these ratios, and has continued without interruption on that basis to the present time.

One of the first difficulties we met in application of these ratios was that on boiler waters colored by organic contamination we would find a sufficiency of carbonate to meet the carbonate-sulphate ratio, determinations being made by the titrations with phenolphthalein and methyl orange in the customary way, and yet on the surfaces of these boilers calcium-sulphate scale would be deposited. It was at this juncture that we developed the modified Winkler method of titration on boiler waters (Bulletin 24), since it avoided completely any effect of organic matter on the titration. We have used this method of determining the alkalinity relations in boiler waters from that time on.

Because of the decomposition of sodium carbonate into caustic in the boiler water and because elimination of scale by the use of sodium carbonate and its necessarily concomitant causticity has, so far as our experience goes, always been relatively uncertain, whether slight or high causticity and carbonate concentrations have been maintained, we were led in the end to prefer in all cases the use of phosphate as the final conditioning radical in the boiler water, since it is stable and stays in the water ready for use. The difference between carbonate and phosphate is the difference between a backfield defense man whose tackling is uncertain and one whose tackle is a death grip.

And then, too, it is our conception of a boiler water that the alkalinity therein should be the minimum compatible with freedom from corrosion and cleanliness of surfaces.

Just recently a plant operating at 400 lb. pressure for certain reasons changed temporarily from the use of phosphate to maintenance of a recommended alkalinity in the boiler water. Under control by phosphate and with from 30 to 50 per cent make-up, the evaporative surfaces had remained clean to the metal for many months, and there had been no tube loss. With return to caustic and carbonate as final conditioning chemicals, and with the maintenance consistently of a small concentration of alkalinity in the boiler water, tubes burned out within six weeks' time, and the scale that caused the burn-outs was calcium-sulphate scale.

Apparently the experimentation with static equilibrium in bombs is not in agreement with operation and the dynamic equilibria of boiler waters. We evidently must know more in order to bridge this hiatus.

Everett P. Partridge[11] **and W. C. Schroeder.**[12] The results outlined in the paper are of particular interest in connection with the study of the SO_4–CO_3 ratio for the prevention of sulphate scale made by the writers.[13] The author is to be congratulated on the opportunity afforded him to investigate solubility relations in complex solutions at elevated temperatures and on the exceptional facilities at his disposal. His method of attack does not allow him to obtain successive check samples from the same solution after varying periods of time, but if a sufficient number of duplicate determinations are made in each case, it should be possible to establish the equilibrium concentrations quite accurately, in spite of the analytical difficulties introduced by the low solubility of the different calcium salts at the higher temperatures. In this connection the writers hope that the author will eventually publish his original data in as complete a form as possible, since this will allow more intelligent interpretation of the results than is possible with the smooth curves given in the paper. In this type of work the data frequently show perverse inconsistencies, but these inconsistencies may lead to subsequent important conclusions.

The manner in which the author has presented his results may lead to misinterpretation in several cases, since he has indicated the solid and liquid phases added to his bombs, rather than those actually present at the time of sampling. In any case where Na_2CO_3 solution was added to an initial solid phase of $CaSO_4$, the equilibrium solid phase would contain $CaCO_3$, while the solution should contain chiefly Na_2SO_4, as he has himself noted in his Tables 2 and 3. The initial phases added in different runs are compared in Table 4 with those that must actually have been present if equilibrium were attained.

TABLE 4

Figure number	—Initial substances— Solid phase	Liquid phase	—Substances at equilibrium— Solid phase	Liquid phase
8	$CaSO_4$	Na_2CO_3	$CaSO_4$ $CaCO_3$	Na_2SO_4 Na_2CO_3
10	$CaSO_4$	NaOH	$CaSO_4$ $Ca(OH)_2$[a]	NaOH Na_2SO_4
11	$CaCO_3$	Na_2SO_4	$CaCO_3$ $CaSO_4$[a]	Na_2SO_4 Na_2CO_3
12	$CaCO_3$ $CaSO_4$	Na_2CO_3	Ca_2CO_3 $CaSO_4$	Na_2SO_4 Na_2CO_2
13	$CaCO_3$ $CaSO_4$	Na_2SO_4	$CaCO_3$ $CaSO_4$	Na_2SO_4 Na_2CO_3
14	$CaCO_3$ $CaSO_4$	NaOH	$CaCO_3$ $CaSO_4$ $Ca(OH)_2$[a]	NaOH Na_2SO_4

[a] Above certain concentrations as subsequently noted.

In the case of these figures where new substances should have appeared in the solid phase, interpretation of the results would depend upon complete analysis of the final solution and petrographic identification of the substances in the residual solid material.

The method of attack employed affords several opportunities for cross-checking results. For example, Figs. 8, 12, and 13 represent results obtained with systems which should have been almost identical if equilibrium had been attained and experimental error had been eliminated. In each case the final solid phase must have been $CaSO_4 + CaCO_3$, and the solution must have been chiefly Na_2SO_4, with a relatively low content of Na_2CO_3. Barring the possible effects of crystal form and particle size upon solubility, the results obtained when $CaCO_3$ was produced in the solid phase by precipitation should not differ from those obtained when $CaCO_3$ was initially present. In Figs. 8 and 12 the equilibrium was being approached from one direction, in Fig. 13 from the opposite direction, and the agreement is generally within the probable limits of experimental error. Examination of the original data might indicate even closer agreement than is shown in the three figures.

It would be expected that the addition of solid $CaCO_3$ to a system saturated with respect to $CaSO_4$ would have little effect on the equilibrium concentration of Ca, which would tend to be slightly higher, while the SO_4 would tend to be slightly lower than when the solid $CaCO_3$ was not present. Substantial agreement would therefore be expected between Figs. 5 and 7. This agreement is realized at the three lower temperatures. The writers believe that the point at 540 deg. fahr. in Fig. 7 is low and that further experiments will yield results closely in agreement with Fig. 5. Similarly, the close agreement between Fig. 9 and Fig. 8 would be expected, since the final conditions in the two cases differed only by the presence of $CaCO_3$ in the solid phase and of a low concentration of Na_2CO_3 in the liquid phase in Fig. 8. The original data upon which Figs. 8, 9, 12, and 13 are based might therefore be profitably considered together. The maximum discrepancy between values for corresponding molecular concentrations and temperatures in these four figures is only slightly greater than 0.1 millimols per liter, or 4 p.p.m., a range of variation which is quite possible and even probable in this type of work.

The initial drop in Ca concentration with increase in Na_2SO_4 concentration shown in Figs. 8, 9, 12, and 13 is quite in line with modern theories of solution, while the practically constant values for Ca at higher concentrations of added salt may also be interpreted satisfactorily by these theories. The drop in Ca concentration with increase in NaOH concentration shown by the curves in Fig. 10 is, however, difficult to understand until it is realized that at a concentration of about 2 millimols per liter of NaOH at 360 deg. fahr., and at progressively lower concentrations at higher temperatures, $Ca(OH)_2$ would appear in the solid phase. Further addition of NaOH would then merely produce $Ca(OH)_2$ in the solid phase and Na_2SO_4 in solution. The increasing concentration of Na_2SO_4 would tend to depress the solubility of $CaSO_4$, while the presence of an appreciable concentration of NaOH would tend to depress the solubility of $Ca(OH)_2$, resulting in Ca concentrations lower than those corresponding to the solubilities of the respective substances in pure water. Incidentally, $CaCO_3$ was undoubtedly present in addition to $Ca(OH)_2$ and $CaSO_4$ in the solid phase in Fig. 10 as well as in Fig. 14, unless the NaOH solution used had been specially prepared and protected to prevent absorption of CO_2 from the air.

Very little difference would be anticipated between Figs. 10 and 14, even if no $CaCO_3$ had been present in the solid phase in the former case. The apparent discrepancy between the curves for 360 deg. fahr. in the two figures may be attributed to experimental error, although it is impossible to guess which more nearly represents the truth.

In the course of our own work on solubility equilibria in boiler waters we have found a decided tendency for $CaCO_3$ to give high values in the absence of appreciable amounts of other dissolved salts. Due to the hydrolysis which $CaCO_3$ undergoes in contact with water, interpretation of results is only possible when a complete analysis is available. The values given in Fig. 6 are valuable as approximations, but are not significant as equilibrium data until the corresponding concentrations of OH, CO_3, and any other ions present in the solution as impurities and the concentrations of CO_2 in the vapor phase are known. The results of the author's equilibrium experiments will be awaited with great interest.

---

[11] Non-metallic Minerals Experiment Station, U. S. Bureau of Mines, New Brunswick, N. J.

[12] Department of Engineering Research, University of Michigan, Ann Arbor, Mich.

[13] Paper on "The SO_4–CO_3 Ratio for the Prevention of Sulphate Boiler Scale," presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

In two of his groups of experiments, Figs. 8 and 12, the author produced $CaCO_3$ in the solid phase by the action of Na_2CO_3 solution upon solid $CaSO_4$. In Fig. 11 the reverse reaction was taking place, which accounts satisfactorily for the increase in Ca concentration with increasing concentration of Na_2SO_4 used as starting solution. As the Na_2SO_4 concentration was increased, the system would tend to approach saturation with respect to $CaSO_4$ as well as $CaCO_3$. An approximate calculation on the basis of some of our measurements indicates that at 360 deg. fahr. $CaSO_4$ probably first appeared in the solid phase when the initial solution contained about 12 millimols per liter Na_2SO_4. At the higher temperatures, saturation with respect to $CaSO_4$ would be reached at progressively lower initial concentrations of Na_2SO_4. The minima in the curves of Fig. 11 at low concentrations probably are not real, since the values in the absence of any added salt are likely to be high as a result of supersaturation.

This paper has presented briefly a great amount of data in generalized form. The writers feel that in attempting to simplify the presentation the author has perhaps offered too great an opportunity for misinterpretation. In considering boiler-water equilibria, particularly in previously unexplored regions, it is much safer and much more conclusive to measure what is taken out than what is put in. Since the paper states that the solution samples were completely analyzed, it should be possible, when the investigation is completed, to present the results on the basis of direct measurement. In representing solubility equilibria, particularly when the solution is complex, it is very convenient to plot the logarithms of stoichiometric solubility products for the saturating substance against the square root of the total ionic strength of the solution, as described in the paper by the writers. The writers have a strong predilection for petrographic determination of solid-phase constituents and would urge that this convenient and valuable tool be employed in cases where formation of a new solid is suspected.

With slight reservations, the writers agree with the conclusions drawn by the author. The second conclusion, that the solubility of calcium carbonate in the presence of sodium carbonate or hydrate is practically zero, may, however, be misinterpreted to mean that feeding soda ash equivalent to the Ca concentration of a feedwater will prevent scale. Tests of scale formation in an experimental boiler described in the writers' paper show that this is not so. In two tests when soda ash slightly more than equivalent to the Ca content of the feedwater was fed continuously, thin deposits of anhydrite scale were formed, although the Ca concentration in the boiler water was extremely low. Since definitely measurable, although small, concentrations of CO_3 were present at all times in the boiler water, this result necessitates modification of the author's fourth conclusion.

The solubility of $CaCO_3$ in the presence of a low concentration of Na_2CO_3 is not actually zero, but it is so low that accurate measurement is difficult. Our own work has shown that at 365 deg. fahr., corresponding to 150 lb. per sq. in. gage pressure, the safe operating SO_4–CO_3 ratio for the prevention of sulphate scale is at least 100 and may be appreciably greater, so that the maintenance of 10 p.p.m. of CO_3 in a boiler water should protect it against sulphate scale if the SO_4 concentration is below 1000. This CO_3 must be actually present, however. A great deal of unjustified criticism has been directed at internal conditioning with soda ash simply because careless sampling and unreliable titration methods for CO_3 indicated relatively high concentrations of this ion when it actually was present in very low concentrations. An accurate method for combined carbon dioxide such as that worked out by the writers may allow the use of soda ash as a conditioning chemical for boilers well above the pressure limit of 200 lb. per sq. in. set by Dr. Hall. The limiting factor will be the rate of hydrolysis of Na_2CO_3 at the higher temperatures.

One caution seems advisable in the utilization of equilibrium data for boiler-water control. In any actual boiler depositing material from solution under operating conditions, there must be a constant tendency toward supersaturation, which may result in an approximately steady state appreciably different from the equilibrium attainable in a closed system. Although equilibrium data are indispensable as the first step, the definition of practical operating limits in boiler-water control should be made on the basis of steaming tests in an experimental boiler, preferably an actual industrial boiler operated under competent control.

AUTHOR'S CLOSURE

The author appreciates very much the suggestions made by those who have discussed his paper. They all emphasize the fact that we still have a large amount of work to do before we can correlate theories of scale formation with the question of solubility of the calcium salts. The data which the author has collected will be published from time to time in detailed form, as suggested by Dr. Partridge. In the present paper the material had to be presented in a very condensed form.

The author would again like to call attention to the fact that the direct relation between solubility of the calcium salts and scale formation on the heating surfaces of steam boilers has not been established, and we may find that relative solubility is not a major factor in scale formation.

Piezometer Investigation

By CHARLES M. ALLEN[1] and LESLIE J. HOOPER,[2] WORCESTER, MASS.

C. M. Allen

This investigation had for its object the determination of a standard piezometer for commercial use and the study of the hydraulic effect of various conditions of operation upon different forms of piezometers. Piezometers were compared in operation with suitable reference orifices, the differentials being measured with hook gages. A number of factors concerning the performance of piezometer orifices were analyzed. The paper gives results covering a variety of forms and conditions and should assist in establishing a standard form of piezometer.

L. J. Hooper

THE object of this investigation was (1) to determine a stable type of piezometer suitable for use as a standard in commercial work, and (2) to determine those factors which have the greatest bearing in obtaining correct results.

The experimental work was conducted at the Alden Hydraulic Laboratory of Worcester Polytechnic Institute. The general layout of the apparatus may be seen in Fig. 1. A 12-in. pipe line was used for this work, as suitable water velocities, ease of regulation, and uniformity of flow and pressure conditions were readily obtained. This line is connected to the main 40-in. penstock above a 36-in. by 16-in. venturi meter and below the Johnson differential surge tank. The 40-in. penstock, which is about 400 ft. long, takes its water from the second or middle pond and supplies a 100-hp. water wheel under 30 ft. head in the main laboratory.

From Fig. 1 it is seen that the 12-in. line branches off from the main penstock and runs horizontally about 33 ft. across the laboratory.

Then it rises 4.2 ft. and again runs horizontally 34 ft. at right angles to its former course to a 12-in. by 6-in. venturi meter. At the end of the venturi meter is a regulating valve, and from there the water discharges either into a waste way or, for calibration purposes, into a weighing tank.

At the entrance to the 12-in. line two $^3/_8$-in. mesh screens were placed to prevent leaves and sticks from entering the pipe and causing trouble with the test piezometers. As the direction of the current of water in the main penstock was across these screens, they cleaned themselves every time the 12-in. line was shut down.

For this work smooth water-flow conditions are essential. In Fig. 1 it is seen that there are two right-angle bends in the pipe above the test section. These bends were in planes normal to each other. This condition would tend to give a whirl to the water that might seriously affect the accuracy of the measurements. Therefore a water-flow straightener was placed in the pipe just below the second elbow. This was a sheet-metal vane 3 ft. long that divided the pipe into quadrants. This effectively checked any tendency of the water to whirl. To further quiet the water, stilling screens, which consisted of two $^1/_4$-in. mesh screens close together with the wires at 45 deg. to each other were placed in the pipe at the flange joint upstream from the test section.

The test section was located about 6 ft. upstream from the venturi meter and 0.4 ft. upstream from the end of the 18-ft. section of pipe. In Fig. 1 it is seen that the water straightener was 29.6 ft. and the stilling screens 17.9 ft. upstream from the piezometer section. In order to have the pipe wall and hence the surface flow as smooth as possible, the pipe was scraped for a distance of 7 ft. upstream from the test section and brushed with a stiff wire brush for 3 ft. upstream.

At the test section 12 holes were drilled radially at equal intervals around the pipe and tapped for a $^3/_8$-in. pipe thread. The orifices were made up in brass plugs which were screwed into these holes. After being put in place the inside surface of the plug was filed and scraped flush with the wall of the pipe. (See Fig. 2.)

Since there is no independent method of measuring pressure head in a pipe other than piezometers, it was necessary to choose arbitrarily comparison or reference orifices. Four of these reference orifices were installed on two diameters at right angles to each other. These orifices had $^1/_8$-in. holes, square edges, and surfaces flush with the penstock wall. Other piezometers to be compared were installed in the intermediate holes, as shown in Table 1.

The elevation of the pressure head at the test section was several feet above the roof of the building. The small differences in the readings of the various piezometer orifices made the use of sensitive hook gages imperative. Therefore a differential-pres-

---

[1] Professor of Hydraulic Engineering, Worcester Polytechnic Institute. Mem. A.S.M.E. Professor Allen was born at Walpole, Mass., on Dec. 12, 1871. He received his B.S. in Mechanical Engineering from Worcester Polytechnic Institute in 1894, his M.S. in 1899, and his D.Eng.Hon. in 1929. He has been on the teaching staff of the institute in part-time capacity since his graduation, for the past 20 years serving as Professor of Hydraulic Engineering. Professor Allen has been engaged for 30 years in consulting and testing-engineering practice in paper-mill and water-power lines, making power and efficiency tests throughout the United States and Canada. He has done considerable research work in connection with the friction of gears, rating of all forms of water-measuring apparatus, and, in recent years, hydraulic model testing. He is a Vice-President of the Society.

[2] With Prof. C. M. Allen, Worcester Polytechnic Institute. Jun. A.S.M.E. Mr. Hooper was born in Essex, Mass., on Feb. 15, 1903. He received his B.S. degree in Mechanical Engineering at Worcester Polytechnic Institute in 1924 and M.E. degree from the same institution in 1929. The first three years after graduation he was engaged in hydraulic test work in Brazil, and for the past four years has been engaged in hydraulic research and commercial work at the Alden Hydraulic Laboratory of the Worcester Polytechnic Institute, and has just been appointed a part-time Instructor at the institute.

Contributed by the Hydraulic Division and presented at the Annual Meeting, New York, N. Y., Nov. 30 to Dec. 4, 1931, of The American Society of Mechanical Engineers.

Note: Statements and opinions advanced in papers are to be understood as individual expressions of their authors, and not those of the Society.

TABLE 1 PIEZOMETERS TESTED

Piez No.		Description
1		Square edged 1/8" orifice used as a reference.
2		Square edged 1/8" orifice used as a reference.
3		Square edged 1/8 orifice used as a reference.
4		Square edged 1/8 orifice used as a reference.
5		Square edged 1/16" orifice.
5A		Piezometer with 27/32" orifice and 1/16" radius of rounding.
6		Square edged 1/4" orifice
6A		Burr removed by countersinking with large drill point.
7		Square edged 3/8" orifice.
7A		Conical piezometer of 60 degrees.
8		Square edged 1/2" orifice.
10		Piezometer with 1/8" orifice and 1/16" radius of rounding.
10A		Conical piezometer of 45°. 1
10B		Modification of conical piezometer.
10C		Piezometer recessed 1/32"
10D		Piezometer recessed 1/16"
11		Piezometer with 1/8" orifice and 1/8" radius of rounding.
11A	See Fig. 14	Inserted tube piezometer. Similar to a pitot tube but lacking the impact orifice. Tube 5" long and 1/2" o.d. Four 1/8" square edged orifices 3" from point.
11B		Burr removed by two light countersinking operations.
11C		Piezometer recessed 1/4"
11D		Piezometer counterbored from inside
12		Piezometer plug projecting 1/8"
12A		Piezometer plug projecting 5/8"
12B		Piezometer with 1/8" orifice and 1/32" radius of rounding
12C		Conical piezometer of 30 degrees.
12D		Similar to trailing Pitometer orifice.
13		Piezometer plug projecting 1/16"
13A	See Fig. 14	Teaball piezometer. One inch sphere on end of a 1/8" pipe. No. 60 holes drilled all over the ball at regular intervals.
13B		Piezometer plug recessed 1/8"
13C		Cup shaped recess in piezometer tube.

Note- All piezometers have 1/8" orifice except where noted.

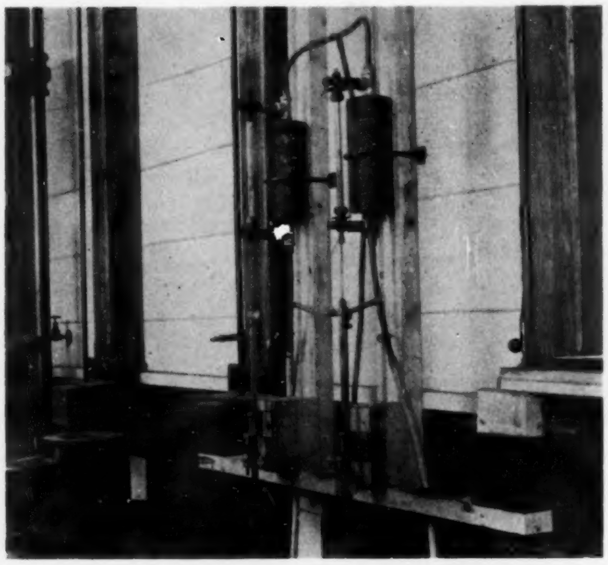

FIG. 5 DIFFERENTIAL-PRESSURE HOOK-GAGE MANOMETER

sure manometer with two hook gages was made up for this test work.

A sectional view of one of the head gage pots is shown in Fig. 3. The stilling pot was made up of a piece of 4-in. boiler tube with two heads welded in, $^1/_2$-in. pipe fittings being used to connect regular water-column fittings to the stilling pot. The lower water-glass fitting was equipped with a small stuffing box, through which passed the hook-gage point. About 1 in. down from the point a small guide was soldered so that the point was kept in a central position in the tube.

Fig. 4 is a diagrammatic sketch of connections for these gage pots. Two of these instruments were mounted side by side on a suitable base, as shown in Fig. 5. The air connections at the top were joined, and a common line went into an air tank of about 2 cu. ft. capacity. An ordinary tire pump was used to raise the pressure in the air tank so as to balance the water pressure. The water-pressure connections were first tied by an equalizer, and then passed through valves to the orifice connections on the 12-in. pipe.

In normal operation all the air passages were open, so that equal air pressure existed in both hook-gage pots and the air tank. The water-pressure equalizing tube was closed and the water-pressure tubes were connected to the desired piezometers. Between runs the water-pressure tubes were closed and the water-pressure equalizing connection was open so as to obtain a zero reading. From time to time the zero reading was checked by removing the gage glasses and laying a machinist's spirit level on the hook-gage points.

Before trying out the gages it was feared that there might be some difficulty in seeing the "pimple" on the water surface through the glass. It was found that not only was the point clearly observable in the usual manner, but that there were two other equally accurate ways of taking the reading of the water surface. By observation from below, the image of the point is very plainly seen. As the point approaches the water surface the image and the point approach each other. The point at which they meet can be seen very clearly, and the water level is accurately determined. In the third method a small frosted lamp bulb was held directly behind the water column, throwing the point and the meniscus into strong silhouette. Here again the meeting of the point with the water surface is very clearly seen. Fig. 6 shows the meniscus and the point at time of reading according to the third method. All three of these methods were compared for accuracy and there was no choice among them.

PROCEDURE

In preparation for a run the air was first blown out of the venturi-meter connections and the zero reading was checked on the mercury U-tube of the venturi meter. Then the regulating valve was opened until the desired flow was obtained in the 12-in. pipe. In the meantime the water-equalizing valve on the hook-gage pots had been opened so that a zero reading could be taken. Then the water-pressure hose from each gage was connected to the desired orifices, and care was taken to remove the air all along the water-pressure line. Before opening the line valves wide, the air pressure in the tank was raised until it balanced the water pressure. After the line valves were opened to insure stable hydraulic conditions, 10 to 15 min. elapsed before taking any readings. Then two check readings were taken with about a 2-min. interval between. A reading of the venturi meter was recorded at the same time.

With the readings of an orifice completed, No. 2 hook gage was connected to the next orifice to be read, while No. 1 was left connected to the main reference orifice throughout the tests. As each orifice was connected the air was blown out of the tubing before starting to take a reading.

Following a run, the flange bolts were removed and that section of pipe containing the piezometer section was revolved 180 deg., and another run was made at the same velocity and using the same reference orifice. Since the water-flow straighteners and stilling screens were not moved, it seems safe to assume that the water came down the pipe in much the same way for both runs. By averaging the results of the two similar runs the effect of oblique or turbulent flow on the piezometers was removed.

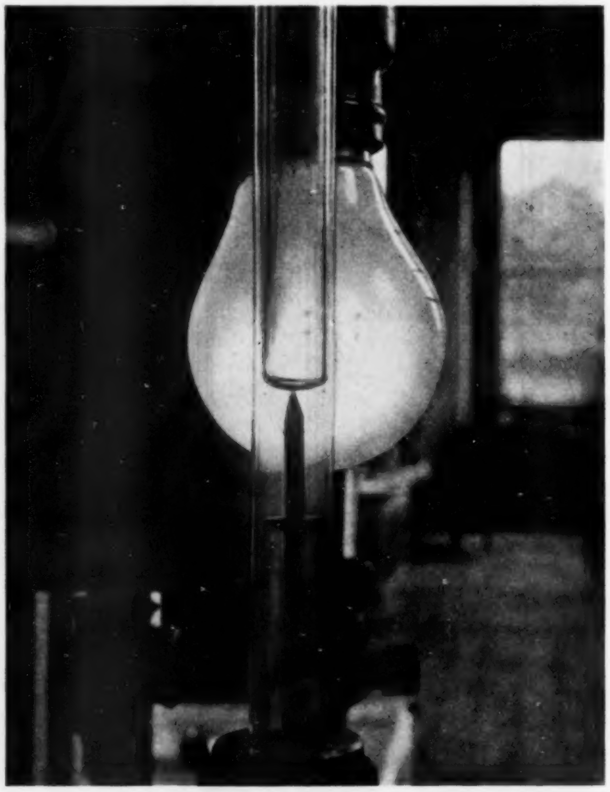

FIG. 6 READING THE DIFFERENTIAL-PRESSURE HOOK-GAGE MANOMETER

At the start, the reference orifices did not agree as well as might be expected. During the course of tests the four reference piezometers were improved until at the end of 19 runs they all read practically the same when they were located at the same point with respect to the flow. After six more runs had been made, the procedure in regard to revolving the pipe was abandoned, inasmuch as the same answer was obtained by averaging the reading of the reference piezometers.

DATA AND COMPUTATIONS

Three sample data sheets, which contain the data for one complete set of runs, are shown in Tables 3, 4, and 5. The computations were made as follows, the first set of readings in Table 3 being used as an example:

Difference in level = reference reading — test reading — zero correction
= 1.480 — 1.379 — 0.108 = —0.007

Mean velocity head = computed from venturi deflection
= $V^2/2g$
= $Q^2/A_1^2 2g$
= (venturi constant)^2 (deflection)/(A_1^2 $2g$)
= (5.66)^2 (0.95)/(0.6168) (64.4)
= 0.81 ft. of water.

Deviation = difference in level/velocity head
= —0.007/0.81
= —0.9 per cent of the mean velocity head

RESULTS

Table 2 presents a summary of all the results that were obtained in this piezometer study. The more obvious conclusions indicated by this study are described in detail.

Care in Making Connections. The utmost care is necessary in removing air and leaks from all pressure connections. In starting the tests, the zero correction by water level did not check that

---

[a] No. 1 up. Run No. 16.

[b] No. 4 leveled and carefully squared. Found surface projected 0.005 in.

[c] No. 1 up. Run No. 17. Conditions as for No. 16.

found by the machinist's level by 0.002 ft. A bubble of air about the size of a pea was worked out of one of the pipes, and thereafter the readings were checked. In another case the readings of one test on piezometer No. 5 with an opening of $^1/_{16}$ in. were lower by 0.005 ft. than those of a previous test under identical conditions. The trouble was found to be a leak in a pressure-tube connection, and the quantity of water escaping was only one drop per second.

Expression of Error. An examination of the results, Table 2, indicates that the error of any piezometer remained constant when expressed as a per cent of the velocity head. Runs were made at two velocities, and for like conditions the percentage errors remained constant within the limits of accuracy of measurement. As might be expected, the error of a piezometer is caused by the local water velocity passing by the orifice, and the error therefore is correctly expressed as a per cent of the local velocity head at the piezometer. A partial traverse made with a teaball piezometer proved this to be a fact. But due to the difficulty

TABLE 4 SAMPLE DATA SHEET NO. 10

(Piezometer Tests, March 6, 1928)

Zero Readings:	No. 1	1.469	1.470	1.470
	No. 2	1.361	1.361	1.361
	Diff.	0.108	0.109	0.109
